Animals (Scientific Procedures) Act 1986

Non-technical summaries for project licences granted July - December 2021

Contents

1. Models for endocrine neoplasia 11

2. Exposure of rainbow trout to crude oil 19

3. Investigation of vitamin d metabolism in sheep 25

4. Novel approaches in bone repair 30

5. Improving treatment options for individuals with diabetes and developing intervention strategies; using beta cell replacement and regenerative therapies 37

6. Modelling cancer biology and therapy in mouse 47

7. Modelling brain tumours in the mouse 55

8. Mechanisms underpinning thrombus formation, stability and vessel repair 64

9. Developing therapeutic drugs for cancer including the establishment of tumour models 71

10. Non-invasive mucosal rodent immunisation 82

11. Normal and leukaemic blood cell development 90

12. Generation of new anti-tumour strategies for epithelial cancers 99

13. Blood clot properties in thrombosis, thromboembolism and atherosclerosis 106

14. Centrosomes and cilia in development and disease 114

15. Neuronal recording on GA Aged Animals 119

16. Infectious disease in pigs and ruminants 125

17. Regulation of gene expression in vertebrate development 136

18. Role of the inhibitory neurotransmitter naag and its transporter in pathologies involving glutamatergic dysfunction 142

19. Cellular electrophysiology of cardiac arrhythmias 151

20. Development of combined treatments for cancers 158

21. Control of blood flow and cell function in the brain and other organs, in health and disease 168

22. Assessment of biological response to novel ocular drug delivery formulations and devices 176

23. Provision of services to investigate novel health technologies 185

24. Induction of anti-tumour immunity 197

25. Immune regulation at mucosal and barrier surfaces 205

26. Neuron-glia biology in neurodegenerative disorders 214

27. Immune-based treatments for cancer 221

28. Cell fate determination and morphogenesis during early mammalian development 229

29. Synapses in health and disease 240

30. The nervous system influences on pancreas development and physiology 254

31. The pathogenesis of a neglected tropical skin disease 261

32. Understanding and treating preterm birth related pregnancy disorders 270

33. Gamma delta t cells and body surface immunity 280

34. Developing anti-malarial transmission blocking interventions 292

35. The chicken chorioallantoic membrane (cam) assay for biomaterial testing in tissue engineering 301

36. Development of novel therapy strategies for skin diseases 312

37. The role of transposable elements in cichlid fish development and evolution 321

38. Understanding the mechanisms and mediators involved in adverse pregnancy outcomes 330

39. Understanding trait variation in migratory birds 339

40. Developing flare-responsive intra-articular steroid injection 345

41. Investigating mechanisms and novel therapeutics for critical limb ischaemia 355

42. Visual processing in frogs 365

43. Production of normal blood 371

44. Breeding and maintenance of genetically altered and germ free mice 378

45. Molecular imaging and radionuclide therapy research for cancer 387

46. Minimising tissue damage in electrosurgery 395

47. Role for xxx in gene regulation 401

48. Brain development and neuronal network maturation 408

49. Airway fibrosis 415

50. Hypoxia, carbon dioxide and acid sensing in respiratory chemoreceptors. 422

51. Assessment of bioaccumulation in fish 428

52. Translation of the immunological synapse 435

53. Control of worm infection by the immune response and drugs 443

54. Defining immune mechanisms that promote inflammatory arthritis and associated co-morbidities to identify new therapeutic targets. 451

55. Development of vector control strategies and intervention methods concerning the spread of malaria 460

56. Novel drugs for intractable cancers 469

57. Establishing the pathophysiological impact of cigarette smoke extract in mice as a model for chronic obstructive pulmonary disease (copd) 478

58. Improving our understanding of the bovine immune system 491

59. Defining osteoarthritis mechanisms 502

60. Understanding genetic and diet effects on the productivity and environmental footprint of dairy cattle. 510

61. Investigation of drug resistance mechanisms in haematological malignancies 517

62. Imaging and treating tumours 525

63. Novel nanomaterials as delivery vehicles for drug and cellular therapies 533

64. Technical development of refined phenotyping assays. 544

65. Antibodies for research and clinical purposes 556

66. Study and manipulation of the tumour immune microenvironment for cancer therapeutics 564

67. Investigating tick-borne bunyavirus interactions with ticks and how these interactions affect transmission and pathogenesis of viruses in a small animal model 573

68. Neural mechanisms of pain control 582

69. Immunotherapy of amyloidosis 590

70. Strategies to improve donor organ function in a porcine model 601

71. Investigating immune responses in mice 606

72. Generating new models of human cancer 613

73. Signalling in normal and abnormal blood cell function 620

74. Targeted tumour therapy 628

75. Understanding how climate change affects mammalian immunity and control of infection 641

76. Early safety assessment, investigatory and efficacy studies 649

77. Cellular and molecular mechanisms of the mouse embryo development 664

78. Tumour suppression and therapy 676

79. The effects of aging and prior injury on tissue regeneration and fibrosis 686

80. Zebrafish models to identify determinants of outcome in immune-mediated disease 696

81. Antibody production for clinical and research applications 702

82. Immune signalling in infection and cancer 710

83. Cancer and the microenvironment 721

84. Vascular regulation of fibrotic disease 728

85. Environmental adaptation in fish 737

86. Dna double-strand break repair, immunity & cancer 744

87. Mechanism of action of vaccines and adjuvants 751

88. Impact of drugs and environment on the brain through the lifespan 757

89. Role of protein degradation in health and disease 764

90. The integrated stress response in respiratory disease 771

91. Phenotypic plasticity and adaptation of cichlid fish in response to novel environments 782

92. The impacts of marine engineering on wild fish 790

93. Development of live bacterial therapeutics for the treatment of cancer 798

94. The role of nitrite in coronary artery disease and its associated risk factors 806

95. Modulating the immune response in cancer 816

96. Trans-generational effects of age in birds 825

97. Investigation into the inflammatory mechanisms associated with inflammatory bowel disease and intestinal cancer 835

98. Cell surface receptor functions in fertility 843

99. Cell biological pathways in neurodegeneration 849

100. Exploring the role of the cell surface molecule podoplanin in fibroblast-macrophage cross talk in arthritis 858

101. Genetic analysis of metastatic cancer 869

102. Host-pathogen interactions and vaccines 876

103. Investigating the mechanisms driving cardiac fibrosis and its effects on cardiac function 883

104. Treatment of chronic inflammatory disease 891

105. Determination of cns efficacy and safety pharmacology 897

106. Therapeutic potential of tregs 907

107. The ecophysiology of fish 915

108. Immune mechanistic models of autoimmune disease 921

109. Mechanisms of cardiometabolic disease 927

110. Developing and studying novel mouse models of glioma development and progression 943

111. Creation and repair of ano-rectal fistulae in a porcine model 951

112. Tissue function and metabolism in heart disease 958

113. Preclinical evaluation of cancer therapeutics 966

114. New therapeutic strategies to treat chronic pain 976

115. Pathways of filopodial formation 989

116. Standards in virology 996

117. Ecology and epidemiology of infectious disease in wildlife 1010

118. Mechanisms of metabolic regulation in health and disease 1017

119. Neural circuits in health and disease 1028

120. Tau pathology in alzheimer's disease 1035

121. Supply of materials to develop and maintain tests for transmissible spongiform encephalopathies 1047

122. Immunotherapy and vaccine development for cancer and sars-cov-2 1054

123. Studying host interactions in tumour and metastasis 1061

124. Developing treatments for huntington's disease 1069

125. Mouse models of chronic inflammatory clinical conditions. Word document missing 1076

126. Colorectal cancer initiation and progression 1088

127. Tuberculosis immunity and vaccine development 1095

128. Impact of hormones and inflammation on reproductive health and disease 1103

129. Prevention and treatment of sepsis 1112

130. Synaptic and circuit mechanisms for neural computation 1119

131. Improving prognosis from vascular dementia 1125

132. Evaluation of cancer therapies in orthotopic cancer models 1133

133. Production of antibodies, antisera and blood products iii 1140

134. Investigating the immunology of cancer and the development of cancer therapeutics 1149

135. Isolation and propagation of virus in eggs 1156

136. Developing non-viral gene therapies 1164

137. Molecular mechanisms of t cell mediated immune responses 1173

138. Understanding immune cell development and its functional consequences 1183

139. Mechanisms of cardiac arrhythmogenesis – insights from murine model 1190

140. Modelling gene therapy for congenital bladder dysfunction 1201

141. Metabolism as a novel target for cancer therapy 1208

142. The role of morphological and genetic abnormalities in tumour progression 1217

143. The use of immunological tools for monitoring farm cattle health and prevalence of bovine tuberculosis (btb) 1228

144. Production, breeding & cryopreservation of genetically altered mice 1236

145. Discovery of cancer genes and assessment of their therapeutic potential 1241

146. Molecular basis of neurodevelopmental disorders 1251

147. Acute and chronic kidney disease: translational studies using the pig 1257

148. Reproductive toxicology 1268

149. The reciprocal interaction of inflammation and cancer 1277

150. Nucleic acid sensing and interferon-regulated genes 1284

151. Breeding, production, archiving and the application of assisted reproductive techniques of genetically altered mice 1292

152. Mechanisms of neural circuit development in health and disease conditions 1299

153. Development of an implantable device for the treatment of brain tumours 1306

154. Understanding epithelial tumour initiation 1316

155. Imaging neurons to understand memory formation and loss 1326

156. The biology of body weight and body composition 1334

157. Repair and protection of the retina and optic nerve 1343

158. Analysis of skin carcinogenesis in transgenic mice 1354

159. Mechanisms regulating neural stem cell activity and neuronal production 1362

160. Information processing in neural circuits 1369

161. The regulation of platelet function as a central mechanism for the control of cardiovascular function and development 1376

162. Molecular determinants of brain development 1390

163. Neuronal and glial function and dysfunction across the life-course 1399

164. Understanding the mechanisms of the carotid body hyperactivity caused by chronic hypoxia 1406

165. Regulation of immune responses in cancer 1418

166. In vivo pharmacokinetic and pharmacodynamic properties of potential new treatments for cns and other disorders 1427

167. Brain networks in epilepsy and neurodevelopmental disorders 1435

168. Towards mechanistic understanding and improved treatment of nervous disorders 1441

169. Lymphocyte development and ageing 1452

170. Gene and environment influences contributing to psychiatric disorders 1460

171. Studies on the neurobiology of sensation 1469

172. Production of genetically altered animals and provision of tissues (service provision) 1484

173. Preclinical validation of intraperitoneal delivery of chemotherapy for treatment of ovarian cancer 1492

174. Understanding the neuronal network involved in the regulation of glucose metabolism, feeding behaviour and energy expenditure 1500

175. Target investigation and characterization of potential medicines 1510

176. In vivo assessment of novel injectable hydrogel biomaterials for spinal disc repair 1519

177. Vascular calcification in kidney dysfunction 1527

178. Environmental stresses in forages affecting ruminant digestive physiology 1536

179. Models for experimental therapeutics of childhood cancers 1542

180. Understanding and developing new treatments for neurological diseases 1549

181. Alternative pre-mrna splicing control and its contribution to tissue injury and pain 1559

182. The physiological roles of clathrin diversity 1569

183. Breeding and maintenance of genetically altered mice 1578

184. Glymphatic system in the ageing brain 1586

185. Immune responses in tumour development 1593

186. Central nervous system control of physiological functions 1600

187. Neuronal circuits regulating metabolic and cardiovascular health 1607

188. Analysis and therapy of cerebellar disease 1616

189. Vascular protective genes in angiogenesis 1624

190. Role of natriuretic peptides in cardiovascular homeostasis and disease 1636

191. Vaccine candidates for group a streptococcus infections 1644

192. Novel mechanisms of co2 signalling in the physiological systems 1649

193. Nutrition of growing and mature ruminant livestock 1657

194. Investigation into the mechanisms causing acrodysostosis type 2 and related therapies 1665

195. Neural mechanisms of visual cortical plasticity 1672

196. Immune and inflammatory mechanisms of cardiovascular disease 1679

197. The aberystwyth liver fluke sample-bank for the evaluation of diagnostic tests 1688

198. Analysis of thymus development and function 1697

199. Neuronal mechanisms of appetitive learning 1704

1. Models for endocrine neoplasia

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to increase our understanding of the biology of endocrine tumours, and to develop novel treatment strategies for them. This is because current treatments are largely ineffective, which is partly due to a lack of knowledge regarding the molecular mechanisms driving the development of these tumours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Current treatments for endocrine tumours, particularly those of the pancreatic islets and pituitary are limited, meaning there is a clinically unmet need for the identification of novel drugs, or therapeutic approaches. Therefore, this project is important for increasing our understanding of the molecular biology of endocrine tumours, which will identify novel pathways, and or genetic targets in these tumours, which may ultimately be targeted by novel or existing drugs. In addition, the assessment of the efficacy of any candidate novel therapeutic is important to provide evidence of its potential use in the clinical setting.

What outputs do you think you will see at the end of this project?

Overall, with this project we aim to increase our knowledge of the biology of endocrine tumours. This includes increased understanding of the genetic, and epigenetic pathways involved in the development of pituitary and pancreatic neuroendocrine tumours.

Within this study we also aim to develop and characterise new mouse models based on human genetic studies.

In addition, we aim to explore the use of epigenetic targeting drugs, and other molecules for treatment of these tumours. This will include the development of novel agents, as well as repurposing agents that are already used in the treatment of other cancers, or diseases.

Therefore, our outputs may include:

publications in good quality peer-reviewed journals, as well as abstracts at national and international meetings new mouse models of endocrine tumours novel anti-tumour agents

Who or what will benefit from these outputs, and how?

Our studies will help to understand genetic causes, cellular pathways and the interactions between different organs, in diseases underlying endocrine tumours. In addition, our phenotyping studies may uncover clinical symptoms that have not yet been investigated in patients. In the short term this information may therefore be used to direct future endocrine tumour research, as well as identify new clinical investigations that should be undertaken in endocrine tumour patients.

Our studies will also help to identify novel drugs, or other agents that could be used for the treatment of endocrine tumours in patients. In the long term our pre-clinical studies may therefore provide evidence for future clinical trials testing drugs that are novel, pre-existing or repurposed

Beneficiaries of our project may therefore include: scientists and other researchers clinicians patients

How will you look to maximise the outputs of this work?

To maximise the output of our work, both positive and negative results will be published in peer- reviewed open-access journals. In addition, work will be presented at national and international conferences. Details of unsuccessful approaches will also be disseminated through public databases

e.g. publications submitted to pre-print servers including bioRxiv.org.

Collaborations will be established with international groups, and novel mouse lines will also be made available through archives, for example European Mouse Mutant Archive EMMA.

Species and numbers of animals expected to be used

- Mice: 9500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our studies are utilising predominately adult mice. This is because we are studying the biology, and potential treatments for endocrine tumours, which most commonly develop during adolescence and adulthood in patients. These tumours secrete hormones, for example insulin and prolactin, and therefore can effect metabolic pathways other than those directly occurring at the tumour site. In addition, our research focuses on genetic disorders, for example Multiple Endocrine Neoplasia Type 1, in which patients develop tumours simultaneously in different organs, for example the pancreas and pituitary. It is therefore important to look at whole organism effects, for which mice represent an model that closely recapitulates the human disease.

Typically, what will be done to an animal used in your project?

A typical experience for a mouse on this project would be: aged to 7 months, provide a blood sample from a superficial vein receive twice weekly intraperitoneal injection of an anti-cancer drug for 4 weeks daily administration of BrdU in drinking water for 4 weeks fasting for 4h provide a blood sample from a superficial vein killed by a schedule 1 method

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects due to endocrine tumour development may include, but are not limited to: Alterations in balance and/or walking (<0.5%)

Reduced mobility and/or feeding due to tumour effects (<2%)

Increased urination or drinking due to disturbances in glucose metabolism (~10%)

Weight loss and loss of condition due to metabolic disturbances, e.g. due to insulin secretion from pancreatic neuroendocrine tumours (<5%)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity of this licence is expected to be moderate. The majority of mice bred under this licence will be tumour bearing (>60%), and therefore have the potential to experience adverse effects. These adverse effects will be monitored closely to ensure they are not prolonged, or severe, and mice will be culled as soon as the detailed humane endpoints are met.

Control mice that do not develop tumours will also be bred (<30%), however they may be used in phenotyping and drug studies, within which they may also meet the moderate severity due to procedures including repeat imaging (<5%) and administration of novel anti-cancer agents (<5%).

It is expected that (~20%) of mice will be controls that will only be used as breeders and therefore will be sub-threshold.

In summary, the expected severities of the mice wil be: moderate (60%); mild (20%); subthreashold (20%).

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying the biology, and identifying novel treatments for endocrine tumours. These tumours secrete hormones, for example insulin or prolactin, and therefore can effect metabolic pathways other than those directly occurring at the tumour site. In addition, our research focuses on genetic disorders, for example Multiple Endocrine Neoplasia Type 1, in which patients develop tumours simultaneously in different organs, including the pancreas and pituitary. It is therefore important to look at whole organism effects, for which mice represent a model that closely recapitulates the human disease.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of cell culture models, and are striving to develop primary cell models that may be able to replace some mice in some preliminary studies. For example, we are trying to immortalise and grow cells taken from mouse organs in the laboratory, and these could be used to test whether new drugs might be effective, before they are tested in live mice. In addition, we will assess potential therapeutic agents in already established cell lines before undertaking mouse studies.

Why were they not suitable?

We have been successful in establishing primary parathyroid cultures, and pancreatic islet cultures in preliminary studies, however these cells are not viable for long periods in culture and do not proliferate, as they do in vivo. Therefore, the assessment of novel therapeutic agents is limited as one of the measures of efficacy is reduction in proliferation. In addition, it is not possible to assess the effects of treatment, and hormone secretion on non-tumour cells and organs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies.

Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are based on estimates from previous years performing similar research studies to address similar questions and numbers of test agents.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animals are only bred as required to supply animals for experimental requirements. The number of animals required for the experimental studies is determined by power calculations to achieve an effect size. The group is in contact with our establishment's statistics department who offer advice on statistical requirements. We may also use online tools e.g. experimental design assist (https://eda.nc3rs.org.uk), and regularly check the nc3rs website for alternative approaches.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In all our mouse work, we use statistical analysis to ensure that the minimum number of mice are bred for the study, and that we use only the number of mice that are required to produce meaningful and useful results in order to answer the experimental questions. We are able to study the effects of drugs in multiple organs within an individual animal, for example in mice which develop tumours in more than one organ. Similarly, we can image the same mouse several times to study the development of organs or tumours, rather than using several mice once. In addition, we will use tools for colony management (e.g. MCMS) to ensure we do not overbreed and waste animals. We are also trying to establish cells from mice that will grow long-term in the laboratory. These could be used to replace some mice for the early stages of testing of new drugs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have previously established and characterised mouse models for use in this study and further models of endocrine tumours, based on human diseases will be established using our prior experience with techniques and facilities that we have readily available. Our conditional Men1 models are particularly useful for assessing the effects of drugs since unlike the conventional Men1 knockout models, all mice develop pancreatic tumours, and all tumours develop at the same age, allowing for more accurate comparisons between treatment groups. Thus, the age of tumour development is more defined and the organs in which they will develop; thereby making it easier to predict when the mice may begin to have symptoms that could cause distress. Furthermore tumours can develop as early as 5 months, therefore reducing the length of the protocol.

Why can’t you use animals that are less sentient?

Mice will be used in our studies and were chosen as they represent the lowest mammal, displaying a sufficiently similar endocrine system, and genetic similarity to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our team has developed expertise and experience in mouse welfare, and have refined our tests to ensure that the highest quality data is generated for the least welfare cost. We are also keen to minimise severity and increase the welfare of these animals. To ensure this, we will use non-invasive tests that only cause temporary discomfort where possible. For

administration of drugs, a small pilot study will be undertaken for new drugs, with increased cage observations and welfare checks to ensure that the drug is safe. We also aim to use long acting drugs where possible to reduce the frequency of dosing. During every test, mice are closely observed and anaesthetics or analgesics used when appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will conform to the ARRIVE guidelines on animal studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We attend termly gold standard animal welfare meetings at which a University representative of the 3Rs gives regular updates. We also consult the 3Rs and LASA websites for techniques and alternative models. In addition, we will have regular discussions with the animal technicians, and NACWO, as well as other researchers, to share experience on new, more refined techniques.

2. Exposure of rainbow trout to crude oil

Project duration

5 years 0 months

Project purpose

- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Fish, Crude oil, sensory, taint

Animal types	Life stages
Rainbow trout, oncorhynchus mykiss	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To maintain an expert panel, trained in sensory assessment, to detect hydrocarbon taint in fish and shellfish in the event of a major oil spill. The project provides a set of reference materials – rainbow trout exposed to oil over a set period of time varying in PAH (polycyclic aromatic hydrocarbon) concentrations – required to monitor panel performance and train new assessors.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Contaminants can enter the natural environment through anthropogenic (human) activities and accumulate in the tissues of fish and shellfish and in severe cases, these contaminants can present a risk to human health. Some contaminants such as polycyclic aromatic hydrocarbons (PAH's) can be detected as a taint in the foodstuffs. The project results in the production of a reference material for training and performance monitoring of an expert sensory taste panel trained in the detection of hydrocarbon taint in fish and shellfish. The sensory panel provides a rapid and sensitive method for detecting taint

following pollution incidents allowing the Government to take action, closing Fisheries where necessary, preventing potentially contaminated food reaching the commercial market. Thus protecting the general public from potentially contaminated fish and shellfish.

What outputs do you think you will see at the end of this project?

This project aims to ensure that a panel of expert sensory assessors retain their expertise and perform taint assessments which produce reliable and robust data. Recruitment and training of new assessors is an essential part of the project to maintain a pool of trained assessors.

Who or what will benefit from these outputs, and how?

Taint assessment provides a rapid and sensitive method for detecting taint following pollution incidents. This may be considered as a screening method prior to chemical analysis which would be used to confirm the presence of contamination. This allows swift action to be taken, closing Fisheries where necessary, preventing potentially contaminated food reaching the commercial market. Human health is protected and the reputation of the seafood and aquaculture industries safeguarded reducing the potential to damage the economy following a pollution incident.

How will you look to maximise the outputs of this work?

This project aims to ensure that a panel of expert sensory assessors retain their expertise and perform taint assessments which produce reliable and robust data. Recruitment and training of new assessors is an essential part of the project to maintain a pool of trained assessors.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rainbow trout (Oncorhynchus mykiss) are used they are a farmed species available in the size and numbers available for the project. Farmed trout offer a consistency in raw material over time as they can be obtained from the same farm where conditions are controlled with respect to diet, water quality, disease and size. Rainbow trout can tolerate a high stocking density and show no signs of distress when moved to a smaller tank.

Typically, what will be done to an animal used in your project?

The project exposes live rainbow trout to crude oil (2.5ml per 100 litre tank) over a period of exposure times. A maximum of 7 fish per tank, equivalent to a stocking density of 28 kg/m3, are exposed for up to 4 hours at a temperature of 15 °C (± 1 °C).

What are the expected impacts and/or adverse effects for the animals during your project?
Rainbow trout can tolerate a high stocking density and show no signs of distress when moved to a smaller tank. No adverse effects recorded in previous studies, experience to date suggests that the fish tolerate the oil exposure without any apparent clinical signs

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severity category Mild for all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Taint which appears in the fish muscle, is a result of the oil entering the fish through the gills and skin from the water. The intensity of taint resulting from fish exposed to crude oil will vary according to the length of time the fish is exposed to the oil. Spiking a sample (fish fillet) with crude oil will not give an accurate representation of taint which would naturally accumulate in a live animal exposed to the same oil as the whole oil would be present in the sample.

Which non-animal alternatives did you consider for use in this project?

Chemical analysis by GC-MS (gas chromatography mass spectrometry) Protein assay to look at the biological effects of exposure to PAH contamination.

Why were they not suitable?

Chemical analysis cannot replace the use of live animals for taint analysis as it is a sensory procedure (determined by smelling and tasting). Chemical analysis is a lengthy analytical procedure, typically a maximum of 10 samples can be analysed with results available after 3 days. In the event of an oil spill an expert sensory panel can rapidly assess many samples (40-50 per day), giving a rapid response to the potential contamination of a fishery. Swift action can be taken by authorities to close the fishery and prevent contaminated fish being taken and reaching the food chain, thus protecting human health.

Protein assay requires tissues to be sampled from live fish. In the event of an oil spill sampling would have to be conducted by highly skilled/trained personnel. Specialist equipment and storage facilities would also be required (tissue samples to be kept at -80

degrees C prior to analysis). It would not be practical or possible to adhere to scientific procedures following an oil spill.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of fish used is based on providing sufficient material (fish muscle) required to run a taint panel every 2 months. A panel will typically consist of between 7-12 assessors, each assessor is required to taste each sample. Within each training session a range of samples are presented ranging from absence of taint to extremely high taint. This is achieved by exposing live fish to crude oil over a period of time. A suitable range of intensities can be achieved by exposing fish for periods of time extending from 20 minutes to 4 hours. Each year the project requires 72 fish, of these 56 are exposed to crude oil and the remaining 16 unexposed and used as controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The concentration of PAH in the fish flesh is required to reach the detection and recognition threshold of the stimulus (oil taint) for 50 % of the assessors to ensure taint is detected.

Previous experimental trials have shown that the relationship between taint score and PAH (polycyclic aromatic hydrocarbons) concentration is optimised at the exposure intervals used for the project, thus ensuring the desired results can be achieved using fewer exposure times leading to fewer animals being required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Previous experimental trials have shown that taint intensity reaches a plateau after 8 hours. The minimum number of exposure periods has been selected to provide tainted material over a range of intensities (absent to extremely strong).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rainbow trout (Oncorhynchus mykiss) are used as they are a farmed species available in the size and
numbers available for the project. Farmed trout offer a consistency in raw material over time as they can be obtained from the same farm where conditions are controlled with respect to diet, water quality, disease and size. Rainbow trout can tolerate a high stocking density and show no signs of distress when moved to a smaller tank. No visible signs of stress have been recorded during the exposure period.

Why can't you use animals that are less sentient?

Animals are required to be of a size large enough to provide sufficient tainted material for assessment by a panel of expert assessors. Rainbow trout are shown to tolerate conditions such as high stocking density.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedure has a severity rating of mild and all animals are euthanized at the end of the trial. Animals are observed at regular intervals throughout the 4 hour procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Refer to the current Government legislation – ASPA

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Refer to the current Government legislation - ASPA

3. Investigation of vitamin d metabolism in sheep

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
    - Improvement of the welfare of animals or of the production conditions for animalsreared for agricultural purposes

Key words

Sheep, Vitamin D, Rickets, Supplementation, Trial

Animal types	Life stages
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to define the best way to prevent vitamin D deficiency in sheep.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have recently discovered that many sheep develop severe vitamin D deficiency during the winter in Scotland. In some cases this can lead to painful and debilitating skeletal complications including rickets. We propose to undertake an objective study to define the best way to prevent the development of hypovitaminosis D in extensively farmed sheep during the winter.

What outputs do you think you will see at the end of this project?

We expect this programme of work to allow us to define a strategy to prevent hypovitaminosis D in sheep during the winter period where there is an absence of UVB light in temperate regions. We will disseminate our findings in a peer reviewed manuscript. We will also share our results via Scottish farming networks through regional talks and seminars.

Who or what will benefit from these outputs, and how?

The principal beneficiary of this work will be sheep living in temperate regions since we anticipate that our work will define how they can be protected from the development of low vitamin D status and its associated metabolic complications. Through the improved welfare and health of the sheep in temperate regions over the winter period, this project will also boost the wider farming sector through improved productivity and profitability of their farming activities.

How will you look to maximise the outputs of this work?

We will disseminate this work widely through a scientific publication, talks and outreach activities as exemplified in our previous work on vitamin D metabolism in other species.

Species and numbers of animals expected to be used

- Sheep: 180

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are studying sheep because they are the animals which develop low vitamin D status over winter and it is sheep whose health and welfare we are seeking to improve.

Typically, what will be done to an animal used in your project?

The sheep will be given either an injection or oral bolus of vitamin D and will have their vitamin D status assessed before and after the intervention through the measurement of vitamin D metabolites in serum samples harvested at regular timepoints post vitamin D administration.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not envisage any serious side effects during this project. The only potential complication is hypervitaminosis D and associated hypercalcaemia but at the doses of vitamin D used, we do not expect this to happen. If a sheep in a control group develops any clinical evidence of metabolic bone disease, it will be immediately withdrawn from the

study and administered vitamin D. If an adverse event occurs we expect all to be mild in nature.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not expect to have any side effects beyond standard minor complications of blood sampling such as localised bruising at the venepuncture site. If these occur all will be mild. Although technically possible, we do not expect hypervitaminosis D and associated hypercalcaemia to occur. If this does then the complication is likely to be transient and mild. Again, although technically possible, we do not expect any of the control, untreated sheep to develop rickets during the lifetime of the experiment. If this complication occurs it is likely to be mild since it will be detected early due to close monitoring of sheep and we envisage that our early results will define how best to boost vitamin D status in sheep. We plan to begin this work in the autumn and measure 25(OH)D ASAP after sample collection. We then hope to be able to treat any remaining sheep with the most appropriate vitamin D supplementation approach ahead of the timepoint when clinical signs of rickets emerge. Therefore, we expect that the risk of the untreated sheep getting clinical skeletal disease is very low in our experimental approach and even if this does occur, it will be detected early once clinical signs are mild.

What will happen to animals at the end of this project?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are seeking to establish how best to prevent hypovitaminosis D in sheep and there is no meaningful way this can be explored other than by studying vitamin D metabolism in sheep.

Which non-animal alternatives did you consider for use in this project?

There are no meaningful non animal alternatives available to us which could allow us to address the research aims of this project.

Why were they not suitable?

There are no meaningful non animal alternatives available to us which could allow us to address the research aims of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We plan to undertake a single experiment at two different sites. In each experiment we plan to have 30 control, non supplemented sheep, 30 sheep administered with oral vitamin D and 30 sheep administered with injectable vitamin D. We have allocated 30 sheep to each group based on a power calculation which utilises data from our previous studies. Based on a mean 25(OH)D concentration of 7.9nmol/l at the start of the study and a standard deviation of 4.3nmol/l and with 90% power and at 5% significance, we require study groups to each contain 30 sheep to be able to detect an increase to 11.6 nmol/l. This experiment will be undertaken on two Scottish flocks. Consequently, the total number of animals which will be used is 180 (90 in each experiment).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We utilised historical data from near identical populations of animals to guide a power calculation to define the minimum number of animals needed for each study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have used a power calculation using objective, high quality and relevant data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will study sheep and will simply be administered vitamin D in a manner that is routinely done as part of standard management practice, namely through injection and oral drench. The only variation from standard veterinary practice is that we will assess vitamin D status objectively through the measurement of serum 25 hydroxyvitamin D (25(OH)D) concentrations before and at several time points post vitamin D administration.

Why can't you use animals that are less sentient?

We can only use sheep since these are the animals in which we are keen to prevent hypovitaminosis D in during winter periods in temperate climates.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will only be administering injections or boluses containing vitamin D and taking blood samples. These are all minimally invasive techniques that are standard management practices. The blood samples will be collected by experienced colleagues who are experienced in venepuncture techniques.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be following standard, well established techniques for collecting blood samples in sheep as well as the administration of injections and oral drenches.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I regularly receive information about the 3Rs from named veterinary surgeons and the wider veterinary and research community.

4. Novel approaches in bone repair

Project duration

5 years 0 months

Project purpose

- Basic research
  - Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Bone, Healing, Materials, Anabolic agents

Animal types	Life stages
Mice	Adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Surgical approaches to bone healing have remained largely unchanged for decades. This project explores how bone healing can be improved and accelerated by testing new agents/approaches to stimulate bone regeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Bone healing is a lengthy process resulting in reduced mobility which directly impacts everyday life at work and home. This work aims to provide new information toward helping individuals recover from a bone injury quicker, and better, to allow them to regain independence and mobility as soon as possible.

What outputs do you think you will see at the end of this project?

This project will provide new information on how the bone regeneration healing process can be accelerated to improve repair and reduce bone healing times. Through the study of our new drug, we hope to show how treatment with this agent stimulates bone healing.

Who or what will benefit from these outputs, and how?

In the short term, the research community will benefit from the validation of a new and rapid approach to testing agents which might stimulate bone repair, and which we will disseminate via research publications, conference proceedings and through institutional channels supporting 3Rs. Furthermore, those suffering from bone fracture or the need to combat accelerated bone loss will also benefit if improved understanding of bone repair is achieved, and the further development of our new bone targeting agent, to treat this problem.

How will you look to maximise the outputs of this work?

The findings from this work will be maximised through the dissemination of data describing this new model system and bone-targeting agent. This will be achieved through typical channels including publications and conference proceedings (with a focus on bone e.g. Bone Research Society, European Calcified Tissue Society). This will be conducted by both collaborating institutions on this project.

Species and numbers of animals expected to be used

- Mice: 1800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice represent the lowest mammalian option for us to study bone regeneration, and which have a mature skeleton resembling that of humans.

Typically, what will be done to an animal used in your project?

Normal animals or animals with a genetic modification related to bone and joint biology will be used. Genetically modified animals may have moderate skeletal defects (e.g. high/low bone mass, longer/shorter bone length). Animals will have a small hole (osteotomy) created in their bones, which represents a small fracture. Test agents which might accelerate the rate at which this bone defect/fracture heals will be given, and the bones monitored during the healing period.

Specifically, experimental animals not used for breeding purposes animals (approx 50%) will undergo general anaesthesia (up to 30 mins), bone defect/osteotomy surgery (in the tail vertebrae or long bone (hindlimb)), administration of agent (typical x28 injections), weekly imaging, dynamic weight bearing analysis (optional for long bone osteotomy groups only), injections of fluorescent agents to visualize bone formation rates (x2 injections), and will be killed up to week 8 via approved methods (including withdrawal of fluids e.g. blood).

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that most animals undergoing surgery will experience a low level of pain shortly after the procedure which will be managed with aseptic technique using sterilised instruments and materials to control for infection, monitoring and pain relief (analgesics).

A minority of animals may show complications in the short term. This might include: wound breakdown - bleeding immediately following surgery will be treated with immediate compression and repair of the wound with surgical glue applied externally. Further breakdown of the wound will be cleaned and re-closed once.

lameness - animals will receive appropriate pain relief prior to surgery and examined at 6-8 hours to ensure that they are pain-free. If animals continue to exhibit lameness or signs of pain, a repeat dose of analgesia will be administered and moist food will be placed on floor of cage. Animals will be inspected, examined and weighed daily until 4-7 days post op, with ongoing inspections and examinations at least twice per week.

The above impacts/adverse effects will be addressed as described for up to 24 hrs before humane end points (below) are actioned.

Breathing problems may occur following inhalation anaesthesia - listlessness or laboured respiration in animals following anaesthesia will be closely monitored during recovery upon a heated stage to maintain body temperature. Animals are typically expected to recover from anaesthesia within 10 mins. If animals are not recovered by 30 minutes humane end points will be actioned

Humane endpoints for this step:

Weight loss of more than 15%

Piloerection, hunched posture

Infection (as inflammation, swelling, redness) or successive breakdown at wound site or tail necrosis

Lameness and listlessness for more than 24hours

Tail Necrosis

Laboured respiration particularly if accompanied by nasal discharge/cyanosis

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity is expected in animals undergoing osteotomy surgery (50%). Mild or sub-threshold severity for control mice and those used for breeding.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Modelling the complex inorganic and organic components of the bone environment, including the cellular and matrix protein aspects, is extremely challenging. Furthermore, it is impossible to mimic the response of this environment to trauma and accurately model the impact of different cell types and matrix proteins. This proposal has used non-animal models to prove that a new agent aimed at improving bone healing is able to stimulate relevant cells in laboratory tests. This evidence supports the use of this agent as a potential therapy to improve bone regeneration and healing. However, it is impossible to determine this without the use of animal models.

Which non-animal alternatives did you consider for use in this project?

We have previously used in vitro cell culture to assess the effect of our new agent, and where a strong stimulation of bone formation and reduced numbers of bone destroying cells were seen. We have also considered the use of ex vivo model systems to address this question, but which are only capable of modelling limited elements of the bone repair process. These include the use of multi-cell cultures and human bone samples.

Why were they not suitable?

Multi-cell cultures such as 3D matrigel cultures or the use of transwell inserts in 2D, do not account for matrix contributions, and human bone samples do not culture well and where the impact of trauma cannot be easily accounted for.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used specific mathematical calculations based upon previous studies and the likelihood of our agent producing positive results, to estimate the number of animals we will use in our study. For all experimentation, the lowest possible number of animals will be tested whilst ensuring that the experimental result is robust.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used statistical analysis to calculate the minimum number of animals necessary for this project. In addition, longitudinal weekly imaging of the same animal over the healing phases will be used to reduce the need for multiple animals at different time points.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have used statistical analysis to calculate the minimum number of animals necessary for each experiment within this project. Furthermore, pilot studies will be used to further determine bone healing rates and which will inform further calculations of necessary animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

- Which animal models and methods will you use during this project?
- Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used in a i) long bone and ii) tail vertebrae osteotomy model. This species and procedures have been chosen as they represent the lowest animal model possible to study bone regeneration, and where a modified version of bone fracture will be tested. This offers the opportunity to significantly reduce suffering and harm to the animal induced by unnecessary and complex surgical procedures.

The exploration of a tail vertebrae osteotomy model to clinically measure bone regeneration is anticipated to cause less distress to animals as the proposed defect is considerably smaller than those used in full fracture models, the necessary surgery is considerably less as is the need for external fixators to support the bisected bone. Furthermore, the overall systemic impact of the defect upon the whole body is less due to the remote site of injury and significantly reduced necessity of tail vertebrae compared to long bones (e.g. femur). Although a small degree of pain and discomfort associated with this procedure is anticipated, it is expected to be a considerable reduction versus that of a long bone fracture, and where similar scientific information might be generated.

In addition, animal handling will be kept to a minimum and where the scoop and lift technique will be used, particularly with regard to protecting the tail following tail osteotomy surgery.

Why can’t you use animals that are less sentient?

Less sentient animals do not possess the same sort of skeletal structure. Small rodents are the lowest mammals which can be used to recapitulate human bone healing.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be monitored closely during the first 48 hrs following the procedure, and after which a standard monitoring time frame will apply. Pain will be managed through the use of analgesics as necessary. Dosing regimens will be explored to reduce the number of injections at different sites. This includes the use of small minipumps which may be implanted under the same anaesthesia as osteotomy surgery, and can deliver agents without the need for repeat injections.

We will also first determine whether the tail vertebrae model is effective in assessing bone regeneration, and where reduced numbers might be used if the more invasive long bone osteotomy model becomes necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow all guidelines indicated by the NVS, NACWO and research institution and including in relevant publications such as 'The Design of Animal Experiments', and the 'Handbook of Laboratory Animal Management and Welfare'.

We will follow the LASA guidelines for aseptic surgery and analgesia, which can be found on http://www.lasa.co.uk/wp-content/uploads/2018/05/Aseptic-Surgery.pdf and the Home Office Minimum Standards for Aseptic Surgery (www.procedureswithcare.org.uk/ASMS2012.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend routine Animal Welfare Meetings (former Gold Standard) and continue to engage with Institutional efforts to promote the 3Rs, including our continued participation in Institutional 3Rs day, and workshops.

5. Improving treatment options for individuals with diabetes and developing intervention strategies; using beta cell replacement and regenerative therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Diabetes, Islets of Langerhans, Insulin, Mesenchymal Stromal Cells, Transplantation

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, aged, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the work carried out under this project is to improve treatment options for people living with diabetes and to develop intervention strategies to delay the onset of diabetes in those at risk. The project will address two main objectives; (1) Improving the survival and function of transplanted islets by reducing early inflammation at the implantation site; (2) Defining strategies that help to prevent chronic immune cell mediated destruction of endogenous pancreatic islets and transplanted islets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Type 1 Diabetes (T1D) is an autoimmune disease in which the immune system destroys the insulin- producing islet beta cells in the pancreas. Approximately 422 million people worldwide have diabetes, 400,000 in the U.K, and its prevalence is gradually increasing. Diabetes is associated with increased morbidity and early mortality due to the complications associated, including eye damage, cardiovascular complications and kidney disease.

Islet transplantation offers the perfect treatment for T1D offering continuous, real-time, glucose responsive insulin delivery avoiding short-term risks of low blood glucose (hypoglycaemia) and longer term risks of microvascular complications. However, islet transplantation is still an experimental therapy with caveats and clinical limitations. Islet transplantation can improve quality of life for people living with Diabetes who have difficulty managing blood glucose levels despite their best efforts with intensive insulin therapies and extensive advice from diabetes specialists. Following this procedure, the number of daily insulin injections/insulin administration via a pump can be significantly reduced and, in some cases, stopped for at least a few months, and up to five years after. Islet transplantation can improve quality of life by eliminating/reducing hypoglycaemia and stabilizing blood glucose levels, which reduces the psychological stresses associated. Islet transplantation is likely to reduce the probability of long-term secondary vascular complications. Improvements to systemic immunosuppressive regimens has potential to reduce unwanted side effects of some currently used drugs. Improving the efficiency of islet transplantation will benefit individual islet graft recipients, and by saving on the scarce human islet graft material, will allow the treatment of many more people with T1D.

Defining novel therapeutics which improve the functional survival of the insulin-secreting islet beta cells, has significant potential to contribute to improvements in clinical islet transplantation, as a therapy for T1D. Additionally, this work has potential to help maintain the survival of endogenous pancreatic islet beta cells to delay and/or prevent the onset of Diabetes. The strategy to develop therapeutics that reduce inflammation of the transplanted islets themselves, as well as cells within the environment to which the islets are transplanted (immune cells and endothelial cells lining the blood vessels), enhances the likelihood of successful therapeutic intervention.

What outputs do you think you will see at the end of this project?

The studies outlined under this project proposal will generate new information regarding the potential of novel strategies to improve islet transplantation and beta cell replacement therapies for the treatment of diabetes.

The studies will be disseminated through publication in scientific journals and communication of findings at scientific and clinical conferences.

Who or what will benefit from these outputs, and how?

These studies will generate information that will be of direct clinical relevance in improving the outcome of transplantation therapy for Type 1 Diabetes (T1D). At present, clinical human islet transplantation can be offered to only a small subset of people with T1D, who develop severe hypoglycaemia (low blood glucose) unawareness. Unfortunately, at present not all people with hypoglycaemia unawareness can be offered a transplant. Improvements to the efficiency of clinical islet transplantation, as well as immunosuppression strategies, will mean that islet transplantation can be offered as a therapeutic option to many more people with T1D. These studies are also likely to identify potential therapies for delaying the onset or even preventing T1D.

Islet transplantation improves quality of life for patients who have difficulty managing blood glucose despite their best efforts with intensive insulin therapies and extensive advice from diabetes specialists. Following this procedure, the number of daily insulin injections/insulin administration via a pump can be significantly reduced and, in some cases, stopped for at least a few months, and up to five years after. Islet transplantation differs to some of the other forms of treatment such as insulin pumps, because the islets are infused by a simple procedure into the portal vein (liver), which means that the insulin does not need to be delivered by an external technological device ie Insulin pump. Islet transplantation can improve quality of life by eliminating/reducing hypoglycaemia and stabilising blood glucose levels, which reduces the psychological stresses associated. Islet transplantation is likely to reduce the probability of long-term secondary vascular complications. Improvements to immunosuppressive regimens has potential to reduce unwanted side effects of some currently used drugs.

Information generated from this project may impact on the outcomes of islet transplantation within a relatively short period (5 years) by identifying straightforward modifications to clinical islet culture/transplant procedures. Any impact on intervention of T1D onset is likely to take longer (10 years) because of the time frame of drug development and testing in clinical cohorts.

The identification of novel anti-inflammatory/immunomodulatory mediators has potential to improve the survival of stem cell derived beta cells after transplantation. Therefore, in the longer term, this research may contribute to the potential of using alternative islet/beta cell sources as a replacement therapy to treat diabetes. This will further increase the number of people living with diabetes who are likely to benefit from this research.

How will you look to maximise the outputs of this work?

These studies will generate scientific data and information useful to researchers and clinicians within the diabetes field. The information generated from this project will be made available to clinicians in the diabetes field, and members of the UK Islet Transplantation Consortium. The research outcomes will be disseminated at scientific and clinical conferences and in scientific journals.

Species and numbers of animals expected to be used

- Mice: 2300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Aim One and Two of this project is to improve the efficiency of clinical islet transplantation as a therapy for Type 1 Diabetes (T1D). The use of experimental animals is unavoidable, since we need to carry out preclinical studies in mouse models of islet transplantation that mimic the clinical procedure. Wherever possible experiments will be performed in vitro, using islets isolated from mouse pancreas (this is not a licensed procedure under the 1986 Act). However there is no suitable in vitro model for the complex mechanisms regulating whole body glucose control, which involves many tissues and organs, including liver, muscle, fat, endocrine organs and immune cells. We will use adult mice for these experiments, since in the clinical scenario, individuals with T1D who may be offered an islet transplant will be adults.

As part of the scientific objectives of aim two, we will define therapeutic strategies that help to ensure the survival of endogenous insulin secreting islet beta cells that are under attack from the immune system during the development of diabetes. The causes of diabetes are complicated and involve complex interactions between the islet cells and immune cells. Therefore, preclinical studies that can determine the capacity of a therapeutic strategy to delay diabetes onset need to be done in mouse models that mimic the clinical scenario in humans.

Typically, what will be done to an animal used in your project?

For islet transplantation experiments, mice will be administered an injection of a chemical called streptozotocin, which selectively kills the insulin secreting islet beta cells. After this injection mice become diabetic within 5 days. It is necessary that the mice develop high blood glucose, so that it is possible to fully determine the effects that our modification to the transplant procedure has upon blood glucose control and cure rate in islet transplant recipients.

Mice will receive transplants of insulin secreting islet cells, transplanted beneath the kidney capsule, or into the liver via the portal vein. Occasionally, islets may be transplanted beneath the skin (subcutaneous transplantation), into the peritoneal cavity or into the muscle. Mice will be unconscious for the transplantation procedure to ensure no unnecessary stress, and will be administered analgesics prior to the procedure to minimise any pain. Mice regain consciousness following the transplantation and will be monitored in the hours following the transplantation to ensure that they have recovered promptly as

they should do. Transplanted mice are then monitored daily in the first week post transplantation and every 2-3 days for the remainder of the post-transplantation monitoring period.

Mice will typically be monitored (blood glucose and weight) for 4 weeks after transplantation. However, longer monitoring periods (up to 20 weeks) will be necessary in experiments where we need to evaluate the efficacy of a defined immunosuppressive modification to delay immunological graft rejection. Some mice that have been transplanted with islets underneath the kidney capsule may have the islet graft-bearing kidney removed surgically at the end of the post-transplantation monitoring period to check that the cells were working properly. Specifically, mice that have been cured by the islet graft should revert to hyperglycaemia if indeed it is the islets transplanted underneath the kidney capsule that are responsible for the cure from diabetes.

For experiments that aim to determine whether we can delay the onset of diabetes, we will use mice that have the DNA and genetics that mean they spontaneously develop diabetes. In these mice, we will give them defined therapies to try to delay or prevent diabetes occurrence. These therapies will be given by simple procedures, such as injections with defined dosing schedules. The development of diabetes will be monitored by testing blood glucose using a glucose meter (the same way that humans can test) and a small drop of blood collected by making a small pin prick in the tail (this will be the way that we monitor blood glucose in islet transplanted mice too).

What are the expected impacts and/or adverse effects for the animals during your project?Hyperglycaemia (high blood glucose) can cause a small amount of weight loss, which is usually kept to a minimum after islet transplantation due to the blood glucose lowering capacity of the transplanted islets. Animals that have high blood glucose (above 20 mmol/l for 2 consecutive readings) may be given subcutaneous insulin injections to prevent excessive weight loss.

High blood glucose can also cause thirst and more frequent urination than normal. Therefore, availability of water will be monitored regularly and bedding will be changed on a very frequent basis. The insulin injections will also limit how high blood glucose becomes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals used for this project are expected to experience procedures of moderate severity. This includes the mice who spontaneously develop diabetes and the mice that are given an injection to make them diabetic before investigating strategies to improve transplantation outcomes.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Many of the initial studies will use cells and/or islets isolated from experimental animals. These experiments will be performed under controlled conditions outside the body, in vitro, but there is no in vitro model to mimic the complex control of blood glucose following islet transplantation which involves many organs including liver, muscle, fat, gut, lymphoid and endocrine tissues. Experimental in vitro systems cannot fully measure complex interactions of immune cells within tissues. Initial immune cell studies will be done using isolated immune cell subsets in tissue culture. However, understanding integrated immune processes is key to understanding human disease progression and graft rejection.

Which non-animal alternatives did you consider for use in this project?

Detailed in vitro studies, which do not require the use of animals, make up the majority of this project.

We will use immunological assays using immune cell populations from human volunteers, cell lines which are similar to human and mouse cells, and in some cases using cells and tissues collected from animals. These assays will assess whether our therapeutic strategy can reduce unwanted inflammatory and immune attack and destruction of the insulin-secreting islets.

We will also use in vitro endothelial cell lines (the cells which line blood vessels) inflammation assays, to investigate potential therapeutic strategies that may be used to limit inflammation-mediated loss of transplanted islets. Investigating endothelial cell inflammation is important because in the clinical situation, islets are transplanted into the blood vessels of the liver.

These non-animal alternatives are designed to mimic the islet transplantation environment in vitro, so that less animals need to be used to address our scientific questions.

Why were they not suitable?

A number of non-animal alternatives are suitable for investigating the likely effective dose of therapeutics and their mechanisms of action. These will be used before progressing to the animal studies outlined in this project.

However, there are no non-animal alternatives that are appropriate for fully mimicking the complexity of interactions between inflammatory/immune cells, endothelial cells and islets in the setting of Type 1 Diabetes (T1D) pathogenesis or beta cell replacement to treat T1D. Therefore, our promising in vitro studies will need to be investigated using animal models of diabetes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In general, experiments will use group sizes of between 6-12 animals. Precise group sizes for individual experiments will depend on the scientific question. For example experiments that involve investigating whether a particular treatment has any effect may require small group sizes, whilst an experiment to determine whether there is any significant difference in efficacy between two treatment groups may require more animals, particularly where more variation is expected in the outcomes. For transplantation experiments, animal numbers were calculated based on our own and other previously published studies, which have used mouse models of islet transplantation to determine whether a therapeutic modulation can improve outcomes. The number of mice which have particular genes that make them susceptible to developing Diabetes with a similar progression and underlying pathology to that seen in the human condition, has been estimated based on published studies and communication with colleagues (who have expertise in maintaining these mice colonies) indicating that the incidence of spontaneous diabetes is 10-40% and 70-90% in male and female mice, respectively. It is expected that each mother would have 2, or 3 litters maximum, based upon breeding between ages 6 weeks and 12 weeks, and an anticipated litter size of approximately 5 pups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design for this project we have referred to NC3Rs guidelines online (https://www.nc3rs.org.uk/experimental-design), to ensure that animal numbers are reduced to a minimum. The outline of this project is designed so that transplantation experiments and intervention strategies to delay or prevent the onset of diabetes will be carried out as an absolute end-point following in vitro experiments that demonstrate robust and reliable efficacy.

Experimental protocols will be designed to reduce animal numbers. For example, in islet transplantation experiments where islets are implanted under the kidney capsule and the

mouse cures from diabetes, the islet graft-bearing kidney will be removed at the end of the monitoring period to assess whether the animal will develop high blood glucose again. This proves that the transplanted islets are the cause of the animal curing, as opposed to regeneration of the islets in the pancreas, and thus removes the need for sham/mock operations in control animals. We will refer to the ASRU GA Breeding and maintenance framework for guidance on breeding and colony maintenance.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For experiments using diabetic mice, other tissues, such as the kidney, bladder, brain, heart and eyes may be collected after the mice have been humanely killed, to look at potential effects of secondary complications of diabetes, alongside the primary objectives looking to improve transplantation outcomes as a cure for diabetes or intervention strategies to prevent diabetes.

All in vivo work will be reported according to the updated ARRIVE guidelines, as published this year in PLOS BIOLOGY.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For some experiments, mice will be administered an injection of streptozotocin, which selectively kills the insulin secreting islet beta cells and therefore, the mice become diabetic within 5 days. This can cause a small amount of weight loss. Mice then receive a transplant of insulin producing cells and compounds designed to improve the survival of transplanted cells. This procedure is needed, so that it is possible to fully determine the effects that our modification to the transplant procedure, has upon blood glucose control and cure rate in diabetic animals. Mice will be unconscious for the transplantation procedure to ensure no unnecessary stress and will be administered analgesics prior to the procedure to minimise any postoperative pain. Mice will be monitored in the hours following the transplantation to ensure that they have recovered promptly as they should do. Transplanted mice are then monitored daily in the first week post transplantation and every 2-3 days for the remainder of the 1-month follow-up period. Animals that have extremely high blood glucose will be given subcutaneous insulin injections to prevent excessive weight loss and suffering.

For intervention studies aiming to delay or prevent Diabetes, we will use a strain of mice which has genes that make them susceptible to developing Diabetes. This strain of mice spontaneously develops diabetes in a similar way to humans and so many of the aspects of disease progression and pathology are the same. For example, similar immune cells (T cells) are important in disease progression for humans and this strain of mice, as is the autoimmune (the body's own immune system destroys its own insulin secreting islet beta cells) nature of the disease. This allows us to effectively investigate novel strategies to delay or prevent diabetes.

Why can't you use animals that are less sentient?

All experiments will be conducted in mice, which provide the most ethical model. Mice show similar glucose control mechanisms to humans, so data obtained are valid for translational studies in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal suffering is minimised by aseptic surgical procedures and by postoperative analgesia for all surgical procedures.

Blood samples will be small (less than 1 microliter) and the total taken will not exceed 15% blood volume in any 28 day period. Following sampling, pressure will be applied to the puncture site to stop bleeding. When taking blood samples mice will not be restrained as this will cause unnecessary distress. Instead, they will be allowed to move around the cage freely, whilst taking the blood sample by a small pin prick to the end of the tail, which can be done in a matter of seconds.

Fasting of mice to achieve baseline blood glucose prior to glucose tolerance tests will be limited to a minimum to reduce distress where possible. Mice will always have free access to water.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines available on online resources including NC3Rs (https://www.nc3rs.org.uk/), Frame https://frame.org.uk/ and the "Strategic Planning for Research Planning Programmes" guidance available here, articles on pubmed (https://www.ncbi.nlm.nih.gov/) and LASA guidelines (https://www.lasa.co.uk/) will be followed, and reviewed on a regular basis.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Scientific literature regarding the most appropriate animal models of diabetes (Pubmed) will be reviewed regularly. The NCR3Rs website will be reviewed regularly

(https://www.nc3rs.org.uk/) to determine where there are potential refinements to procedures, as well as opportunities to reduce and replace the use of animals. I will further discuss possible refinements with the establishment named vetinary surgeon.

6. Modelling cancer biology and therapy in mouse

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph

Key words

cancer, cancer stem cells, therapy, metastasis, tumour

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify genes that influence the development and progression of cancer and to demonstrate whether alteration of these genes (or gene products), either directly or through pharmacological intervention, has a therapeutic effect.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The spread of tumour cells throughout the body is the cause of more than 90% of patient deaths and there is currently a dearth of available therapies for this clinically important, but poorly understood process. Our work aims to identify genes that influence this process and to test novel therapeutics and therapeutic approaches that interfere in these genetic pathways, thus preventing the development and progression of cancer within the body.

What outputs do you think you will see at the end of this project?

New information on the underlying biology of cancer that drives the development and spread of the disease around the body. This will be disseminated through publication of our findings in academic research journals and will lead to new grant funding to explore these findings further. We aim to identify new therapeutic agents that target these novel biological processes and this may lead to the development (and publication) of novel therapeutic products for use in future clinical trials.

Who or what will benefit from these outputs, and how?

There will be the immediate impact of our work to the cancer research community with respect to the addition of new knowledge of cancer biology.

Regarding its long-term impact on human health, the subsequent development of therapeutic agents identified during this project, to the point where they may be used in clinical trials of cancer patients, is a long-winded process requiring further extensive testing of the toxicity and efficacy of these agents in animal and laboratory models. These subsequent tests lie outside the remit of this project.

Consequently, the introduction of any novel therapeutic agents identified during this project into clinical trials and its subsequent impact on cancer patients would take a minimum of 2-3 years after the completion of these studies.

How will you look to maximise the outputs of this work?

All knowledge generated during this project will be disseminated as peer-reviewed publications and presented at national/international conferences/scientific meetings. Data will be shared via open access journals and repositories. We will continue to actively engage with the general public via events within the University/local communities and via national cancer charities. Progress and successes in key milestones will be released via University research pages, newsletters and social media.

Species and numbers of animals expected to be used

- Mice: 2250 adult males and females

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The progression of cancer, where tumours grow then disseminate to other parts of the body, is a complex multi-stage process that encompasses many changes in the interactions between tumour cells and a large variety of different 'host' tissues. These interactions are essential for the success of the tumour to spread, and each has been modelled in the laboratory to some degree - but in order to represent the entirety of this process - and thus to model the effects of inhibiting one or more of these elements on clinical outcome, it is necessary to observe the process in a complete animal model.

We intend to explore the genetic basis of this process and mouse transgenic models are the most advanced genetically tractable models which approximate most closely to the tissue architecture of humans. They also remain the primary model for the propagation of human tumours within a whole organism host in which human tumours retain their tissue architecture and ability to disseminate and seed at distal sites within the host.

Typically, what will be done to an animal used in your project?

Mice will either be genetically predisposed to developing cancer or will be transplanted with cancer cells and then the effects of anti-cancer agents or alteration of the genes of interest will be assessed.

In the case of genetic predisposition, existing genetically altered mice will be sourced from other projects with authority to breed and maintain genetically altered animals, and subsequently maintained and bred to generate experimental mice with predisposition to develop tumours.

Animals with genetic predisposition will be monitored or scanned for signs of tumour burden and may be subjected to administration of substances or cells that may affect the course of tumour development (via one of several routes including for example, blood stream, subcutaneous or intra-muscular).

In the case of transplantations, either wild-type or genetically altered mice will be injected with cancer cells (under the skin, within the body cavity or organ or into the bloodstream) or surgically transplanted with tumour tissue and monitored or scanned for signs of tumour burden and may be subjected to administration of substances or cells that may affect the course of tumour development (via one of several routes including for example blood stream, subcutaneous or intra-muscular).

What are the expected impacts and/or adverse effects for the animals during your project?

The primary adverse effects originate from tumour burden. These include adverse effects of malignant tumours such as weight loss, hunching, inappetance, lack of grooming. Additional tissue-specific clinical signs of pancreas tumours may include weight loss from the haunches, abdominal distension, pallor in the extremities (e.g., paling feet). Lung

tumours may cause breathing difficulties. These signs of morbidity may be evident for several days but usually no more than one week before humane killing. In some models of disease spread (metastasis) there may be infrequent (approximately 5%) instances of sporadic sudden death brought about by vascular blockages caused by the circulating tumours cells.

Following surgery (during embryo transfers or transplantations) there may be tissue inflammation which may cause transient minor discomfort and will be managed with the use of analgesics.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 40% of mice will either harbour no genetic alteration as a result of breeding or will be harbouring a genetic alteration (either immune compromised or harbouring a genetic alteration potentially affecting tumour burden) but will be symptom free and therefore will be categorised as Mild.

Approximately 60% of mice will either have developed tumour burden spontaneously due to their genetic alteration or will have been transplanted with tumour cells and their symptoms will have been managed with respect to the adverse effects of tumour burden, so will be categorised as Moderate.

Approximately 1% of mice may experience sudden onset death (as a result of metastatic tumour burden) and will be categorised as Severe.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to be able to model the complex biology of tumour interactions with normal cells in a tissue microenvironment in which the tumour cells are able to migrate from the proximal site to distant tissues via the lymphatic and/or blood system. This allows us to understand the role of individual (abnormal) genes in complex tissue systems and also allows us to determine the effect of disrupting these genetic pathways on the metastatic process.

Mouse models of cancer are clinically relevant and accurately recapitulate the full spectra of human disease at the genetic, cellular and tissue level. Cancer is multifaceted disease that initiates with genetic mutation in cells; however, for tumours to progress to malignancy mutant cells 'hijack' normal biological processes (e.g., immune cell infiltrate, stromal cells, extracellular matrix modification) to support tumour progression. Mouse models accurately model all aspects of tumour complexity that would be technically challenging to achieve using ex vivo or in vitro cell systems alone.

Which non-animal alternatives did you consider for use in this project?

We use a variety of non-animal alternatives in our research. The majority of these involve monolayer cell culture, 3D-organoid and primary tissue (human and mouse) culture in the laboratory as a reductive approach to unravel molecular cell biology of a phenomenon at the single cell level. Organoids also allow for high-throughput experimental approaches, e.g., testing efficacy of pharmacological inhibitor before administering to animals. However, these systems cannot entirely replace the need for animals in this project.

Why were they not suitable?

These alternative models and assays each measure single aspects of cancer progression: for example, cell migration, cell division, cell death and there are numerous variations in practice that include mixed cell types (tumour and non-tumour) in the assays. However, none are capable of recapitulating the series of events leading to cancer metastasis, or mimic the multiple cell interactions that it involves.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is estimated empirically to be 75% of number of mice used in the preceding project licence for this project. This takes into account the increased use of alternative non-animal models used in our work and the evolution of the project towards pre-existing animal models which minimises breeding requirements.

We estimate this will include 3 genetically altered mouse lines involving multiple conditional oncogenes and experimental transgenes. Transplantation experiments will be performed according to our published studies and we predict that the number of experiments to be performed will be approximately two-thirds the number performed under our previous project licence as we will be completing final preclinical evaluation of Bcl3 in

Objective 2, while progressing cFLIP studies (Objective 1) and up to two additional target gene pathways from Objective 3.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There has been an increased use of non-animal models of cancer in our laboratory and previous introduction of scanning modalities which allows us to non-invasively monitor tumour progression in mice over time rather than have to use multiple animals at single time points for specific experiments investigating disease progression.

All experiments are based on previous studies performed within the host laboratory using identical or similar mouse models designed using the NC3Rs Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to source experimental animals for transplantation studies from other projects or establishments with authority to supply genetically altered animals (eg commercial services) rather than breed our own stocks which can lead to the generation of 'excess' stock animals.

In the majority of cases optimum cohort sizes for individual experiments have already been established through empirical observation from our previous licensed work or from the published literature. In each case the minimum number of animals required to obtain statistically rigorous outcomes have been identified. Specific measures that have been incorporated into our experimental designs to reduce mouse numbers include: breeding heterozygous pairs/trios to increase efficiency in the generation of transgene heterozygosity; dividing harvested tumour target tissues into multiple fixatives (e.g., OCT, FFPE, frozen) in order to maximise the output of each induced animal; including pilot studies (2-4 mice) to ascertain optimal dosing of pharmacological inhibitors

Transplantation of established tumour lines dramatically reduces the variability of tumour latency and growth kinetics compared to primary tumour transplants and sporadic tumours. Power calculations have already been applied to many of these transplant models and, due to their inherent uniformity, relatively small tumour cohorts (eg. n>6) are required for statistical rigor.

Where possible, bilateral transplants will be performed in order to halve the number of animals required to generate sufficient experimental tumours. This may include asymmetric bilateral transplants in which experimental tumour cells may be transplanted opposite to an unmodified (control) tumour in the same mouse. This has the advantage of minimizing variability between experimental and control arms of an experiment, thus reducing cohort sizes

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Breeding strategies and long-term tumour cohort studies require that the animals be maintained for prolonged periods of time (more than one year). In all cases, but particularly for these animals, care is taken to ensure where possible that they are kept in small sibling groups (more than 2) in appropriately sized cages and that suitable 'apparatus' is provided to help enrich their environment.

The principal impact on animal suffering in this project will be tumour burden and the involvement of secondary tumours to vital organs. This may occur in GA mice or following tumour transplantation. Suffering will be minimised by: (i) close adherence to maximum permissible tumour size according to Workman and co-workers (Workman P., Aboagye, E., Balkwill, F. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010). https://doi.org/10.1038/sj.bjc.6605642); (ii) using, where possible, established GA models and established transplantation models, with predetermined tumour latency, growth kinetics and secondary tumour involvement; (iii) use of non-invasive imaging techniques to identify secondary tumours early, prior to external signs of morbidity; (iv) use of tissue specific and inducible conditional transgenics in GA mice to restrict aberrant phenotypes and tumour growth to adult tissue.

Suffering may also occur following adverse reaction to transplantation, surgery or injection. We have pro-actively refined our intravenous and subcutaneous xenograft techniques to significantly improve recovery rates. For example, intravenous injection of tumour cells is now performed under light or no anaesthesia to alleviate pulmonary distress and significantly improve recovery rates.

Why can't you use animals that are less sentient?

The most appropriate tumour models must recapitulate the tissue and circulatory architecture of humans and so mammals (which possess mammary structures to mimic breast cancer for example) and higher vertebrates (pancreas, prostate, upper and lower GI) are the most appropriate experimental models for the majority of solid tumour types in humans.

Tumour development and progression is primarily a disease of adult/aged tissues and occurs over a period of weeks or months and so it is necessary to perform these

experiments in adult animals for prolonged periods of time. Therefore, immature life stages are not appropriate for our research studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements will include frequent monitoring of induced animals, post-operative or anaesthetised animals. Exogenous substances/agents will be administered at the minimum dose, as determined using NC3Rs guidelines for best practice and dosing regimes, and following consultation with our collaborators. All procedures will be carried out by trained and experienced staff with the support of experienced animal facility staff/NACWOs/NVS (e.g., application of anaesthesia, analgesics, surgical techniques). Clear humane end points are detailed for each protocol.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

This project will be carried out in accordance with ARRIVE guidelines and involving collaboration with experienced cancer researchers with track records of excellence in the field of tumour xenografts and in the use of genetically altered mouse models of disease.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Engage with our Establishment’s Regional Programme Manager for the NC3Rs on a regular basis via local workshops/meetings, newsletters and social media.

7. Modelling brain tumours in the mouse

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain tumours, cancer stem cells, neural stem cells, radiotherapy, epigenetics

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Brain tumours are the second leading cause of cancer related deaths in males ages 20-39 and the fifth leading cause of cancer-related deaths in women ages 20-39. Patients with glioblastoma survive about 140 days on average rising to 14 months if they are suitable for radical treatment. Survival trends for these patients have not improved in recent years and these tumours represent a rare exception to the general trend of cancer survival in the UK. Brain tumours also account for a large proportion of childhood tumours. Medulloblastoma is the commonest brain cancer seen in young children. The main treatments available to children with medulloblastoma today are surgery, radiotherapy or chemotherapy. These treatments can be effective and kill the tumour cells in a proportion of patients; however they are almost invariably also causing severe side effects which are particularly damaging in young children as their brain is growing quickly.

We are studying the cell of origin of brain tumours and we are trying to identify novel genes and pathways that control their behaviour. In particular we are looking at stem cells:

these cells are found in every organ and can develop into specialised cells, thus contributing to the maintenance and 'regeneration' of the organ. We find cells behaving as stem cells in tumours too, they play an essential role in "regenerating" the tumours and so killing them is crucial. We are trying to establish the difference between these tumour stem cells that keep proliferating – producing other tumour cells endlessly – and normal stem cells, which stop proliferating when the body stops needing new cells. If we can understand how a tumour stem cell controls its proliferation, we can start generating more targeted drugs that specifically kill these cells in a more effective and also much less toxic way.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This research will help us to understand how to improve the treatment and therefore the survival of patients with brain tumours. If we know what allows tumour to grow, we will be able to design new more effective therapies.

What outputs do you think you will see at the end of this project?

The research data to be generated are:

- generation and characterisation of advanced pre-clinical models of brain tumours
- description of mouse brain tissue as well as establishment and characterisation of mouse cells cultured in a dish, both healthy and in the context of tumour development
- whole genome datasets obtained through RNASeq, small RNASeq, ATACSeq, ChIP Seq and WGS, on mouse tissues and cells
- design and validation at pre-clinical level of novel therapeutic approaches, including testing 10-15 compounds with the aim to take the most promising forward to clinical trials.

We will disseminate the results and conclusions of the research to broader audiences. We will present the work at meetings and at invited seminars at various institutions. We will publish our findings in international peer-reviewed journals with the best possible visibility. We will organise and participate in workshops, charity events, and road shows to provide training and dissemination of information. Our lab has a close relationship with several charities and we host regular lab visits, which include direct involvement of patients and their families in the design of our studies. We regularly interact with clinical patient groups in the context of grant applications (preparation and review).

Who or what will benefit from these outputs, and how?

This basic science programme of work will provide us with a better understanding of the molecular basis of the development of malignant brain tumours, in particular it will elucidate the contribution of molecular changes to DNA structure impacting gene activity (epigenetic changes) to the regulation of tumour formation and maintenance.

This project will have important implications not only for cancer research and therapy but also for neuroscience, stem cell biology and developmental biology.

Most importantly, this project has the potential to significantly impact on patients' health. Gaining a better understanding of the underlying biology and development of brain tumours, is essential for drug development. The work undertaken as part of this project uses, wherever possible, cells directly derived from human brain tumours, and uses the most up-to-date in vivo models in which to test novel and repurposed treatments. The brain tumours we study have some of the worst prognoses of any cancers, and work such as that which is proposed here is essential to find treatment pathways that will significantly impact on patient survival outcomes. This is only made possible by using experimental systems that best recapitulate brain tumours by using environments as close as possible to human disease. One of the overarching aims of this project is to provide robust pre-clinical evidence that could inform the design of future clinical trials.

We will work with science journalists to submit press releases of our most prominent publications to reach the goal of engaging a wide public audience. Moreover, our research will provide new contents for the Institute and School website.

We will engage with charities, patient groups and all parties' parliamentary groups to enhance public understanding and awareness of our research.

How will you look to maximise the outputs of this work?

We have an extensive network of collaborations both nationally and internationally. In generating data that can be accessed on open forums and presenting at national and international conferences, we will ensure that the wider research community is able to benefit from our work.

This programme of work promotes collaborations between wet-lab scientists and bioinformaticians, providing training that bridges different research fields. Indeed recent developments in high-throughput methods place significant challenges to next generation life scientists and clinicians, who are expected to have expertise in molecular and cellular methods but increasingly require also in depth knowledge of bioinformatics approaches to be able to develop interdisciplinary programs. Individuals involved with the project will directly benefit from the interdisciplinary training provided and transferable skills obtained.

Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have many physiological and genetic similarities to humans, therefore they represent excellent models for studying complex diseases and response to treatments that affect humans. Additionally, the lifespan and reproductive process in the mouse allow experiments modelling whole disease courses to be carried out on a relatively short timescale. There are extensive tools available, in our lab and beyond, for the manipulation of the mouse genome also making the mouse an excellent model, and especially important for cancer research, immunodeficient mice are available that allow human cancers to grow within a mouse - allowing detailed research into how cancer interacts with the host environment and the best model for new treatments.

We will use both young and adult mice, as we want to use mice of ages that match those in which human disease occurs. Glioblastoma and metastatic brain tumours are the most common brain tumours that occurs in adults, and medulloblastoma is the most common brain tumour of children.

Typically, what will be done to an animal used in your project?

The majority of mice used in this project will be used for breeding and these mice will only undergo momentary discomfort for marking procedures. A proportion of mice will undergo induction of brain pathology, which will entail either genetic induction of tumours or injection of tumour cells, either directly or via the bloodstream, into the brain. Subsequently a proportion of these mice will undergo treatment for the resultant tumours with drugs and/or radiation and/or simulated biopsy. Mice typically take from two weeks to a few months to develop tumours, and will be humanely culled once symptoms develop or at defined timepoints after induction of brain tumours to study their origin and development. Tumour cells may be labelled to facilitate their identification within the brain and their isolation for analysis.

Some mice will undergo focal irradiation to their brains, for the purpose of examining the molecular mechanisms that underly the side effects of radiotherapy. Some of these mice will be given drugs to test whether they can be used to protect against these side effects.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the animals will develop sign and symptoms related to the induced brain pathology including circling, holding the head on one side, disturbance of equilibrium, reduced movements, hunchback position, hypersensitivity upon touching and handling, decrease in food intake, separation from cage mates, disturbance of eye movements, limb weakness. Rarely they may also exhibit no activity when stimulated, persistent laboured breathing, difficulty in locomotion restricting access to food or water, seizures, or limb paralysis. The duration of these effects is usually short (hours-days), and mice will be humanely culled once symptoms develop as per established protocols.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We will use approximately 12000 wild type and genetically modified mice over 5 years. Whilst a proportion of these mice will develop symptoms of the diseases we want to study, the majority of them will only be used for breeding and/or for procedures which do not cause discomfort to the animals. The overall severity of these experiments is moderate, we expect 40% of the total number of mice to fall in the moderate category.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Complex diseases such as brain development and tumour formation can only be studied in whole organisms and the mouse is a well characterized model system to mimic human diseases. Mice are the animals best suitable for this type of experiment: They are vertebrates and they are mammals, so they share many of the physiological properties found in humans. The mouse, like humans, develops similar brain and the presence of stem cells within it as well as the almost identical mechanisms involved in growth and differentiation of these cells makes the mouse brain ideal model systems to study diseases of this organ. Moreover, the mouse is the only mammal in which the genetic tools to specifically delete genes in specific cell types are available. The of new mouse models, closely mimicking the human neoplasms, are very valuable tools to evaluate response to new therapeutic approaches.

Which non-animal alternatives did you consider for use in this project?

For many mechanistic studies, in particular the cooperation of genes, we will use, whenever possible, cell biology and molecular biology methods, mainly primary cells but also cell lines. For example, in vitro models have been developed in which cultured neural stem cells and progenitor cells as well as primary tumour cells derived from surplus surgical material are used. With this approach we plan to gain insights into control of proliferation and differentiation of normal and neoplastic cells lacking or overexpressing specific genes. Importantly we have introduced 3D organoid-based in vitro model to mimic some aspect of tumour biology such as the interactions between the tumour cells and the surrounding brain tissue.

Why were they not suitable?

To establish whether a tumour originate from a stem cell in situ and how tumour cells migrate through the brain and interact with other resident brain cells, such as for example inflammatory cells or blood vessels, cannot be simulated in vitro, not even in the context of 3D organoids. Likewise preclinical validation of novel treatments, including testing efficacy and side effects, can be achieved only in a in vivo setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We are constantly reviewing our procedures in order to improve wellbeing and to reduce the numbers of animals used. Where possible, we utilise approaches that do not require animals such as cell culture and computational biology. Unfortunately, it is not possible at the moment to completely replace the use of animals with other approaches.

We plan to work with approximately 30 different genetically modified mouse strains (already available or newly generated according to the needs of the project) over the 5 years of the project licence. We have many years of experience in using the mouse as a model system and experiments are designed to use the lowest number of animals required to generate statistically significant data. All the strains will be bred for maintenance (Protocol 1) and for supplying mice to experimental protocols (Protocol 2, 3 and 4). According to our previous experience approximately 350 mice per strain per year will be necessary. This number includes animals that will be unsuitable for further experimental use, which is inevitable when generating compound mutants with complex combination of genotypes. This is due to the fact that some experiments require very specific genetics and to establish the breeding of mice with a very specific genotype, several rounds of

breeding are required, and in each of these rounds only the mice with the correct genotype are selected, whilst those that do not inherit the mutations of interest cannot be further utilised.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

NC3R guidelines have been used, and animal group sizes (usually 8-10 animals for experimental groups) have been set after consultation with a statistician, and with consideration of our own previous xperimental work. The relatively high number of animals in each experimental group is due to a certain degree of variability of the parameters (cell growth, cell division, brain invasion or cellular death, etc) that are going to be analysed. All our experiments are planned on the basis of statistically robust sample size calculations to ensure the experimental groups are neither too large nor too small to detect the effects of the procedures. Control groups will be shared between studies whenever possible Occasionally historic controls may also be used, if appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, lines will be bred to homozygosity to increase the frequency of useful experimental animals, thereby reducing the total number of animals needed.

Increase of survival is the most commonly used approach to determine treatment response. However, as this determines an endpoint only and cannot capture the dynamic of tumour growth and regression we will monitor a representative group of xenotransplanted mice by in vivo imaging, which can determine tumour volume, prior to endpoint. This reduces the number of mice, in that timepoint culls are not necessary to assess growth dynamics of a tumour.

Moreover, when possible, alternative approaches will be used to minimise the number of mice. For example, intracranial injection of viruses will be used to initiate tumours in the brain when appropriate (Protocol 3). With this method the crossing of genetically altered mice strains is not needed and therefore allows the reduction of the number of mice used in these experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically engineered mouse models, viral-mediated delivery of tumour inducing genes and orthotopic xenografts of human brain tumour cells. Surgical procedures will be performed under conditions of strict asepsis, surgery will not be commenced until areflexia, as sign of appropriate depth of anaesthesia, is demonstrated. Circulatory and respiratory monitoring will also be carried out to confirm depth of anaesthesia. Analgesia will be used as appropriate to alleviate pain and distress and all animals will be kept warm during and after surgery and inspected regularly. We have over the last few years significantly refined the method of anaesthesia and the method of injecting cells and reagents. This has resulted in a very small number of unexpected complications and faster recovery from anaesthesia.

Why can’t you use animals that are less sentient?

Non-mammalian animals have many significant limitations as models for the study of the initiation and development of human brain tumours: they do not share as many of physiological and stem cell properties with humans as mammalian models, and the genetic tools available for their study are more limited. The choice of life stage of the animals to be used has been made to ensure we best mimic human diseases – all studies relating to glioblastoma and brain metastasis biology will be performed in adult mice, whilst all studies examining medulloblastoma will be performed in un-weaned mice (induction of tumour) and juvenile or adult mice (treatment). The development and growth of a tumour as well as whether a novel treatment is effective can only be studied in living mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals that are expected to develop pathological phenotypes, including developmental abnormalities, neurodegeneration or tumour growth will be closely monitored for pre-defined humane endpoints specific to each phenotype, and culled as soon as these endpoints are met. This will ensure that the suffering of animals is kept as brief as possible and to the minimum possible severity. We have extensive past experience with these phenotypes, all humane endpoints are specifically tailored to monitor brain pathology and are in agreement with the UKCCCR guidelines on humane endpoints and limiting clinical signs. Brain imaging will be used where possible to develop scientific endpoints that allow animals to be killed before symptoms of pathology develop.

All surgical procedures will be performed aseptically, with the most reliable and least stressful analgesia and anaesthesia used for each procedure. Animals will be cared for in the post-operative period, including close monitoring, maintenance of body temperature with heat mats, and provision of fluid support and palatable food wherever necessary.

Two non-schedule 1 methods will be used in selected cases. Animals of all ages (from newborn to adult animals) will be killed by decapitation with prior anaesthesia when isolation of primary neural (neuronal and glial) cell cultures or of primary tumour cell cultures is planned. Perfusion fixation under terminal anaesthesia results in a better conservation of tissue architecture in certain organs including brain, nerves and muscles and improves the quality of subsequent tissue analysis (for example cryosectioning and immunofluorescence, vibratome sections).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All the experiments planned for this research build on a long tradition at this institution of treating animal welfare as a priority. Almost all of the experimental approaches to be adopted have been performed here many times in the past and are associated with detailed standard operating procedures aimed at minimising the number of mice to be used. When any new genetic lines of mice are generated, or if a substance is administered to an animal, they are examined very carefully for any signs of abnormality.

We perform extensive literature searches to assess the continued validity of our models and to design,develop and implement measures which refine lesioning methods particularly in relation to lesion size and severity. We use anaesthesia and analgesia when necessary. We have recently introduced multimodality imaging, which allows examination of animals at multiple and repeated timepoints, importantly also at times when the animals are asymptomatic. This enables a timely identification of the lesions and also a reduction of the number of animals required.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs by regularly checking the resources available on the NC3Rs website (https://www.nc3rs.org.uk/the-3rs) and subscribing to the NC3Rs mailing list for regular updates. We will implement any advances that we can over the course of the project in close cooperation with the named veterinary surgeon.

8. Mechanisms underpinning thrombus formation, stability and vessel repair

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

thrombosis, stroke, heart disease, antithrombotic drugs, platelets

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this research is to understand the normal and disease processes that govern thrombus formation and breakdown. In the future this will guide on the design of new more effective drugs to prevent thrombosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Thrombosis kills 1 in 4 adults in the Western World. Current drugs on the market are only effective in a subset of patients with many experiencing further episodes of blood clot

formation. A major concern is the side effects associated with these drugs, in particular bleeding complications. Understanding the body's own 'control' system against unwanted clot formation could allow us to target thrombi in disease situation more effectively. To do this we need a more precise understanding of all the different elements that regulate these pathways in vivo. This will enable us to identify mechanisms that may be more effective and safer targets for new antithrombotic medicines.

What outputs do you think you will see at the end of this project?

This translational project will generate new information on the mechanisms that underpin thrombus formation and stability in vivo. The outputs will be disseminated at conferences at both the national and international level and will be published in scientific journals.

Who or what will benefit from these outputs, and how?

Thrombosis is a major issue that affects 1 in 4 people worldwide. Heart and circulatory diseases cause more than a quarter (27%) of all deaths in the UK, equivalent to more than 160,000 deaths each year or one death every three minutes. Healthcare costs relating to heart and circulatory diseases are estimated at £9 billion each year. The cost to the UK economy (including premature death, disability and informal costs) is estimated to reach £19 billion each year. While we have successfully reduced the number of deaths associated with thrombosis in the past 20 years there is no change in the prevelence of the disease. In fact, with an ageing population and escalating obesity, metabolic syndrome and diabetes in the Western world the rates of thrombosis are increasing. We need to develop more efficient ways of diagnosing and treating thrombotic complications to improve patient care and reduce the burden on society.

Our research will focus on defining the mechanisms governing thrombosis & haemostasis. A deeper more developed understanding of these pathways and interactions will permit the design of more specific and tailored treatments in the future. The information gained from this project will likely benefit patients within 10 years as below:-

Short term: colleagues and collaborators will benefit from the data directly and inform on further research.

Medium term: novel methodology and tools, such as biosensors

Long term: drug development/pharma benefits if potential novel therapeutic targets are identified.

How will you look to maximise the outputs of this work?

We have several collaborators around the UK and of course the funders will also disseminate the outputs from the project. Publications arising from this research will be communicated within the scientific community but also to an audience more widely such as conferences to scientific and clinical communities. In addition, we hold several outreach

activities to publicise our research on blood clots in a community setting, including pupils at various stages of education.

Species and numbers of animals expected to be used

- Mice: 4800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The adult mouse model is relevant to our studies because they are the lowest sentient species in which we can address our questions relating to the mechanisms governing thrombosis and haemostasis. The mouse is the most widely used and accepted animal system for these types of studies. There are also an extensive array of genetically manipulated mouse models and established techniques available.

Typically, what will be done to an animal used in your project?

Blood will be harvested under anaesthesia. The procedure will be performed once per animal under anaesthesia after which the animal will be humanely killed.

Other mice may be born with a mild genetic defect that does not cause distress or pain. Mice may be mated with other mice carrying the same genetic modifications. Other mice will have blood collected under anaesthesia and then will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

- Genetically altered (GA) animals will be maintained with no significant impairement of their well- being. The colony will be carefully maintained and monitored by the animal care staff who have experience of changing phenotypes, breeding and birthing problems, changes to pre weaning loss etc

- Animals will be fully anesthetised by experienced staff using an appropriate method of anaesthesia. The appropriate depth of anaesthesia will be maintained throughout the procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity level for this protocol for all mice is mild (GA animals) (57%) and non-recovery (43%) blood collection will be performed under terminal anaesthesia.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The majority of our work (80%) is carried out ex vivo using human blood from normal volunteers or patients samples. The use of animals is currently still required due to the complex nature of the haemostatic cascade. Multiple factors govern the regulation of this system, including circulating proteins, various blood cells, flow rates and the vascular endothelium. It is necessary to evaluate the impact of these components simultaneously to understand how this system is regulated. We also require blood from genetically modified animals which lack specific proteins of interest. Establishing the importance of these proteins is only feasible by genetic manipulation which must be achieved in an animal system.

Which non-animal alternatives did you consider for use in this project?

We considered and will use human subjects to address some of the questions in this project.

Why were they not suitable?

Experiments with human subjects are limited to ex vivo whole blood models, due to ethical reasons. We have various models we can utilise to mimic the human vasculature, which include flow and blood cells. However, these systems lack the endothelial surface and therefore important regulators of the haemostatic cascade. We are also unable to knock out specific proteins to directly assess their function.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The major use of animals is in the generation of genetically altered mice and their litter-matched controls. The experimental design involves undertaking a series of studies to investigate cellular and functional processes governing thrombus formation and stability. The majority of these studies will give clear-cut answers from between 5 – 8 animals, although in some situations, we may need to increase this to obtain significance or to obtain sufficient sample. For example, where tests are known to be associated with wide variation such as flow-based studies of thrombus formation or where we require to isolate sufficient cell numbers for flow cytometry analysis. We will use information from our collaborators with experience of these specific mouse lines, including litter size and obtain advice from the animal care staff to ensure that we apply an optimum breeding strategy and minimise the number of breeding animals required. These strains are not currently being used by other laboratories in the UK and therefore it is necessary for us to set up these breeding colonies. Unfortunately, it is not feasible to ship blood from our collaborators in the USA, as the cells are unstable, will become activated during transit and have a short life-span. We will maximise the use of additional mice by using the wild-type mice breed as controls in the experiments. Heterozygote mice will be used to optimise and refine experimental protocols to overall reduce the numbers required.

For studies to investigate haemostasis and thrombosis in mice we will use established statistical tests to determine the statistical significance of a result. Where appropriate, we will consult with a statistician to ensure that we are using the appropriate number of mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Reduction will be achieved by first performing in vitro experiments on human blood to optimise techniques, such as the ex vivo model of thrombus formation. Preliminary work on these mice strains was performed in a collaborating laboratory. Combined with published work this has provided us with information in terms of designing our experiments and the number of animals required to perform such assays. We maximise the number of tissues we can obtain from a single animal and can store blood cells and products and progenitor cells from the bone marrow and spleen for later biochemical studies and other tissues for immunohistochemical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animal numbers bred for use on this Project will be minimised as far as possible by matching breeding to experimental requirements. Pilot studies, appropriate statistical analysis and power calculations will be employed to refine the number of animals used.

The methods chosen will generate the greatest amount of data for the fewest animals used. To maximise the information gained from a single animal we aim to take perform multiple in vitro analyses on each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse haemostatic system is considered a strong model for that found in humans and has the advantage of genetic manipulation. Therefore, in this project we propose to use mice to address specific aims of the proposal that can only be addressed by genetic ablation of specific haemostatic proteins and receptors. Pain, suffering and distress will be minimised as we aim to perform these procedures on mouse blood which will be collected following terminal anaesthesia.

Genetically altered mice strains. The animal care staff will closely monitor the colonies and are experienced in the detection and analysis of phenotypic changes, health concerns and other colony changes including birthing problems, pre weaning loss etc. Any animals showing signs health concerns will be used for tissue or humanely killed. The unit uses GA passports and phenotypical abnormalities will be recorded and if animals are sent to a collaborating institute this information will be released with them.

All mice will tube handled or cupped, no mice will be single housed other than for welfare reasons (e.g. fighting).

Why can’t you use animals that are less sentient?

Non-sentient animals cannot be used for our studies since they lack recognisable platelets and other essential components of the haemostatic cascade.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are committed to refine procedures in line with the 3Rs and will explore various mechanisms to minimise welfare costs. To ensure this:

1. Members of the laboratory will be encouraged to check the NC3Rs resources page

2. Our Named Information Officer will keep us up to date regarding changes in best practice, new courses and will advise of additional training that is necessary to comply with changes in legislation.

3. The laboratory is continually monitoring scientific literature in the haemostasis field, where refinements to these types of procedures are reported. If there are significant changes or advances in practice will up-skill either through training courses or visiting laboratories to receive guidance.

4. Advice will be taken from the experienced animal care staff to ensure optimal procedures and being utilised and incorporated into the daily care of the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance for the project will be taken from the NC3Rs website (hubs and microsites). This includes links to publications, other online resources, and video and training materials. The vast array of resources guide on the general principles underlying the experiments highlighted in this project, including anaesthesia, breeding strategy and numbers, and experimental design. Changes in current guidelines will be implemented to the project in line with current literature and published reports. We consult with experts to implement improvements in animal welfare. Local refinements will also be implemented.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are registered to the NC3Rs and subscribe to CRACK IT innovation platform and receive updates on advances through NC3Rs newsletters, and various websites including Norecopa, FRAME and Centre for Alternatives To Animal Testing (CAAT).

9. Developing therapeutic drugs for cancer including the establishment of tumour models

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph

Key words

cancer, therapy, drug discovery, pharmacology, tumour models

Animal types	Life stages
Mice	adult, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new and improved medicines for the treatment of cancer. As part of this aim, we also plan to develop new cancer models to try to improve the relevance of our animal studies to human disease, or to refine existing models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In 2018, over 17 million new cases of cancer were diagnosed worldwide, while 9.6 million people died from the disease. It is estimated that by 2040 there will be 27.5 million new cases of cancer each year. In the UK, over a quarter of all deaths are cancer-related. Cancer is a complex disease with more than 200 types of cancer described and the most prevalent types are lung, colorectal, breast and prostate. If cancer is untreated, in the majority of cases it will lead to death. (Source: www.cancerresearchuk.org)

Despite recent advancements in the treatment of cancer, there are still many types of cancer for which therapies are not available. In other cases, therapies are available but they are effective for only a limited percentage of patients. In addition, many patients who do respond to existing therapies eventually develop resistance to these treatments.

Our research project aims to use animals to support our efforts to discover and develop novel therapies for cancer. The use of animals will enable us to mimic complex aspects of the disease in a way that is not possible using cells grown in a laboratory setting. By doing so, we can test the activity of our new drug candidates on tumour growth in a more relevant way in a live animal. The use of animals in our research enables us to develop new cancer drugs to treat patients who have terminal disease and few treatment options.

What outputs do you think you will see at the end of this project?

This work will provide important data to advance our experimental cancer drugs through the phases of research and development by evaluating their activity in animal models of disease. It will further help us to identify the most appropriate drugs to combine together and will guide clinical teams on dose levels and dosing schedules.

This work will also allow us to understand how our drugs distribute in the body after dosing, and how quickly they are eliminated from it.

This project will also increase our insight into how our drug candidates work and will help discover specific changes in the body that happen in response to the drug. These changes can then be measured in human clinical trials.

This work will further enable us to identify potential targets for new drugs in order to expand treatment options for cancer patients. Work carried out under this licence will also support the development of new methods and technologies to treat cancer patients. The development of new tumour models and/or improvement of existing models will allow us to test our experimental therapies in animals in a manner that more closely represents specific patient populations. Importantly, results may also be used to determine which drugs should not be progressed further, In addition to the outputs mentioned above, we expect to publish our results and to present our findings externally to scientific peers.

Who or what will benefit from these outputs, and how?

This programme of work is expected to enable us to progress new cancer medicines through progressive stages of development. Ultimately, if successful, these medicines will

be approved for use in the clinic to treat patients with cancer who otherwise are likely to die from their disease. Drugs developed using this licence therefore have the potential to benefit millions of cancer patients across the globe.

The development of new or improved cancer models will help us to target the right patient populations with our drugs which will increase the likelihood that those patients will benefit from the treatment.

The work carried out under this licence is also expected to contribute knowledge to the broader scientific community through the publication of our findings, presentation at external scientific meetings, and through collaboration with experts in the field.

How will you look to maximise the outputs of this work?

Our team has an excellent track record of publishing our advances in drug discovery and animal modelling. We aim to publish both successful and unsuccessful results in relevant journals and to share our data and learnings with collaborators to avoid others repeating work. In addition, we often present our research at international conferences for the benefit of the broader scientific community. These public discussions of our results have the potential to lead to new collaborations which provide additional opportunities to develop innovative new drugs and technologies.

Species and numbers of animals expected to be used

- Mice: We expect to use up to 51500 mice over the course of 5 years.
- Rats: We expect to use up to 800 rats over the course of 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are the most common animals used for the type of work that we are doing. They have immune systems that resemble those of humans, which means we can grow tumours in these animals to investigate the effect of our experimental therapies on the immune response to tumours. A large selection of different tumour cell types are available for use in mice and rats such as from lung, skin, or breast cancers. We can therefore evaluate our drugs in many different types of tumours.

In the vast majority of experiments we plan to use mice rather than rats. This is because there are more tumour types available for mice, and there is a larger body of published data for mice to help guide our experimental plans and interpret our results. Occasionally rats may be preferred such as when specific tumour types are available for rats but not mice, when an experimental drug is active in rats but not mice, or when we need to

compare our results with other data generated in rats. An example of this is safety data, where rats are often the preferred species.

We plan to use adult mice that are typically 6-12 weeks old at the start of the study, as the immune system is considered immature in mice younger than this age and therefore would not adequately represent the biology of the cancer patients we aim to treat. Occasionally we may need to use mice that are significantly older than this. This is especially relevant as cancer is generally a disease of middle to old age. For those occasions, we plan to conduct studies on animals up to 18 months of age as our previous experience has shown that this age is sufficient to see immune system changes as a result of ageing but before the mice begin to suffer serious effects of old age.

Rats used in this licence will also be adult stage, typically 6-12 weeks old, at the start of the study.

Typically, what will be done to an animal used in your project?

Animals are kept in high-quality facilities, free from pathogens (disease-causing organisms such as bacteria, viruses, and parasites) and with access to food, water, and environmental enrichment. In all the facilities used, the animal care staff are highly trained in rodent welfare and will ensure the animal suffering is minimised. Animals are housed in groups except in exceptional circumstances, for example when aggressive behaviour puts the welfare of the animal at risk or when cage-mates have been removed for experimental reasons.

Most of the animals will be used for studies that measure the impact of experimental drugs on tumour growth rates. The vast majority of tumours will result from injection of tumour cells under the skin which then grow into a tumour at the site of injection. However, in some instances we will introduce tumours into specific organs through specialised injection routes. For example, direct injection into breast tissue mimics breast cancer, while injection into the bloodstream leads to tumour growth in the lungs.

Producing tumour growth in other internal organs requires surgery, such as to implant tumours into the pancreas or sometimes into the breast tissue. Tumours that grow just under the skin are easy to observe and to measure their size using callipers. Tumours that grow internally are more difficult to observe therefore other methods are employed such as imaging techniques and/or clinical scoring systems to carefully monitor the well-being of each animal.

In some cases, it is not necessary to use animals bearing tumours. For example, tumours are often not needed to determine whether a drug is tolerated by the mice or to measure how much of a drug enters the bloodstream. In addition, we sometimes can use animals that do not carry tumours when we need to understand the impact of our drugs on specific aspects of the immune system.

On some studies, we will apply advanced imaging techniques (such as ultrasound or other imagers that can detect tumours or drugs labelled with special tracers) that allow us to track growth of tumour cells or to follow distribution of a drug throughout the body. To do so the animals will be anesthetised throughout the imaging session.

Blood samples or small samples of tumour tissue may also be collected during some studies to measure levels of drug or other indicators of drug effect over time. Blood samples are usually of a small volume and are taken from a vein in the tail or at the end of the study if larger volumes are needed.

Small pieces of tumour material are collected from live animals under anaesthesia with a fine-gauge needle.

Experimental therapies are most commonly injected into the peritoneal cavity (abdominal cavity), intravenously, or directly into the tumour. Occasionally drugs may be administered orally (typically by gavage, which involves the insertion of a tube through the mouth and down the throat) or rarely, subcutaneously (under the skin). At times these substances may only need to be administered once, but more often they are administered according to a schedule that requires multiple administrations. For example, drugs injected into the peritoneal cavity are typically given two to three times per week,

whereas drugs given orally would typically be administered once or twice a day, often for the duration of the study. In most cases our studies last approximately one month but on occasion when tumours grow slowly could last for 5-6 months. Therapies are most typically administered early in the day so that there is plenty of time to watch for any unwanted or harmful effects.

To understand the impact of our work on the animals, here are examples of a typical study and a worst- case scenario for our most commonly-used method in which a tumour is injected under the skin:

A typical study involves:

- implantation of a microchip under the skin for identification
- injection of tumour cells under the skin
- administration of experimental therapies by one or more of the following routes:
- into the peritoneal cavity (typically this will be done twice a week for three weeks)
- intravenous (typically this will be done once or twice a week for 3-4 weeks)
- orally by gavage (typically this is done once or twice a day for the duration of the study) collection of a blood sample

Worst-case scenario study:

- administration of experimental therapies by one or more of the following routes:
- into the peritoneal cavity (maximum 30 injections over the animal's lifetime)
- intravenous (maximum 14 injections over the animal's lifetime)
- orally by gavage (maximum 120 administrations over the animal's lifetime)
- injection of immune cells by one or more of the following routes:
- into the peritoneal cavity (contributes to lifetime limits for this route)
- intravenous (contributes to lifetime limits for this route)
- intra-tumoral (contributes to lifetime limits for this route)
- when animals are imaged (for reasons outlined above), this is done under anesthesia. The maximum number of times an animal may undergo anesthesia in order to be imaged is 5 times within a 7 day period, or 20 times in total over the animal's lifetime.

At the end of procedures, all animals will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

In our studies, the likeliest sources of adverse effects are from the size and condition of the tumour, from surgical procedures, and from the drug treatment. Animals will be classified as mild or moderate severity according to a scoring system that is based on the degree and duration of clinical observations such as body weight, activity level, posture, and body condition. This scoring system is currently under development, but will take into account the cumulative experience of the animal. For example, two clinical signs of short duration and low intensity might be classified as mild whereas the appearance of three clinical signs for longer periods of time and greater intensity would likely be classified as moderate.

We will humanely kill any animals that have developed large tumours to minimise unnecessary suffering through the use of well-defined tumour burden limits. Generally, studies with subcutaneous tumours will reach these limits within 30 days of implantation, but tumours that grow more slowly could take 2-3 months before reaching the same limit. The slowest tumour type that we currently work with takes approximately 5 months to reach the same size without any drug treatments that might inhibit the tumour growth.

Animals undergoing surgical procedures are assumed to experience pain due to the surgery and so will be classified as moderate severity. Pain relief or anaesthetics will be provided when surgery is performed.

Treatment of animals with cancer therapies may also lead to unwanted effects similar to those experienced by human patients. While humans may experience fatigue or fever soon after receiving the therapy, we observe similar responses in rodents such as reduced

mobility, hunched posture, and piloerection (bristling of fur). Animals that have been treated with vaccinia virus may also develop lesions that are usually found on the tail. Most of these effects will be of short duration and mild but some animals may experience moderate effects. We expect that approximately 30% of animals will be classified as moderate as a result of adverse reactions to drug substances, and the remaining 70% will be mild or lower severity.

At the end of procedures, all animals will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For both mice and rats, we expect the following proportion of severities under this PPL: Mild = 36%

Moderate = 64%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although we do many experiments using cells, molecular biology, and computer modelling, it is still necessary to use some animals for research so that we can more accurately assess the interaction of cancer cells with other cells and organs within the body. Isolated cells and organs do not reproduce the complex nature of in vivo (in a live animal) biology. The use of animals also allows us to understand cancer in the organ of origin or as it spreads throughout the body. An important aspect of our work is to understand how the immune system can be harnessed to attack tumours, and it is not possible to fully recreate these complex interactions outside of a living animal. In addition, regulatory agencies often require animal studies prior to approval of a drug for use in human clinical trials.

Which non-animal alternatives did you consider for use in this project?

Our organization regularly uses a range of in vitro (taking place in a test tube or laboratory dish, outside a living animal) methods. Such methods may include experiments containing a single cell type or multiple cell types grown together, which allows both direct interaction and indirect communication between cells. These types of studies are well-established, 2-

dimensional experiments that are useful to understand the specific ways that our experimental drugs affect cellular function.

More recently, we also have developed a more complex experimental system called 'tumour slice culture system' which involves the maintenance of thin slices of human tumour tissue in a dish. This method preserves the 3D structure of a patient tumour and is expected to be more representative of the biology of the whole tumour compared with the 2D experiments mentioned above. We are also investigating other 3D systems such as spheroids which allow cells in vitro to grow in all directions similarly to how they would grow in vivo, compared with traditional 2D methods in which cells are grown on a flat surface in a petri dish.

Why were they not suitable?

Cell-based methods are useful to gain an understanding of the way that our experimental drugs impact the function of different cell types outside the body, but do not adequately test whether the drugs remain stable after they enter the body, can reach the site of the tumour, or whether they are capable of inhibiting tumour growth in a live animal.

The 3D assay systems such as tumour slice cultures are a valuable addition to our experimental toolbox, however the slice cultures have a short lifespan. In addition, they can show modification of cellular function but do not demonstrate that this effect can shrink a tumour. The spheroid cultures are still being developed.

None of the alternatives investigated can demonstrate how our experimental therapies are broken down by the body, nor can they provide any information about how to schedule dose regimens. Unlike experiments using animals, they also do not permit identification of specific signals produced in the body which can be linked to tumour growth inhibition.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers were calculated based on our use over the last several years, and an expectation that we will increase the number of our studies by approximately 30% beginning this year. This is due to a planned expansion of our team and the number of projects under investigation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our organization includes a team of statisticians who have implemented a Good Statistical Practice program where animal experiments are formally reviewed before they start. This review is conducted by a researcher and a supporting statistician team to ensure the goal, experimental design, and data analysis align. This process ensures the design is robust and the minimum animals are used that are needed to answer the scientific question.

In addition, the following guidelines and online tools are also used to influence the design of our animal studies:

The PREPARE Guidelines, found at https://norecopa.no/prepare

The NC3Rs Experimental Design Assistant, found at https://www.nc3rs.org.uk/experimental- design-assistant-eda.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We ensure small scale pilot studies are carried out for new tumour types or experimental methods which enables us to design our studies using the minimum number of animals needed to achieve our scientific objectives. We also have implemented innovative study designs to reduce animal numbers where possible. We have also developed a new technique to take small samples of tumour tissue from live animals with a small needle, similar to a biopsy. This reduces the number of mice used for some studies because it avoids the need for separate groups of mice to both analyse the tissue and to monitor the growth of the tumour.

During our previous projects we have analysed the tumour tissues of the most frequent types of tumours that we grow in mice in order to define their cellular, molecular, and genetic characteristics. This characterisation has been important for reducing animal use since it ensures we can select the most appropriate tumour type for each experimental question, thereby reducing the overall number of experiments and allowing us to maximise the benefit gained from each mouse. A large amount of data has been generated from our characterisation work and is archived for use by all our scientists to guide the design of future animal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The most common type of tumour that we use involves injection of tumour cells under the skin resulting in tumour growth at the site of injection. This is the simplest method available to grow tumours in rodents and carries the least welfare risks since the tumours are not located in vital organs. They are also the easiest to monitor since they can be easily observed and measured under the skin. This method is preferred except in specific cases when we need to understand more complex questions. For example, we may need to understand the spread of cancer from one site to another, the influence that specific cell types and organs have on tumour growth, and the responses of tumours to our therapies in these varied settings. In these cases, we will use more complex experimental methods in which tumours often develop inside the body cavity. These more complex studies also may involve surgical implantation of tumours. Where possible, non-surgical methods will be used for implantation and imaging methods used to monitor tumour burden.

Why can't you use animals that are less sentient?

Rodents are the lowest species of mammal (meaning they are the least sentient, or least aware of feelings and sensations) that allow us to adequately study the complexity of human cancer and immune system biology. Because many of our experimental therapies are designed to impact the immune system, it is essential that we use adult animals with mature immune systems in our research. Our studies also monitor the growth of a tumour over a period of weeks to months therefore it is essential that the animals are conscious as the use of anaesthesia (an agent that induces a state of unconsciousness) would not be possible for such an extended period of time. In addition, the behaviour of conscious animals also often alerts us to adverse reactions to our therapies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are committed to refining our procedures to minimise harm to the animals and have a track record of doing so. We ensure small-scale pilot or tolerability studies are carried out for new tumour types, experimental methods, or therapies. We carefully monitor tumour burden including the use of whole- body imaging techniques when possible. We also use tumour-free mice in some cases when tumours are not essential. We have implemented innovative study designs to reduce animal numbers and enhanced health checks to minimize suffering. General welfare of the animals is assessed by checking body weight and watching for the development of clinical signs such as activity levels, appearance of the coat, posture, and body condition. When dosing animals with test substances, we dose as early in the day as is practical in order to maximise the length of time that animals are monitored during the day. When unexpected events occur, these will be thoroughly investigated to find out what happened so action can be taken to prevent a reoccurrence. When two or more drugs are scheduled to be injected at the same time, we will also combine them into the same syringe where possible in order to minimize the number of injections administered to the animals. In addition, a non-surgical method of tumour implantation in the mammary fat pad has been developed and is used in preference to surgical methods wherever possible. We have also introduced the use of an improved

method for judging the size of a tumour growing inside the body cavity in our pancreatic tumour studies. This involves the use of a standard set of clay balls of different sizes. The feel of the tumour under the abdomen can be compared against the clay balls to determine the approximate size of the tumour.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our practices are principally guided by the Workman et al guidelines published in 2010 (Workman, P et al. Guidelines for the welfare and use of animals in cancer research. 2010. British Journal of Cancer.

102 p1555). In addition, we follow the ARRIVE guidelines developed by NC3Rs for publication of our work in peer-reviewed journals (ARRIVE Guidelines version 2.0 released in July, 2020 can be found at https://arriveguidelines.org/) and our practices incorporate many of the guiding principles of the PREPARE guidelines (Smith et al., PREPARE: guidelines for planning animal research and testing.

2017. Laboratory Animals.) LASA (Laboratory Animal Science Association) also has a range of published guidance documents with principles that can be applied to our animal studies which are found at https://www.lasa.co.uk/current_publications/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our team is actively involved in promoting the 3Rs and participates in global 3Rs activities including an annual poster competition. This award was given to individuals working on the development of alternative models under a previous project license in 2009, and also a team working on an ex vivo (taken directly from a living organism) tissue slice culture system in 2017. Our team also is aware of advances in 3Rs through the NC3Rs and establishment websites and via participation in conferences and events sponsored by organizations such as LASA (Laboratory Animal Science Association, IAT (Institute of Animal Technology) or NC3Rs.

10. Non-invasive mucosal rodent immunisation

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

vaccine, oral, nasal, inhalation, non-injectable

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to produce safe and effective non-injectable vaccines.

We have a track record in this, and our vaccines will be developed using platform mucosal delivery systems, initiated through our previous research. These delivery systems can be

applied to a wide- range of conditions, designed and optimised using computer modelling to prevent infectious and non- infectious disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines have been the main focus of the World's attention since the COVID-19 pandemic; highlighting their importance in fighting infections. However, while many companies and researchers initially focused on injectable vaccines, products that can be administered by non-invasive routes (eg via the mouth, nose, lungs) have remained a desire by the pharmaceutical industry. These so-called mucosal vaccines can improve effectiveness by protecting the routes of entry of infections (eg skin, mouth, nose, lungs - also known as mucosal surfaces) as well as the whole body (eg via the blood stream), can provide better distribution options to vaccine centres as they don't need cold storage, are safer to administer and are more user-friendly (without the use of needles).

What outputs do you think you will see at the end of this project?

1. New basic information about the mucosal immune system (poorly understood as most vaccines are given via injection and better understood).
2. Understanding and design of optimised vaccines using computer modelling to reduce use of animals in the future.
3. Peer-reviewed publications, conference presentations, postgraduate student theses.
4. Proof-of-concept data to enable grant applications and commercialisation to develop safe and effective products.

Who or what will benefit from these outputs, and how?

The overall purpose of this research is to develop safe and efficacious mucosal vaccines to protect against infectious disease and to prevent non-infectious conditions.

1. Short-term - Animal welfare for animals in vaccine design will be improved as the administration methods are non-invasive
2. Short-term - Scientists will benefit from basic information about the mucosal immune system.
3. Short-term - On the current mucosal licence, we are developing the following mucosal vaccines: anti- COVID-19 nasal vaccine, anti-Myeloid Myeloma (blood cancer) oral vaccine, antibiotic-free oral products for poultry, anti-fertility vaccines for squirrel control, anti-fertility vaccines for rodent control.

4. Long-term - Humans and animals will benefit from any vaccines developed as they will be less invasive than the current injectables and could be used in situations where the current injectables cannot be eg very young children and the elderly.
5. Long-term - Roll out of vaccines will be much easier as mucosal vaccines can be designed without the need for cold storage.
6. Long-term - Over the next 5 years, we anticipate we will attract commercial interest in our platform delivery systems to continue to make an impact to the field of mucosal vaccines. Most our work has been on oral and nasal routes, with less work carried out on topical, pulmonary and vaginal - depending on the diseases/conditions being studied.

How will you look to maximise the outputs of this work?

Applications for grant funding is being carried out with companies and organisations that will be able to take these ideas forward. We currently have pilot studies being carried out on a previous licence - these will be progressed in collaboration. Dissemination of new knowledge will occur once intellectual property is protected, through publication, conferences and interested networks. When we publish, we will use the ARRIVE guidelines so the work is reproducible.

Species and numbers of animals expected to be used

- Mice: 250
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For the last two decades my research has focused on mucosal vaccines. Most of this work was initially carried out on rodents and then progressed to larger species such as ferrets, dogs and sheep through the funding bodies.

After in-vitro screening adult rodents have always been used for initial screening, and has been essential for anti-fertility applications. Mice have been used to screen antibody levels, but rats have been used for hormone and fecundity testing (and found to be more reliable).

Typically, what will be done to an animal used in your project?

The purpose of developing mucosal vaccines is to reduce the stress to humans and animals. Therefore, the main criterion for these products is that they minimise animal suffering in experimental models and that they are “mild” in severity. In addition, the pharmaceutical industry requires as few administrations as possible, therefore our

research will also take this into account in the experimental design. Some of the administration routes require anaesthetic and this is to minimise mis-administration rather than because they cause pain.

Typically 3-4 administrations (each not taking more than a few minutes) will be given over a 2 month period. Pre-administration animals may have food withdrawn for short periods to prevent interaction of vaccine with food if administered orally. Following administration, tail bleeds will be taken a week later for antibody and hormonal measurements. This is a quick process not taking longer than 5 minutes. In some cases drugs may be administered in drinking water to enable control of stomach acid (to prevent interaction of vaccine) or to cause salivation to enable more mucous to be produced to analyse them for protective antibodies. In some types of fertility experiments breeding will be set-up or vaginal smears will be taken (this is a quick process taking no more than a few minutes).

Some animals will experience traditional routes of administration such as subcutaneous and intramuscular and are required as a comparison to the mucosal route results.

What are the expected impacts and/or adverse effects for the animals during your project?

Anaphylaxis caused by antigen administration is possible but rare. To avoid this formulations will be tested in-vitro for toxicity before administration. No adverse effects expected from pre-treatment (eg ranitidine), as it is routinely used in this type of study and from our previous experience.

Injections (for control comparison with mucosal routes): For injections under the skin - minor swelling and redness at the site of injection. Good handling to minimise discomfort and observation after dosing with humane killing of any animal showing major skin ulceration (e.g., non-healing or deep or recurrent ulcers or secondarily-infected ulcers). For injections into the muscle (which we will avoid as far as possible), lameness may occur but this should be mild and short-lived.

Mouth administration: Mild irritation in lining of mouth may occur. If this happens, soft food will be provided.

Oral dosing into the stomach: Minor discomfort at time of dosing, rarely the substance may enter the airway or the oesophagus is damaged (less than 1 in 1000 administrations). Good handling to minimise discomfort and observation after dosing with humane killing of any animal showing signs of mis-dosing or damage. We will also attempt to reduce discomfort by oral dosing through incorporating vaccine into drinking water/food. Any animal showing signs of weight loss will be brought to the attention of animal care staff and, if necessary, the NVS. Non-reversible weight loss going beyond 10% of the animal's initial body weight will constitute an endpoint.

Nasal dosing: Short lived nasal irritation. Increased respiratory rate, which is short-lived and observed in less than 1 in 1000 animals. Good handling to minimise discomfort and

observation after dosing. Any animal showing marked respiratory distress will be immediately culled.

Topical: Mild redness. Possibly mild swelling and discomfort lasting only a few hours. Swelling observed in less than 1 in a 1000. If it persists or the animal shows significant discomfort, NVS advice will be sought.

Vaginal: Short lived mucosal irritation. Good handling and technique to minimise discomfort.

Inhalation: using a nebuliser. Mice will be treated without using an anaesthetic using a Volumetric Spacer or a suitable commercial holder. Rats will be treated by direct nebulisation with/without an anaesthetic or by using a Volumetric Spacer or a suitable commercial holder. In order to carry out pharmacokinetic studies we propose to use a microsprayer system.

Administration of formulation – To reduce discomfort as much as possible, volumes and frequency of drug will not exceed the recommended maximum volumes for the different routes following local good practice guidelines.

Pilocarpine administration results in an increased salivary production, but this effect is transient and the animals tolerate it well.

Anaesthesia – The risk of death from anaesthesia will be minimised by the use of experienced personnel and proven techniques. Anaesthetic mortality is not expected to exceed 1%.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All procedures are expected to be mild for both mice and rats.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The ultimate end of this work is to develop new mucosal vaccines primarily for use in humans but also animals. In order to proceed to human or large animal trials it is

necessary to pre-screen these new vaccines in rodents in order to ensure that they do induce suitable antibody levels.

Which non-animal alternatives did you consider for use in this project?

We have performed database analysis for possible alternatives but there's currently no non-animal substitute for this type of work. We have introduced computer modelling and also use in-silico testing to design our vaccines; this helps replace and reduce some use of animals by only proceeding with in-vivo work when we have identified the best candidate vaccines/compounds.

Why were they not suitable?

Computer modelling and in-silico tests can't currently replace or recreate the complexity of the immune system and, in particular, the mucosal immune system for which less knowledge is available in terms of vaccination.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The establishment statistician has been consulted and based on previous licence use we will use 5 animals per test group.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have always kept animal use to a minimum by careful experimental design in close association with the establishment's statistician and the numbers used give sufficient data to enable vaccine products designed to progress to the next stage of development.

Protocols have also been improved by using in silico modelling to help design our formulations so that fewer experimental groups need to be used

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cell work and computer modelling will be carried out first.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

- Which animal models and methods will you use during this project?
- Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The vaccines being developed are designed to cause the least possible pain, suffering, distress to the end-user, be they people or animals. Therefore, the methods of administration used in this project are not expected to cause pain or suffering other than mild, transient discomfort. These models (rodents) are used as an initial screen and are necessary in order to progress to the next stage of development.

Why can’t you use animals that are less sentient?

Mature animals are needed to obtain the appropriate responses in terms of antibody, hormone, fertility.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are trying to design better vaccines that will reduce the number of administrations and this will be a key goal that will minimise welfare costs and inform future work.

For oral administration, instead of gavage, we have also tried voluntary oral dosing in the past using sweetened chow and will use this whenever possible. Other methods we will consider are outlined in these publications:

https://doi.org/10.1016/j.bbi.2020.04.015
https://www.sciencedirect.com/science/article/pii/S266616672100037X
https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4587624/

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs guidelines on administration of substances, our own local dosing guidelines, the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am very active in the field of mucosal vaccines and am kept informed by reading and publishing work in this area.

In addition, I use the NC3Rs webpages and Named Information Officer at the establishment.

11. Normal and leukaemic blood cell development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

haematopoiesis, blood cancer, ontogeny, therapy

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how human blood cell development (haematopoiesis), changes through the human lifetime, and how this affects the biology of blood cancers (leukaemia) at different ages.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood cell production is a precisely controlled process that starts before birth and continues through the human lifetime. Although adult blood cell production has been studied; not much is known about how blood cells develop in fetal life. These studies will provide us with detailed cellular and molecular mechanisms of how normal blood cells are produced, renew and differentiate throughout ontogeny.

There is growing evidence that many childhood leukaemias start to develop in fetal life. Some rare leukaemias such as those that develop very early (<12months of age), are called infant leukaemia and these children tend to do poorly even with intensive treatment. Newer treatment strategies are urgently needed for treatment resistant infant/childhood leukaemias. To enable this, a more detailed understanding of how and when these leukaemias develop, and whether the biology of treatment resistant disease depends on the developmental stage the leukaemia originates in is crucial. However, the specific properties of fetal cells that make them prone to undergo leukaemic transformation, and the exact cell of origin of childhood leukaemias is not known. This project will i) help identify the prenatal target cell that undergoes leukaemic transformation in infant and childhood acute leukaemia ii) create faithful mouse models of leukaemia using human prenatal and postnatal haematopoietic cells. This will aid in better understanding of the pathogenesis of refractory leukaemia at different ages, and also develop novel therapies for the same.

What outputs do you think you will see at the end of this project?

New information generated at the end of the project:

Detailed characterisation of how blood cells develop throughout the human lifetime.

Creation of novel leukaemia models by transforming human haematopoietic stem and progenitor cells.

Testing novel therapies in the models developed to target key vulnerabilities in treatment resistant leukaemias

All data generated will be shared via publications. They will also be deposited in publicly available repositories after publication, and will form a valuable resource for the scientific community.

Who or what will benefit from these outputs, and how?

The short-term beneficiaries from this study would be scientists studying human haematopoiesis and/or the biology and pathogenesis of childhood leukaemia. Data generated will help in the understanding of the pathogenesis of these diseases. Results will be disseminated at national and international Haematology meetings and via scientific publications. However the main beneficiaries of this project will hopefully be infants and children with abnormal haematopoiesis and/or leukaemia because of a) better understanding of the origins of the disease and b) testing of novel treatments that target

specific molecular pathways identified. It is anticipated that it will take at least 5 years to develop therapies that can reach clinical trials. We will focus on a poor prognosis subtype of childhood leukaemia that occurs in infants <12 months initially, with a view to studying other treatment resistant subtypes in the future.

How will you look to maximise the outputs of this work?

This project forms part of many collaborative studies that are underway with national and international collaborators studying normal and abnormal haematopoiesis. We work in close collaboration with clinicians in hospital settings, clinician scientists, scientists and computational biologists in UK Universities in order to maximise the academic impact of this work. Any new methodology that is established will be shared with the research community. The sharing of knowledge and implementation of novel treatment strategies in national and collaborative international trials will help deliver the benefits of research at a global scale.

Publication of results in highly visible journals and adhering to the funder's policies regarding open access is one way we will clearly communicate our results to a wide audience including other researchers and clinicians. This will include negative results. Along with publication, datasets will be deposited into public repositories so that the raw data will be available to other scientists for re- analysis. We will also make a specific effort to communicate our results to clinician-scientists by presenting our results at conferences both at a national and international level. Publications and presentations will be accompanied by an appropriate summary in the public science arena. Prior to significant publications we will liaise with funding bodies and other media sources for preparation of press releases to the media, so that the dissemination of the research extends to as wide an audience as possible.

Species and numbers of animals expected to be used

- Mice: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Blood formation and leukaemia development are precisely controlled processes that require the living environment, such as bone marrow. Immature blood cells called haematopoietic stem cells (HSCs) are known to interact with other bone marrow cells, and when exposed to culture (non-living conditions), they change their properties. Therefore, these processes have to be investigated using animals. The mouse is the most widely used system to study the formation of normal blood and blood cancers.

Mouse models have demonstrated to be highly relevant and essential for development of an understanding and clinical application of the blood forming system in man, including the application of bone marrow transplantation and understanding of leukaemia since mouse and human stem cells share similar properties. Other advantages of the mouse model (apart from it being mammalian) include the availability of laboratory reagents to study blood functions. Furthermore, leukaemia models in mice can be used to understand the origins of the disease and to develop/ test potential targeted therapies.

Typically, what will be done to an animal used in your project?

Mice may undergo non-lethal dose of irradiation in preparation for transplantation of genetically altered or leukemic cells. They will also undergo blood sampling at regular intervals and on some occasions bone marrow samples may be taken from the femur. Mice will develop leukaemia and in some cases will receive treatments that may modify the disease. Typically this will be by injection but maybe administered in the food or drinking water.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts include transient discomfort or pain when substances are administered, when cells are injected, and blood or bone marrow samples taken. Irradiation of normal, immune- compromised or genetically modified mice can be associated with temporary (approximately 2 weeks) decrease in blood cell production and immune deficiency. The resulting transient low platelets and white blood cells starting from 5-7 days, can cause acute bleedings, anaemia and infections, just as seen in patients undergoing bone marrow transplantation. Some animals might also suffer from transient diarrhoea. Animals transplanted with malignant cells may develop leukaemia or high-grade lymphomas. Leukaemia will be recognised by elevated white blood cell counts (greater than 20% blast cells). Mice may develop anaemia, bleeding, or an enlarged abdomen (defined as >10% increase in body girth).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mouse:
- Mild: 25%
- Moderate: 75%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Blood formation and leukaemia development are precisely controlled processes that require the living environment, such as bone marrow. Immature blood stem cells are known to interact with other bone marrow cells, and when exposed to culture (non-living conditions), they change their properties.

Therefore, these processes have to be investigated using animals. The mouse is the most widely used system to study the formation of normal blood and blood cancers. Mouse models have demonstrated to be highly relevant and essential for development of an understanding and clinical application of the blood forming system in man, including the application of bone marrow transplantation and understanding of leukaemia since mouse and human stem cells share similar properties. Other advantages of the mouse model (apart from it being mammalian) include the availability of laboratory reagents to study blood functions. Furthermore, leukaemia models in mice can be used to understand the origins of the disease and to develop/ test potential targeted therapies. Some aggressive childhood leukaemia subtypes have so far been impossible to recapitulate. Our group has used human prenatal blood cells to model the disease for the first time and this will provide valuable information about how these leukaemias develop and pathways that drive this disease. This model and other new models generated will also be used to test novel targeted treatments in this project.

Which non-animal alternatives did you consider for use in this project?

We will perform a large number of analyses in non living conditions, such as checking how normal and abnormal blood cells grow in the lab and how rapidly; as well as detailed characterisation of their properties, such as genes that are active; and only use animals where these experiments are not possible, or will not allow us to address key questions. The protocols performed have been limited to those for which there are no alternative methods that will allow us to achieve our objectives.

Why were they not suitable?

Attempts to model or maintain haematopoiesis in cell culture have demonstrated that the properties of early haematopoietic cells change so that they prematurely lose their key

functions of self-renewal, and multilineage differentiation. Therefore, some of the objectives listed can only be achieved with the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice include those required for primary, secondary and tertiary transplantation of human haematopoietic stem and progenitor cells and leukaemic cells.

The experiments planned for this license are similar in nature to experiments currently performed in my laboratory, and animal numbers have been calculated based on experiments previously performed and also on the different types of treatments we will use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Investigators will carefully plan experiments to ensure:

Each experiment uses the minimum number of animals required to obtain a statistically meaningful result as determined with power calculations using the NC3R's Experimental Design Assistant.

Breeding strategies are designed to minimise the number of non-experimental mice generated

Mice are sourced from central colonies, and we will collaborate with other groups to ensure any surplus animals from their breeding colonies can be used, to avoid redundant breeding within this project.

For pharmacological studies we will use pilot studies to determine effect sizes, and experimental block design to avoid overpowering the analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Good colony management practices will be followed to ensure that only animals needed for experiments will be produced. Use of a database, which yields reports on colony performance data will be used to assist in colony management.

Maximising yields of haematopoietic cell populations: We have put extensive effort into maximising the number of the cells we can obtain from each animal by rigorously testing the optimal antibody staining concentrations, centrifugation speeds and enrichment methods to ensure that we minimise the number of animals used to obtain the cells. We will plan experiments within the lab, and where relevant across labs, to share tissues and cells from mice.

Molecular analysis on lower numbers of cells: We have developed technical and next-generation sequencing approaches leading to a major reduction in the numbers of cells required for each analysis, thus consequently dramatically reducing the number of mice required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice that are engrafted with human haematopoietic cells: Xenografting is currently the most refined model for studying normal human and malignant cells in a physiological setting. It does not cause any significant lasting harm, except those associated with disease progression in case of engraftment of malignant cells. It is associated with transient discomfort due to irradiation where used; however, this is required for ablation of the endogenous haematopoietic cells which in many cases is a prerequisite for the transplanted human cells to engraft.

Mice that develop haematological malignancies: The mouse currently represents the most accurate model for the experimental study of human haematological malignancies, and the resulting phenotypes are good representatives of the human conditions. For disease phenotypes it is necessary to allow the disease processes to proceed to a clinically relevant stage, which may cause the animal some pain and discomfort for a limited time. However, this is required to obtain information relevant to human health, and will be minimised by frequent monitoring and ending the experiment as soon as an adverse clinical phenotype develops.

Mice that are treated with pharmacological agents: To develop pharmacological strategies to treat haematological malignancies the use of drugs is required. Some drugs that are used to treat haematological malignancies are cytotoxic, and may cause transient pain and discomfort, but no lasting harm. However, their use is necessary to determine if treatments

are able to improve on the current standard of care, and the least toxic alternative will be used.

Why can't you use animals that are less sentient?

The mouse is the least sentient model with a haematopoietic system that sufficiently supports human haematopoietic cells for the study of normal blood cell development and malignancy to be relevant to human health. Blood formation and leukaemia development are precisely controlled processes that require the living environment, such as bone marrow. Immature blood cells called haematopoietic stem cells (HSCs) are known to interact with other bone marrow cells, and when exposed to culture (non- living conditions), they change their properties. Therefore, these processes have to be investigated using animals. The mouse is the most widely used system to study the formation of normal blood and blood cancers. Mouse models have demonstrated to be highly relevant and essential for development of an understanding and clinical application of the blood forming system in man, not the least application of bone marrow transplantation and understanding of leukaemia since mouse and human stem cells share similar properties. Other advantages of the mouse model (apart from it being mammalian) include the availability of laboratory reagents to study blood functions. Furthermore, leukaemia models in mice can be used to understand the origins of the disease and to develop/ test potential targeted therapies. Xenograft assays require transplantation of human cells into live animals. We will use adult mice for most xenograft assays. We will use neonatal mice only if required to develop particular types of early life leukaemia models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When undertaking work with animals to achieve our aims we have carefully chosen the least severe procedures to minimise the pain and adverse effects for the animals. Specific examples of refined procedures in the laboratory include:

Conditioning of haematopoietic cell transplant recipients with split radiation dosage: In order to detect the activity of the transplanted cells, the host animal's own haematopoietic system must first be depleted by irradiation, in the same way as is done with humans receiving bone marrow transplantation as a therapeutic modality. In order to minimise the morbidity and mortality associated with irradiation, a split of two half doses of irradiation, rather than a single full dose which, in association with temperature and noise monitored housing, provision of moist food and extra bedding, and rigorous monitoring has resulted in very low levels of morbidity and mortality. Recipient mice will be given antibiotics to prevent infections.

Administration routes: Cells, drugs and biologically active agents will be administrated by the least invasive route in the first instance when multiple routes are available for example orally in water or feed rather than by intraperitoneal route. Procedures that are likely to

cause more than transient discomfort will be performed under anaesthesia with adequate cover with pre and post operative painkillers.

Aseptic techniques will be used for administration of substances with special consideration to maintaining body temperature and hydration. If multiple subcutaneous injections are required, a subcutaneous device will be installed that can deliver the multiple doses, instead of repeated injections. For experiments that involve treatment of haematological malignancies to model the clinical standard-of-care we will define the least harmful treatment type that achieves clinically relevant results.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgery will be performed following LASA aseptic surgery guidelines.

We will use the NC3Rs Experimental Design Assistant (EDA) online tool or similar software to design experiments.

We will conduct and report our experiments for publication according to ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attendance at local animal welfare meetings is required. The NC3R's newsletter is reviewed and relevant points discussed with all members of the team. Attendance at local 3R's events is also encouraged.

12. Generation of new anti-tumour strategies for epithelial cancers

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Therapy, Virus, Cells, Immune system

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to support the development of potential new cancer treatments and to understand the effects and mechanism of action of our anti-tumour drug candidates when administered alone or in combination with other therapies, some of them currently used in clinics. Our drug candidates aim to help the immune system to fight against the cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding how our drug candidates work after systemic administration would help in selecting the best candidates to progress with to better address specific strategies (for example choosing the appropriate combination therapy or cancer indication) to treat cancer patients.

What outputs do you think you will see at the end of this project?

EnAd Our drug is an oncolytic (cancer-killing) virus currently being evaluated in clinical trials to treat a range of late-stage epithelial (such as breast, colorectal, lung) cancers. In these trials, EnAd it has demonstrated a good safety profile as well as a successful delivery to disseminated tumours, and there are indications that this may be associated with a favourable anti-tumour immune response. Under the previous licence, variants of the virus have been studied: those variants were designed to offer improved anti-tumour efficacy through enabling the virus to produce therapeutic agents within the tumour to assist the immune system in identifying the tumour as a foreign body and fighting against it. Currently three of these mentioned engineered versions of EnAd (T-SIGn viruses)this virus have entered clinical trials evaluating their efficacy at treating a range of late- stage epithelial cancers, with encouraging early data emerging. This project aims to generate more mechanistic data to better understand how our drugs work systemically, to be able to identify the best combinations with currently available therapies to treat different cancer's indications for which few or no other treatment options are available. In addition to this, under this licence new variants of EnAd our virus will be studied and the most notable potential benefit would be the successful translation of those engineered versions into the clinic and their subsequent development towards approval for the treatment of patients.

Who or what will benefit from these outputs, and how?

Under this licence, the quickest potential benefit would be the identification of good combinations of EnAd variants of our virus and other therapies currently used or being evaluated clinically, which will, in the longer term, lead to improved treatment options for patients with a range of late-stage epithelial cancers.

In addition to this, we aim to successfully develop new mechanistically different T-SIGn viruses versions of the virus for translation into the clinic and their subsequent approval for the treatment of patients with cancers for which few or no other treatment options are available.

How will you look to maximise the outputs of this work?

Results obtained from the work carried out under this licence will be broadly discussed both internally and with collaborators, to generate new available knowledge and to be able to deliver successful approaches into the clinic. Where possible, we will also seek to publish new data and associated methodologies and experience through presentations at conferences, submission to peer-reviewed journals etc.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Full evaluation of our drugs needs to be addressed in a living system at the age of developed mature immune system and mice are the species with the lowest neurophysiological sensitivity in which our work can be carried out.

Typically, what will be done to an animal used in your project?

Typically, each mouse would experience the following procedures - or less than the ones listed below depending on the experiment:

Chemoablation followed by injection of human stem or immune cells (less than 2000 mice will experience this under this licence)

Implantation of tumour cells (and then 3-4 weeks for cells to grow)

Induction and maintenance of anaesthesiaanaesthesia for tumour volume measurement (maximum 3 days per week)

Administration of test substances

Blood sampling (up to 10% blood volume may be collected on a single occasion, but no more than 15% in any 28-day period)

Approved humane method of killing or cardiac bleed under terminal anaesthesiaanaesthesia

What are the expected impacts and/or adverse effects for the animals during your project?

The most common expected adverse effects will be tumour ulceration, whereby small wounds can develop on the surface of the tumour, and weight loss following chemoablation of mice where mice are reconstituted with human immune cells. Weight loss will be managed using replacement diet, such as fluid therapy orally administered via a gel diet. Observations made during post-mortem analysis of killed mice will be used to refine models and tighten humane endpoints to ensure suffering is always minimised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All the work carried out under this licence will be of moderate severity or below.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Full evaluation of our drugs - such as the systemic delivery, as well as the recruitment and activities of cells of the immune system to destroy the cancer in situ - rely on complex interactions and need to be addressed in a living system.

Which non-animal alternatives did you consider for use in this project?

The transition of experiments into animal models follows on from extensive in vitro and ex vivo (taking place in a test tube, culture dish, or elsewhere outside a living organism) work to ensure each candidate variant of the drug is fully functional, as well as 'safe'. This includes a huge amount of work performed with cell lines, and primary cells from either healthy donors or cancer patients - with informed consent.

This ensures that no animal work is carried out where the desired information could be obtained via alternative methods and that in vivo (taking place in a living organism) studies are designed around a deeper understanding of our drugs being assessed. This limits the number of mice required under this licence, but it cannot replace them entirely.

Why were they not suitable?

There are some mechanisms which can't be assessed with in vitro or ex vivo experiments: for instance, the recruitment of immune cells to the tumour microenvironment, or the biodistribution of the virus particles/transgenes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is a rough estimation based on the objectives detailed under this licence and the studies planned for the foreseeable future, although it does of course take into account the projection of our research over the next 5 years.

Extensive planning and regular in vivo meetings within our research team and external collaborators will ensure that we get the most out of each study, minimising the number of animals used but without compromising the experimental outcome (minimising need for repeating experiments and ensuring the appropriate number of mice is used to get significant results).

Calculations has been made considering that we estimate to run studies with 60 mice each - this is a number which allows us to cover all the experimental conditions. On average across the 5 year of this licence, we consider that as a team we will run 8 of these kind of studies per year, plus possibly a couple pilot studies (with 20-30 mice each).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Biostatistics are carried out prior to embarking on studies, utilising data acquired in pilot (or similar previous performed) studies to ensure that group sizes and randomisation are appropriate to minimise the need for repeating experiments and to ensure that excessive (or too low and therefore risk for inconclusive results) numbers of mice are not used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Pilot studies will be performed to ensure the correct setup for new experiments.
- Once we implant mice for a study, we aim to obtain the maximum amount of information from it: therefore, when the humane end point is reached and the mouse is killed by schedule 1, several readouts are planned.
- By investigating new approaches utilising ‘in-house humanised mice’ or in vitro cultured immune cell transfer we hope to reduce mouse to mouse variability and therefore reduce the numbers of mice required to confirm an anti-tumour effect.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All worked carried out under this project licence will utilise mice.

A great deal of care is taken to ensure that our studies are as refined as possible, to minimise suffering. The process of refinement runs in parallel to all of our in vivo studies to ensure that even 'tried and tested' models are subject to scrutiny, and to enable the application of more appropriate humane end points wherever possible.

Why can't you use animals that are less sentient?

Full evaluation of our drugs - such as the systemic delivery, as well as the recruitment and activities of cells of the immune system to destroy the cancer in situ - rely on complex interactions and need to be addressed in a living system with fully mature immune system to mimic what would happen in the human body.

Mice are the species with the lowest neurophysiological sensitivity in which our work can be carried out, and many mouse models are readily available and extensively studied which can be used to bridge the gap between mouse and human immunology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During the experimental design carried out under this licence, we will deeply consider both the welfare refinement (to improve the animal experience) and the scientific refinement (to improve the data collection). Every detail of those aspects matters for the refinement of the entire animal experience.

General procedural refinements applied to studies carried out under this project licence include:

- Treatment will always be delivered at the smallest effective delivery volume
- Warm boxes will be used to maintain body temperature where extended anaesthesia is required and to dilate blood vessels for injection to minimise bruising
- After administration of substances, animals will be carefully monitored during the whole study
- Post-mortem analysis of mice at the end of studies enables us to better understand our models and to apply tighter humane endpoints wherever possible
- Human blood utilised in studies bridging the gap between human and mouse is obtained from clinical sites that allow for the same donors to be ordered repeatedly. Another approach that we are developing
- in-house is the generation and expansion of immune cells (from human blood) already 'committed to react against a specific target'. This avoids toxicities associated with the immune cells from human donors adversely reacting with mouse tissues.

- Animal welfare meetings held with other local licence holders enable the sharing of information so we can all ensure our studies are designed around a broad knowledge of current best practice to ensure the minimum welfare cost for the animals (considering for example the amount and frequency of cells injected into the mice according to the best outcome for desired results)

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA guidelines NC3R's

RSPCA UFAW

Guidance on the Operation of the Animals (Scientific Procedures) Act 1986 and surrounding animal legislation

Guiding principles on good practice for Animal Welfare and Ethical Review Bodies PREPARE guidelines

ARRIVE guidelines UKCCR guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Useful webpages kept under consideration:
https://www.understandinganimalresearch.org.uk https://www.animal-ethics.org
https://www.nc3rs.org.uk

Also, I we will be constantly in contact with NACWO and vets to ensure the best practice is always performed.

13. Blood clot properties in thrombosis, thromboembolism and atherosclerosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Thrombosis, Blood coagulation, Thromboembolism, Fibrin, Clot structure and function

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Recent studies in patients with heart disease and in patients with clots in their leg, brain or lungs identify the structure of the blood clot, and its stability, as a potential cause of the disease.

Currently it is not known which clot architecture is optimal in terms of providing normal clotting at a site of injury, or after surgery, while at the same time reducing any risk of developing a blood clot in the heart, brain, lungs or leg. The aim of this project is to analyse which clot structure(s) support optimal blood vessel repair and reduce the risk of disease-causing and ultimately deadly clots.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Gaining knowledge about which clot structure is optimal blood vessel repair, but reduces the risk of clots in the brain, heart, leg or lungs (thrombosis), will enable improvements in treatment of conditions where clotting plays a role. A critical areas of patient benefit is likely to arise from finding out which clot structures reduce the risk of thrombosis to enable the development of new drugs that target clot structure, making them easier to breakdown or remove using catheter mediated clot removal devices.

What outputs do you think you will see at the end of this project?

Studies focused on clot architecture will lead to an improved understanding of its role in determining thrombosis rates, thrombus size and resistance to thrombolysis by clot busting drugs.

Models on clot embolization will lead to an improved understanding of the role of clot structure in clot instability and embolization, both in terms of pulmonary embolism and ischaemic stroke.

Studies focussed on clot structure and crosslinking will deliver on understanding the roles of crosslinking in inflammation driven thrombosis, and understanding the roles of crosslinking in atherosclerosis and atherothrombosis.

Together, these outcomes will elucidate processes that underpin pathological clot formation during thrombosis, thromboembolism and atherosclerosis.

Who or what will benefit from these outputs, and how?

New models of thromboembolism will benefit researchers interested in such models around the world. New models of thromboembolism may also be of future interest for the pharmaceutical industry, for the testing of anticoagulant or thrombolytic drugs. Clinicians and patients will ultimately benefit in the form of improved treatment and care based on clot structure and stability.

Short-term, medium-term and long-term benefits:

Short-term: Increasing and disseminating new scientific knowledge in the field of thrombosis and bleeding disorders by peer reviewed publications in scientific journals, presentation of data at national and international scientific meetings, press releases on research outcomes where appropriate.

Medium-term: Assistance of other interested researchers in new models and techniques. Sharing of models, strains and reagents with other groups, nationally and internationally.

Long-term: Improvements in treatment and care of patients with thrombosis and thromboembolism. Note that these long-term benefits are beyond the timeframe of this project licence application.

How will you look to maximise the outputs of this work?

We will disseminate outputs to the academic audience through national and international scientific meetings and workshops. We will further disseminate via publication in peer-reviewed journals. We will also communicate outputs to the lay audience as appropriate through press releases.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Choice of species. The mouse is a useful model for preclinical modelling of diseases of thrombosis, thromboembolism and atherosclerosis. This is because of the large number of available genetically- modified models, basic similarity between mechanisms of haemostasis, thrombosis and vascular wall pathologies in mice and humans, and the extensive amount of work that has already been performed and published using mice.

Choice of life stages. The thrombosis, thromboembolism and atherosclerosis protocols will be performed on mice that are normally 8 weeks or older, and at least not younger than 6 weeks of age (minimum age limit).

Typically, what will be done to an animal used in your project?

Mice will be bred with specific mutations in blood clotting factors. These mutations are well supported for normal life and do not cause the mice any specific harm or suffering, but change pathophysiological responses when diseases of thrombosis, thromboembolism and atherosclerosis are triggered. This enables the discovery of new disease mechanisms that may help to develop new treatments for the disease.

The protocols used for triggering thrombosis, involve surgical exposure of blood vessels and application of thrombosis triggering agents or ligation of the blood vessel. This procedure normally lasts no longer than 30-60 minutes. The procedure is either terminal under full anaesthesia, or immediately followed up by surgery to close the site of application and pain relief where needed. In animals that are followed up in time, follow up will last no longer than 2 weeks and more often less than 48 hours.

For the atherosclerosis protocol, mice will be fed an atherogenic (high fat) diet to induce atherosclerosis ("furring up") of the main artery (aorta). This procedure will last up to 20 weeks. At the end of the procedure, the aorta will be taken out for observation in a terminal procedure under full anaesthesia.

Substances may need to be administered (e.g. fluorescent markers for imaging of clots, specific inhibitors, drugs or inflammatory markers) during or before above mentioned procedures. This may occur through injection, oral adminstration or using a portable minipump. No more than 4 substances at any one given time will be administered, and all substances and their administration procedures are well tolerated with minimal discomfort.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the procedures the mice will undergo during this project will have no or minimal (mild) adverse effects. This is because the breeding of the genetically modified mice does not incur any adverse effects because the mutations are well tolerated unless challenged, and because some procedures are performed under full terminal anaesthesia.

Some of the procedures may incur some discomfort that ranges from minimal or mild to moderate. Pain incurred by surgery in recovery experiments will be minimised using pain relief. In experiments based on thrombosis affecting cerebral blood circulation, cognitive, behavioural or motor skills may be impaired. Mild discomfort will be allowed for up to 2 weeks with careful monitoring and appropriate pain relief. Should any animal show signs of deviation from normal health (piloerection, hunched posture, inactivity or inappetence, >15% weight loss) the experiment will be terminated immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Up to 20% of the mice may show signs of mild severity discomfort (1500 from P1), and up to 80% may show signs of moderate severity (1000 from P2, 1000 from P3, 1000 from P4, 500 from P5).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are three key reasons why the aims of the project cannot be achieved without animal studies:

At present, there are no suitable laboratory alternatives that are able to replace our animal studies, as the studies require viable intact tissues, blood vessels and natural blood circulation, which currently cannot be cultivated or obtained using tissue culture.

Mice are a good model for pre-clinical studies of thrombosis, atherosclerosis and thromboembolism, because basic mechanisms regulating venous thrombosis and other vascular pathologies are similar in mice and humans.

Genetically modified mice allow for targeted and precise testing of the role of certain genes, cells and coagulation factors in thrombosis, thromboembolism and atherosclerosis.

In all experiments, in which the experimental results can be obtained without involving animals, in vitro approaches will be employed. Prior to starting animal experimentation, a comprehensive literature search will be undertaken to ensure that the factor under study is indeed very likely to be involved and also to exclude the possibility that a similar study has already been published. The murine studies will be complemented with and compared to clot structure studies using thrombi obtained from patients after thrombectomy, where the mechanisms leading to thromboembolism cannot be determined.

Which non-animal alternatives did you consider for use in this project?

Currently there are no suitable laboratory methods that fully replicate and can therefore replace the complex interactions between the vessel wall and the blood in determining thrombosis. However, two main technical approaches will be taken that in part replace immediate animal studies, reduce the number of animals needed and underpin the studies proposed in this project licence.

Mutagenesis studies of (generation of mutations in) recombinantly expressed human coagulation factors to test their functional effects using laboratory experiments before introducing the same or similar mutations in the genetically modified mice strains. Using this in vitro approach achieves two main objectives a) similar functional effects can be observed in the mice due to the large degree of evolutionary conservation of the clotting factors between humans and mice, and b) mutations to be introduced will be well tolerated in the mice.

Laboratory flow microsystems will be established that in part replicate the vascular biology of clot formation under flow and used first, before seeking confirmation of the findings in an animal model with the full complexity of the vasculature and the flowing blood.

Why were they not suitable?

Human recombinant protein and mutagenesis technique is very useful to test specific hypotheses about the effects of particular mutations on protein structure and function, and

while they underpin the studies using animals proposed in this project licence, they cannot test specific hypotheses regarding the role of these proteins and mutations in disease.

Laboratory flow microsystems are very useful to test specific hypotheses regarding the interplay of flow and clot formation, but they are not able to test specific hypotheses regarding the role of this interaction in disease development, progression and outcome.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice needed for the studies have been estimated based on 1) prior data and the variation in this data using similar mouse studies, 2) prior data and the variation in this data using laboratory methods directly underpinning the studies, and 3) statistical methods to estimate the minimal number of mice needed to test the hypotheses (objectives) of each part of the studies, based on the size of the effect observed and the variation in the data, with a particular degree of certainty (normally >95%).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Following steps were taken in experimental design to reduce the number of mice to be studies in this project to the absolute minimum: 1) laboratory experimentation wherever possible to replace or underpin any animal study, 2) a high level of expertise and skill of operators involved in the animal studies, 3) statistical methods to estimate the minimal number of animals required to test the primary hypotheses with >95% certainty, 4) using one animal at a time to undertake several measurements (e.g. thrombosis induced in separate blood vessels in the same animal) where possible and acceptable and in terminal procedures under full anaesthesia only, 5) avoiding any possible repeats of previously published literature, and 6) obtaining as many tissue and vessel samples as possible from all animals for laboratory testing.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A number of measures will be employed to optimise and reduce the number of animals included in the studies. This includes but is not limited to: 1) efficient breeding strategies where possible and safe to reduce the number of breeding pairs needed to achieve the required numbers, while being mindful of avoiding possible inbreeding and its effects, 2) laboratory studies using recombinant (laboratory) human proteins and flow microsystems

instead of animal studies where possible, 3) efficient use of all tissues and blood of all animals that are included and reach the end of the study, sharing this amongst researchers involved in this project licence and beyond, and 4) use and constant review of statistical methods to ensure that optimal animal numbers are being studied to be able to test the hypothesis (objective) with a reasonable degree of certainty, taking into account the level and variation of the effect observed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The development of blood clots in mice will be studied. The blood clots will be triggered using established methods (e.g. chemical triggers, blood flow reduction) in main blood vessels in the animal (e.g. vena cava, femoral vein or artery, carotid artery). About half of the experiments using chemical injury will be performed under general anaesthesia and

the animals will not wake up at the end of these experiments, so they suffer minimal harm. Other experiments will involve recovery for up to 2 weeks after thrombosis. The model involves careful surgery to minimise suffering and the animals normally recover without any major adverse effects or distress. Any animal showing signs of more than minimal pain or distress will be humanely terminated.

Why can't you use animals that are less sentient?

The blood vessels in which thrombosis is triggered will need to be fully developed and therefore immature animals cannot be used. About half of the experiments are performed under terminal general anaesthesia. The experiments that involve recovery are required to study thrombosis that develops more slowly over time and is therefore more similar to thrombosis in patients with deep vein thrombosis, and to study the role of clot architecture in thromboembolism (e.g. pulmonary embolism and stroke).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The surgical skills and post-operative care of the animals, including pain relief are state-of-the-art, and similar to those experienced by patients undergoing vascular interventions. Where potential situations arise that animals show signs of pain and distress after the procedure that exceed minor levels of harm, monitoring and pain-relief will be increased. In

case any situation occurs of more than the scheduled level of discomfort, animals will be euthanised immediately.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance published on the LASA, LAVA and NC3Rs websites will be followed for research and testing using animals. Guidelines will be reviewed on a regular basis including guidance from the facility's veterinary doctor. With regards to field-specific developments in vascular and blood clotting animal models, guideline documents published by the Models of Thrombosis and Haemostasis Subcommittee of the International Society of Thrombosis and Haemostasis will be consulted. Implication of any developments will first be discussed with the facility veterinary doctor, and subject to approval of protocol amendments by the Home Office.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advances in the 3Rs will be followed through regular (annual) refresher courses and through communications with the veterinary doctor in charge of the facilities. For the implementation of any advances in 3Rs, protocols in use will be reviewed with the personal licence holders on the project and appropriate modifications will be made where necessary. Any such modification will first be checked with and approved by the Home Office and with the facility's veterinary doctor before implementation.

14. Centrosomes and cilia in development and disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cilia, centrosomes, development, neuroscience

Animal types	Life stages
Zebra fish	embryo, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how centrosomes and cilia contribute to vertebrate development, with an emphasis on neural development, and to model neurodegeneration, seen in Parkinson's and other diseases, in fish embryos.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cilia are hair-like structures on the surface of cells, for example the airway where they sweep up dirt from the air we breathe in. Most cilia in the body act as signalling masts, housing the cellular receptors- antennae - that pick up signals cells use to communicate with each other in backboned animals like humans. This communication is affected in a number of human diseases so it is important to find out how cilia are made and function to understand what goes wrong in these diseases, like polycystic kidney disease. Cilia may

also be affected and involved in the progression of neurodegenerative diseases like Parkinson's. This may offer a route to diagnose this disease but first it must be found out how cilia are affected in this disease.

What outputs do you think you will see at the end of this project?

This project will advance basic science, adding to fundamental understanding of the processes that go on in cells and the body. It will generate new perspectives on important diseases. This information will be published in peer-reviewed scientific publications.

Who or what will benefit from these outputs, and how?

The immediate benefit, during the licence or shortly afterwards, will be to fellow scientists investigating these problems. The new knowledge gained will change the experiments and projects they undertake. The longer term benefit - 10 years or more will be to patients with diseases in which cilia are involved. Knowledge generated by this project could give rise to new diagnostic tests for Parkinson’s. For other diseases that involve cilia, the knowledge may lead to the development of new treatments. Such diagnostic tests or treatments are not part of this project so would require further research and development by commercial entities.

How will you look to maximise the outputs of this work?

We will be collaborating with other research groups, nationally and internationally. We will publish our research in peer-reviewed scientific journals. Involvement of collaborators at these institutions will aid widespread dissemination of the work.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 640

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

One of the main advantages of using zebrafish is that their eggs develop fast and are see-through. This means we can see the results of our experiments quickly. For this project, zebrafish are excellent as cilia are also widespread in all relevant tissues and organs as they develop. Because we will be using eggs for most of our experiments and observations, will be doing few procedures on adult fish. We will need to do some biopsies to test their genetics but otherwise, the fish will lead full lives, breeding to lay eggs that we then study.

Typically, what will be done to an animal used in your project?

We will be creating lines of zebrafish that carry certain mutations, certain genes inactivated or replaced with altered versions. This is achieved by CRISPR using freshly laid eggs. When these eggs hatch and grow into adults, small biopsies from the fins are taken so we can test the genetic status of the fish. These lines of fish will be carriers of the mutations so will not suffer from the effects of inactivated genes. The fish will then be bred to generate the eggs that are studied.

What are the expected impacts and/or adverse effects for the animals during your project?

There will be mild pain associated with the fin biopsies, during recovery as the procedure is done under anaesthesia. This may last one day during initial wound healing. The fin regrows back to its original shape and size.

During fish breeding, there is some stress associated with zebrafish mating and sometime damage to the scales and gills if the adult fish are aggressive. Breeding lasts for one hour; fish are then separated.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For fin biopsies, the severity is expected to be mild for all fish. For breeding, severity is expected to be sub-threshold for 90% of pairings.

What will happen to animals at the end of this project?

Used in other projects
Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals as cells that are grown outside of an animal do not sufficiently resemble those in an animal for us to fully learn how they behave and are affected by different genes and mutations.

How cells behave is strongly affected by the cells neighbouring them. Many tissues and organs are complex, finely detailed structures with many different types of cells. For the tissues we wish to study we cannot yet make these structures in a test tube so we have to use animals. Other animals, such as insects, have different arrangements of cells in some

organs e.g. the brain or lack some structures e.g. the backbone so using them is not an option either.

Which non-animal alternatives did you consider for use in this project?

We do use cultured fish and human cells in our laboratory and we will use them for some aspects of this project.

Why were they not suitable?

These cells do not form the complex structures found in animal tissues and organs which also consist of multiple cell types in close association. We therefore cannot investigate how cilia are involved in the development of these organs or tissues using uniform cells grown in a single layer in a Petri dish.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on the number of lines of fish we will need for this study and the minimum, viable population size for each line.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of adult fish we require is set by the minimum number to keep a line going as a viable population. A pair of fish can lay 100 eggs each week and since we are using the eggs in experiments, this is more than enough material for this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have and will continue to optimise breeding conditions so that we do not have to set up large numbers of pairings for fish breeding to occur. We usually set up six pairs of fish to guarantee laying of the 100 eggs we need for each experiment we perform.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Zebrafish lay eggs so the fish embryos develop outside of the mother. This means that we can see the effects on the embryos without doing anything to the mother or causing harm to any fish fry. Zebrafish eggs and embryos below 5 days old are not protected species under the Animals (Scientific Procedures) Act. The only two procedures the parent fish are put through is being allowed to breed, which is a natural behaviour, and generating lines with altered genes, which involves altering the DNA of the embryos, then monitoring as they develop. In the latter case, we only change one copy of the gene. With the other copy still normal, these fish do not suffer from any effects as one copy of the gene is enough for the cells and tissues to carry on working properly.

Why can't you use animals that are less sentient?

We will be using immature life stages for these studies but to generate embryos that lack certain or have certain genes replaced with altered versions genes, we need parents that have one copy altered. They need to breed to lay the eggs we study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The main procedures we are using are breeding fish and generating new lines. We will refine breeding by using new breeding tanks and ancillary equipment as they become available from manufacturers.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ZFIN website (based at the University of Oregon) and ZIRC (an NIH funded facility) are well- established sources on the best practice for zebrafish husbandry including breeding and generating and maintaining new lines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will check the NC3Rs website on a regular, monthly basis for new information about how to implement changes to 3Rs practice in our setting.

I will have regular, quarterly discussions with fellow zebrafish researchers to ensure we also put into practice new methods relevant to 3Rs.

15. Neuronal recording on GA Aged Animals

Project duration

0 years 2 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Aging, Synapse, Calcium homeostasis, Memory

Animal types	Life stages
Mice	aged, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To complete an experiment that commenced on a previous project license. To understand the effects of a chronic endocannabinoid treatment on the synaptic and cognitive properties of healthy ageing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The average age of the general population is increasing, by 2030 it is predicted that 20% of the UK population will be over the age of 65. A lengthened life expectancy is often accompanied by a decline in cognitive function in healthy aged individuals. Impairments in cognitive function, such as memory, result in challenges to everyday life in the elderly population and hence reduces their quality of life. Understanding how the aged brain differs from the adult brain will help us identify pharmaceutical targets which may help

alleviate the cognitive decline. This will have the consequence of improving the quality of life of the ageing population and helping to reduce the societal impact that ageing has.

The age-related cognitive decline was formerly investigated in mice under a previous project license and aged mice exhibited cognitive deficits in hippocampal dependent behavioural tasks and changes in hippocampal physiology. The cognitive deficits thus are likely to be linked to the observed changes in hippocampal physiology. Manipulation of the endocannabinoid system has been linked with restoring cognitive function in aged mice. However the mechanisms of how this is achieved is not fully understood. We suggest that this may be due to reversing age-related hippocampal deficits. To address this, under a previous project license, aged animals were treated with an endocannabinoid agonist and completed a series of hippocampal behavioural tasks and then hippocampal tissue was extracted for recordings. The 17 mice put forward for the current PPL have already undergone chronic endocannabinoid treatment under the previous PPL and now need to reach their scientific endpoint by completing a series of behavioural tasks and their tissue collected to measure pre-synaptic calcium. The data collected from the mice in this PPL will be combined with data collected from the previous PPL to to form a complete study.

What outputs do you think you will see at the end of this project?

The project will provide information on alterations in brain function and related behavioural deficits due to ageing. The data will comprise electrophysiological recordings and measures of behavioural performance in aged mice and controls. Initially the work will be written up as a PhD thesis which will be available via publicly searchable databases. The work may also result in a published journal article (subject to discussion with the previous PPL holder).

Who or what will benefit from these outputs, and how?

The translational potential of this work is likely to be realized in the medium to long term. By investigating brain mechanisms underlying age-related cognitive decline the current study has the potential to aide pharmaceutical development of cognitive enhancers for the aged, promote an awareness of age-related mental health issues and improve differential diagnosis for symptom clusters not specific to age, The beneficiaries thus will be clinicians, pharmaceutical researchers and the general public. The immediate short-term beneficiaries will be the scientific community working in the field of cognitive neuroscience and neurophysiology whose research will be informed by our findings.

How will you look to maximise the outputs of this work?

The PhD thesis will become immediately available (timeframe < 1year). In the thesis, the outcomes will be published and described in detail regardless of whether the approach is successful or not.

Species and numbers of animals expected to be used

- Mice: 17

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice represent the lowest species of sentient animals suitable for this work. They are widely used for this type of work and so the results we produce will build upon a substantial body of existing information both from our laboratory and others. We wish to examine how the signalling properties of excitable cells in the brain change with age and how these changes impact on the ability of the brain to learn behaviours that are known to decline with age. We therefore need to use young adult animals and those that have aged naturally. Further the work under this project was started under a different project and needs to be completed in the same animals

Typically, what will be done to an animal used in your project?

Mice will undergo a series of non-regulated behavioural testing and then will be humanely killed by a Schedule 1 method to obtain hippocampal tissue for ex vivo experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

Most mice age normally but as animals get older, they are more susceptible to conditions that are associated with old age. This might include the appearance of tumours or a general deterioration of the condition of the animal. Based on experience with previously tested animals, no adverse effects are expected from behavioural testing and no delayed adverse effects due to previous endocanabinoid treatment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All aged mice will be used by 20 months of age. At this time point, most mice do not display agerelated adverse effects or only experience mild effects. 20% of aged mice may show moderate agerelated adverse effect, with 80% showing mild or no age-related adverse effects. 100% of non-aged mice are expected to experience sub-threshold severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project will investigate how the physiology of excitable cells within the brain is altered with normal aging. To achieve this goal, we need to be able to examine neuronal function in a realistic and preserved network in animals and tissues that have been aged.

Immortalised cell lines are not suitable for most of this work because they do not form realistic neural networks. Brain slices represent an important model for us because the networks are largely preserved and the slices afford access to single cell recordings, population recordings, easy drug access and modern imaging methods that provide more information than electrophysiology alone. Our approach to this is to use the most relevant model to achieve our aim whilst taking all steps possible to adhere to the principles of the 3Rs. Finally, we have to use animals in this particular experiment as it is a continuation of work using animals.

Which non-animal alternatives did you consider for use in this project?

Related research approaches use immortalised cell lines and mathematical modelling approaches to inform and thereby minimise the use of animals. However, there are not yet available models that can realistically model neuronal activity in relation to behaviour. As the work is a continuation of a project involving mice it needs to be completed using animals.

Why were they not suitable?

Non-animal models are not yet sophisticate enough to replace the experiments detailed in this project. They are very useful for helping to predict the actions of drugs, for example, on relatively simple systems and this informs further work using animals. However, models are limited by the information available and animal experimentation helps to provide that information. The work proposed here is a continuation of work carried out in mice so will need to be carried out in the same species.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experiments performed in this project are a continuation of a larger study from a previous PPL. The data collected from the estimated number of animals under this PPL (17 mice) will be combined with data collected from a previous PPL (18 mice) to ensure sufficient animal numbers. This estimated number of animals for the overall study is based on published work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In general, we use the NC3R's Experimental Design Assistant tool when designing experiments in our laboratory. This allows us to check the statistical analyses and number of animals to use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible we will tissue share within our facility and other colleagues.
A single brain can yield at least 10 hippocampal slices, 5 cerebellar slices and 3 slices of brain stem, for example.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Calcium sensor selectively expressed at presynaptic terminals in the brain.

This mouse line shows no harmful phenotype. It has been used to examine the nature of synaptic transmission in the hippocampus and cerebellum and most recently to show that during the ageing process, calcium levels in the presynaptic terminals becomes disrupted leading to changes in the release properties of synapses and consequently changes in transmission strength and in the ability of synapses to change their strength. Like wildtypes, when aged, this mouse line shows a reduced ability to learn in behavioural tasks associated particularly with spatial navigation that involves hippocampal integrity. By expressing this sensor in mice, it is possible to prepare brain slices from these animals and record, using optical techniques, directly from the tissue without the need for complex electrophysiology or injection of dyes or other agents to measure neuronal activity. This greatly increases the success rate of experiments and allows more experiments to be performed from a single animal, thereby addressing the 3Rs directly. The use of in vitro tissue allows animals to be used with minimal suffering.

Ageing is a natural phenomenon. If animals start to show adverse effects, then they are treated and if that is not successful, then they are humanely killed so they do not suffer. Whilst animals age, they are well cared for by the staff at the facility, observed regularly and provided with food and water and in cage 'enrichment.

Why can't you use animals that are less sentient?

Mice are mammals and their brain structure is similar to that of humans and they undergo and perform behaviours that are reminiscent of those that humans carry out. It is possible to use less sentient species for some experiments involving behaviour but the availability of transgenic mouse models and the similarity of their brains to humans make them a realistic model for aging and age-related diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Only non-invasive behaviour studies will be performed under this PPL. No food or water restriction will be used, and animals will usually be given positive reinforcement of treats after behaviour testing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to experimentation, the researchers have conducted a systematic review of the literature to ensure that the experimentation is necessary and to ensure that the approach we use is likely to yield the expected results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

1. We undergo regular professional development which includes ensuring that we remain aware of the principles of the 3Rs. We will discuss our work with the named persons, keep abreast of developments through NC3Rs and take advantage of advances in relevant technologies.

16. Infectious disease in pigs and ruminants

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Pigs, Ruminants, Infectious disease, Prevention, Pathogenicity

Animal types	Life stages
Cattle	juvenile, adult
Sheep	juvenile, adult
Goats	juvenile, adult

Animal types	Life stages
Pigs	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to investigate disease causing mechanisms of micro-organisms, single or as coinfection, associated with general, enteric or respiratory symptoms in pigs and ruminants of different breeds, their prevention via vaccines or treatments, their detection via novel diagnostic tools and their distribution under field conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The outcomes of this project are a better understanding of infectious pig/ruminant diseases which ultimately will lead to improved intervention strategies such as vaccination or changes in husbandry. Pigs and ruminants are investigated as frequently they can be infected with the same pathogens and they also are reared often in close proximity to each other. For example Erysipelothrix rhusiopathiae is a major pig pathogen and also occurs in lambs and in cattle. Similarly, another pathogen we work with, the zoonotic Hepatitis E virus (HEV) occurs in pigs and ruminants. Concurrent infection of farm animals with two or more micro-organisms (viruses, bacteria) is a common scenario and often increases clinical signs. Knowing which micro-organism interact will help to add in decisions on reduction or even eliminate certain pathogens. Timely demonstration of diseases is important for pig herds in order to implement correct strategies. Closely monitoring field pathogens is important as even minimal changes in the pathogen genome sometimes are associated with increased severity or lack of vaccine efficacy. Earlier detection of such changes will help determine consequences and prevention at a time when the effect on the pig population is still marginal. Finally, improving diagnostic tools and establishing new diagnostic tools for early pathogen detection are needed to monitor disease trends and pathogen spread. Having the correct tools available can be critical to prevent rapid pathogen transmission when emerging pathogens enter the UK pig population or new pathogen subtypes appear.

Pigs and ruminants harbor a variety of coronaviruses (CoV) including bovine coronavirus (BCoV), porcine respiratory CoV (PRCV) and transmissible gastroenteritis virus (TGEV). This research will also examine the susceptibility of pigs/ruminants to infection by emerging pathogens, including those that pose a zoonotic risk, e.g., SARS-CoV-2 but also HEV. Understanding whether farm animal species can be a reservoir or intermediate host for such pathogens will provide benefits for public health. For instance, if ruminants can be infected with SARS-CoV-2 and support virus replication, infected ruminants (including their products such as dairy or meat) pose a reservoir for human infections and will need to be assessed further. Also, if the virus is actively able to replicate in ruminants (=a non-human host), viral genome changes will likely be introduced and it is possible that the virus may become more pathogenic for ruminants as well as for humans.

Lawsonia intracellularis, a major pig pathogen that occurs in many other species including ruminants (deer) and is associated with reduced weight gain and enteric disease in affected species, is causing major economic losses to producers, current vaccines are not always effective, often resulting in antibiotic usage. Similarly, Clostridium perfringens also causes diarrhea but in very young animals wihthout interventional tools that can be used. Novel intervention strategies for enteric diseases in livestock are needed.

Overall, this research directly benefits pigs/ruminants and in the long run will result in healthier pigs/ruminants thereby reducing usage of antibiotics and contributing to pig welfare, a healthier environment and better meat quality.

What outputs do you think you will see at the end of this project?

- Novel information on basic pathogen-host interactions and mechanisms of pathogen pathogenicity will be generated.
- Novel information on basis of intraspecies transmission for HEV and E. rhusiopathiae (ruminant, pigs) and the consequences for the pathogens and host species. This can results in novel cross- species vaccines that can be used and offer protection to variety of animal species.
- Novel information on infectious pathogens such as vaccine targets for future vaccine research will become available.
- Peer-reviewed publications on the investigated topics and outcomes will made available to other researchers but also the general public via open access.
- Possible products of this research include novel vaccines for the enteric pig pathogen Lawsonia intracellularis (L. intracellularis), novel treatment for the systemic and respiratory pig pathogen Porcine reproductive and respiratory and syndrome virus (PRRSV) that could complement current vaccines, and potential novel animal models for future study of mechanisms and intervention strategies for human Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infections.

Who or what will benefit from these outputs, and how?

The benefits of this project involve pigs and ruminants, pig and ruminant farmers, meat eaters, veterinarians and scientists at different levels and are summarized below.

Pigs/ruminants

This research directly benefits pigs/ruminants in the long term in several ways. By investigating the consequences of important pathogens on a pig/ruminant and by identifying and testing control measurements against these pathogens, and the possibility of cross-species transmission, this project in the long run will result in controlling diseases

and ultimately healthier pigs/ruminants. Improved diagnostic tools will lead to earlier diagnosis and more timely treatment of pigs which will go beyond the course of this licence. Improving diagnostic tools and establishing new diagnostic tools for early pathogen detection are needed to monitor disease trends and pathogen spread. Having the correct tools available can be critical to prevent rapid pathogen transmission when emerging pathogens enter the UK pig population or new pathogen subtypes appear.

Meat eaters

This research will reduce usage of antimicrobials and contributing to pig welfare, a healthier environment and better meat quality which all is important to people eating the product of the pigs, pork, and living close-by pig farms. Previously, porcine circovirus (PCV2) vaccinated pigs needed significantly less antimicrobial treatment compared to unvaccinated pigs as the general health status in vaccinated pigs was much higher

Veterinarians

Accurate and timely diagnosis of diseases is important for veterinarians in order to implement correct strategies; development of more rapid or multiplex testing strategies can improve therapeutic approach and mitigate disease losses.

Scientists

This research will provide a better long term understanding of the pathogenesis of infectious livestock diseases which ultimately will lead to improved intervention strategies such as vaccination or changes in pig and ruminant husbandry. Closely monitoring field pathogens as part of surveillance studies is important for scientists, veterinarians and diagnostic units as even minimal changes in the pathogen genome sometimes are associated with increased severity or lack of vaccine efficacy or easier interspecies transmission. Moreover, changes in the genome can affect the ability to detect the pathogen. Earlier detection of such changes will help determine consequences and prevention at a time when the effect on the pig population is still marginal. Publications that become available during the course of this project will also contribute to scientific knowledge immediately.

General public

This research will examine the susceptibility of pigs/ruminants to infection by emerging pathogens, including those that pose a zoonotic risk, e.g., HEV, E. rhusiopathiae and SARS-CoV-2. Understanding whether these animal species can be a reservoir or intermediate host for such pathogens will provide benefits for public health. For instance, if ruminants can be infected with SARS-CoV-2 and replicate the virus, infected ruminants (including their products such as dairy or meat) pose a reservoir for human infections and will need to be assessed further. Also, if the virus is actively able to replicate in ruminants (=a non-human host), viral genome changes will likely be introduced and it is possible that the virus may then become more pathogenic for ruminants as well as for humans. Another

virus that needs to be monitored closely as it frequently enters the human food chain via at the abattoir contaminated meat or via pig manure contaminated strawberries and others. Similarly, for bacteria such as E. rhusiopathiae, cattle put in fields or building previously occupied by pigs have a greater risk to acquire infection with this pathogen as we have demonstrated.

How will you look to maximise the outputs of this work?

The outputs of this work will be maximized by collaborations with other investigators within the University but also across other UK institutions and other nations. Any new finding will be presented at farm animal producer and/or veterinarian meetings at the UK, EU and international levels. Knowledge obtained in this research, regardless of success, will be published in international journals and presented at international meetings as we have done in the past.

Species and numbers of animals expected to be used

- Cattle: 130
- Sheep: 130
- Goats: 130
- Pigs: 130

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Pigs and ruminants are being used as they represent the natural host for most of the investigated pathogens.

Life Stages

Pigs

- Juvenile/weaned pigs: Most commonly pigs will be used at weaning or shortly afterwards as vaccines or treatments are often given to young pigs around this time. Furthermore, at weaning pigs are often leaving their farm of origin and are co-mingled with pigs from other sites.
  Comingling frequently results in transmission of pathogens between pigs.

- Neonates: When investigating early diarrhea complexes such as seen with Clostridium difficile, pigs need to be used shortly after birth as Clostridium difficile targets suckling pigs and will cause most damage within the first 3-5 days of life. The biology of this bacterium and intervention strategies cannot be tested at later points as pigs are no

longer susceptible. In an upcoming work we will investigate the microbiome associated with C. difficile infection to develop a tool based on feeding probiotics to young pigs at risk to prevent C. difficile infection and lesions. This can only be studied during the time lesions would normally occur.

- Adults: Occasionally breeding pigs will be used as some vaccines are given to sows to protect pigs in the first 3-8 weeks of life via colostrum antibodies.

Ruminants

- Juveniles: Young animals at 4-6 weeks of age will be used. Ruminants at this age are easier to house and handle and the age is suitable for COVID-19 research.

Typically, what will be done to an animal used in your project?

For typical investigations on conventional sourced pigs/ruminants, they will be obtained from a commercial farm at weaning age, will be randomly divided into several groups and rooms, and after an appropriate acclimation time may be vaccinated against the pathogen under study in the research facility with a re-vaccination 2-4 weeks later if needed. Subsequently after approximately 4-6 weeks after initial vaccination, the animals will be challenged with the pathogen of interest. After vaccination and challenge samples will be collected on a regular basis to determine if the pathogen is present and if an immune response against the pathogen can be detected. Samples that may be collected include blood samples, nasal swabs and/or rectal swabs among others. The various sample types may be tested by PCR to confirm presence and amount of the pathogen, by ELISA for antibodies, or by other tests for cytokine presence and others. At termination of the project the animals will be killed using a schedule 1 method. This may be followed by a necropsy were lesions in the animals are assessed and additional tissues may be collected.

What are the expected impacts and/or adverse effects for the animals during your project?

Mechanism studies and vaccine trials

Expected adverse effects:

- Lumps or redness at the vaccination site. The duration of these adverse effects may last up to 2-3 days.

- Haemorrhage during blood collection. The duration of the direct impact of hemorrhage on the pig is commonly 10-20 min but the pig may be weak for up to 3 h.

- Clinical signs after challenge: Fever, diarrhoea, weight loss, respiratory signs, lethargy. The duration of these clinical signs depends on the pathogen invovled but typically clinical signs may start as early as 1-2 days after challenge for enteric pathogens such

as C. difficile or as late as 5-7 days for respiratory pathogens such as PRRSV.

Control sample derivation for test development (POLE)

Expected adverse effects:

Haemorrhage during blood collection. The duration of the direct impact of hemorrhage on the pig is commonly 10-20 min but the pig may be weak for up to 3 h.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mechanism studies and vaccine trials

Likely/expected level of severity: Mild-to-Moderate. At termination the pigs/ruminants will be killed using a schedule 1 method.

Pigs: 30% moderate, 70% mild

Ruminants: 10% moderate, 90% mild

Control sample derivation for test development (POLE)

Likely/expected level of severity: Mild. At termination the pigs will be rehomed.

Pigs: 100% mild

Ruminants: 100% mild

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are working with the target species and will investigate diseases and intervention strategies in pigs and ruminants. Studying the disease in the natural host is essential in order to inform management and production decisions which are immediately translatable. In addition, we will also develop and validate diagnostic tools important to detect pathogen

presence on livestock farms. For this we need access to known positive and negative control samples which ideally would come in from the target species.

Besides pathogens already present in UK livestock, this research will also examine the susceptibility of pigs/ruminants to infection by emerging pathogens, including those that pose a zoonotic risk, e.g., SARS-CoV-2. Understanding whether these animal species can be a reservoir or intermediate host for such pathogens will provide benefits for public health. For instance, if ruminants can be infected with SARS-CoV-2 and support virus replication, infected ruminants (including their products such as dairy or meat) pose a reservoir for human infections and will need to be assessed further. Also, if the virus is actively able to replicate in ruminants (=a non-human host), viral genome changes will likely be introduced and it is possible that the virus may become more pathogenic for ruminants as well as for humans.

Which non-animal alternatives did you consider for use in this project?

Non-animal derived alternatives including cell lines, organoids, tissue sections have been identified and will be used whenever possible to generate data.

Why were they not suitable?

It is not feasible to quantify organ colonisation, systemic spread, tropism or immune responses mediating pathology or protection solely in cell-based assays or organ culture systems such as lung or liver slice cultures. Non-animal derived alternatives as listed above, are not suitable to study the development of a disease, infectivity of a certain pathogen, determining if vaccines protect an animal and generation of positive controls for diagnostic tests can only be done in live animals. Cell culture systems are not suitable to study interactions between the animal's immune system and the disease causing agent. Similarly, antibody responses ("titre development") can only be studied in pigs/ruminants and not in cell culture systems.

The decision to use animals will only be taken once other avenues of research such as in vitro studies have been exhausted. Alternative routes will be considered whenever possible and feasibility of using alternatives will be assessed for each separate study. Cell culture studies are being done and results will inform future animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers that will be used will be based on planned funded experiments and experience doing similar studies in the past.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- The Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) will be used.
- We will check relevant literature on this topic including published studies for the pathogens investigated.
- We will also seek advise from experts in the area of investigation.
- We will also consult with our statistician.
- Regulatory requirements will be followed for PK studies

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Pilot studies will be done whenever no or limited data are available.
- Animal studies that could be shared with other researchers to investigate two scientific questions at the same time will be preferred.
- Computer modeling to investigate aspects such as infectivity speed will be used in the optimization phase for the animal project.
- Tissues and liquids such blood will be shared.
- Whenever feasible biobanks of tissues or blood will be established.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Pigs and ruminants (sheep, goats, calves) are key reservoirs of the investigated infectious agents and are also be susceptible to pathogens circulating in humans including HEV, Erysipelothrix rhusiopathiae or SARS-CoV-2. Disease is not always reproducible in pigs or ruminants compared to other model species; however usually viremia/bacteremia and shedding can be assessed and is useful to assess intervention strategies such as vaccination. Studying the disease in the natural host or a host that is very similar to the natural host (pigs/ruminants and humans) is essential in order to inform management and production decisions which are immediately translatable.

Other groups have reported using rodent models with many of the infectious agents in pigs we commonly use; however, the outcomes vary between different groups, further emphasizing that the models are not robust. Rodent models may be useful for analysis and characterization of immune responses against selected pig pathogens and in the past our group has used a mouse PCV-2 model. We infected three different mouse lines porcine circovirus type 2 (PCV2) but we were not able to show infectivity, seroconversion, disease or lesions in any of the mice. While it is widely accepted that rodents can play a role in transmission of some pig pathogens, rodent infection, lesion development or disease is questionable and these models are not currently useful for the pathogens we work with to study disease development in the target species.

A clinical scoring system refined under preceding studies will be used to monitor the severity of infections and identify animals requiring increased monitoring, treatment or euthanasia. Commonly we measure rectal temperatures in pigs/ruminants to identify animals that develop a higher than expected fever for a prolonged time.

When vaccines or drugs are used, usually these are typically commercially available and licensed products for pigs/ruminants. While injection site reactions are not expected we typically monitor the reaction sites for up to three days for any reactions. With the expectation of caesarian-derived, colostrum-deprived (CDCD) and colostrum-deprived (CD) pigs in the first days of life, all pigs are group housed. The CDCD and CD pigs that will be housed in individual isolators are separated from their litter mates by Plexiglas allowing them to see their siblings. Refined models are currently being used that comes from years of experience and will be further refined in the UK.

For sample collection we often use oral fluid. Oral fluid collection does not interfere with a pig's normal behaviour as not direct contact is necessary to obtain this sample type and therefore this can be considered as refined procedure.

We will share any propagated serum controls to other potential end users (companies, diagnostic units) so that they do not have to create their own control serum in pigs/ruminants.

Why can't you use animals that are less sentient?

Pigs and ruminants are the target species for the pathogens investigated. Lower species such as mice or rats cannot be used.

Pigs and ruminants can be readily infected with E. rhusiopathiae, pigs can be infected with HEV (unknown for cattle but suspected), pigs and deer (not yet determined for cattle, sheep and goats) are reservoirs for L. intracellularis, pigs and ruminants are targets for coronaviruses including PRCV, bovine respiratory coronavirus and also for SARS-CoV-2. The experimental evidence for SARS-CoV-2 infection in ruminants or pigs is not very clear and needs to be further confirmed to rule out that ruminants or pigs act as possible virus reservoirs for humans. It needs to be further investigated to determine whether or not pigs and ruminants can be consistently infected with SARS-CoV-2 as results so far are

conflicting. After experimental inoculation, research groups confirmed antibody development in all pigs without detectable viremia or virus shedding. Other found not evidence of seroconversion, yet others found seroconversion, virus shedding with infections virus being isolated in few pig. Cattle has been shown to be be susceptible to experimental SARS-CoV-2 (virus shedding in nasal secretions) however, lesions and tissue distribution of SARS-CoV-2 was not investigated. It is important to determine if SARS-CoV-2 can also infect sheep and goats and if there are lesions and viable virus in lungs or other tissues for further assessing these species as possible virus reservoir or intermediate host.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animals will be closely monitored depending pathogen and intervention. A plan for adverse effects is in place for each pathogen and model. Pain management will be provided if needed.

Refinements in place: Pigs/ruminants will be kept in social groups whenever possible. If this is not possible, pigs/ruminants will be able to see each other through glass partitions. All pig rooms/pens will be equipped with environmental enrichment. Other refinements that are in place include usage of real- time PCR cycle threshold numbers or virus genome calculation to inform endpoints.

A statistician will be consulted when planning individual studies to determine the minimal number of pigs needed to have enough statistical power to determine significance if there are true differences between groups.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the NC3R guideline (https://nc3rs.org.uk/the-3rs)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I continuously inform myself by reading relevant literature on 3Rs (mostly online). I will also contact others including AWERB committee members prior to study start and ask for further advise. I also routinely search databases on published information for studies I am intending to avoid possible duplications.

17. Regulation of gene expression in vertebrate development

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Development, Stem cells, Therapy

Animal types	Life stages
Zebra fish	embryo, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand the genetic programs needed to create tissues and organs, such as blood, muscle, pancreas and liver, in an embryo.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The ability to make tissues, or even organs, rather than use donated organs, for transplant is a goal of modern medical science. However, currently scientists cannot precisely recreate tissues with 100% efficiency. For instance, during the process some cells may not form the wanted cell type but form another cell type altogether. In other cases, the 3

dimensional structure of the tissue cannot be recreated and the cells do not work efficiently without that structure. In order to overcome these difficulties, it is important and necessary

to study first in detail the embryonic process of making tissues, so as to better recapitulate it.

With a better knowledge of the genetic programs needed to create tissues and organs, we can apply the knowledge to making tissues outside the body, by coaxing stem cells or other cells to use the same programs. Such 'in vitro' generated tissues can then be used to replace damaged tissue in humans or animals after injury or disease. Alternatively, this understanding may lead to ways of rebooting these programs in the damaged tissue so that repair takes place in the patient's body, without the need to generate replacement tissues in vitro.

What outputs do you think you will see at the end of this project?

We expect to have a better understanding of the genetic programs that direct the formation of different tissues or organs, such as muscle, heart and pancreas. This information will be disseminated through open access publication in scientific journals and presentations at scientific conferences. Results will also be highlighted through press releases if appropriate. We will also have generated large datasets that will be deposited in public archives for use by the scientific community.

Who or what will benefit from these outputs, and how?

The beneficiaries of these outputs in both the short and long term will be other academic researchers studying developmental biology, stem cell biology and regenerative medicine. In the longer term, patients will benefit from application of the outputs to regenerative medicine therapies.

How will you look to maximise the outputs of this work?

Any new knowledge will be disseminated via scientific publication, conference papers and depositing datasets in public archives, allowing other scientists to use the data. Where possible we will collaborate with other scientific groups, for instance with joint PhD students, to ensure maximum output.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are studying how tissues form in an embryo and therefore use embryonic stages. We use the zebrafish embryo for these studies for multiple reasons. The embryos develop in a

simple saline solution outside the mother and so they are easy to observe without needing to perform any procedures on the mother. The embryos are transparent, meaning we are able to visualize internal organs without the need for surgery. When mated, adult zebrafish produce several hundred embryos in one spawning, meaning we have a large amount of material for study, and this limits the number of adult fish we need to keep to ensure we get statistically relevant data. And while fish are not humans, we already know that the early events of embryogenesis used very similar genes and so what we learn in fish is often applicable to humans.

Typically, what will be done to an animal used in your project?

Adult zebrafish used in our project mate to produce embryos, which are what we study. We use very early embryos in our studies, usually before 24 hours of development, which is before a functional nervous system has formed. We keep the adult fish until they are around 18 months old and they mate approximately every two weeks. When appropriate we may alter the DNA of the embryos and grow them to adulthood, and then mate these adult fish to produce genetically altered embryos for studies.

What are the expected impacts and/or adverse effects for the animals during your project?

We may need to take a fin biopsy of adult fish to confirm their genetic status. While this is done with anaesthetic, it is possible that fish may experience transient mild discomfort during the procedure, and in extremely rare cases infection of the biopsy site may occur. We do not expect any adverse effects from the genetic alterations we make, but it is possible that this may happen, e.g. tumours, abnormal behaviour. If we observe adverse effects occurring after fin biopsy or in any genetically altered zebrafish we will euthanise them immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for adult fish that have fin biopsy is mild. Fin biopsies are experienced by ~25% of fish.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to experimentally establish the program of gene expression that controls early development in vertebrate embryos. We need to better characterise these programs so that we can recapitulate them in cells grown outside the body (called in vitro differentiation) for human regenerative medicine therapies and for modelling disease. This is because, although scientists have the ability to make various cells and tissues outside the body, the methods are still not fully efficient. Research suggests recapitulating the program of gene expression used in an embryo can increase the efficiency of this in in vitro differentiation. It is therefore important to establish the detail in the developing embryo.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives include in vitro differentiated stem cells.

Why were they not suitable?

As described above, in vitro differentiated cells do not yet represent a full model of embryonic development, and it is this gap that we seek to fill in this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is based on the number of animals that will need to be raised to generate or maintain GA variants of zebrafish. When breeding fish to maintenance a variant genetic alteration we expect, due to Mendelian genetics, that 50% of the fish will carry the variation. This means that for every 50 fish required, we must breed 100. For generating GA fish by transgenesis or genome editing, we find that 10-50% of fish are GA when we test them, depending on the type of genetic alteration. This means that for every 10 fish carrying the required genetic alteration, between 20 and 100 fish must be raised.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The latest technologies for introducing genetic changes in zebrafish will be used to ensure the procedure is as efficient as possible, thereby reducing the number of animals that need to be used. Power calculations were performed to determine the numbers of GA fish needed for experimental analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We keep our zebrafish in a state-of-the-art aquarium that has health monitoring systems to ensure optimal water chemistry and we use tested feeding regimes that maximise the survival and health of fish. This reduces the number of fish that need to be raised to adulthood as we expect very little death in juvenile stages.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use zebrafish for this project. Adult zebrafish mate to produce embryos, which does not cause the animals harm or distress. Our experiments are performed on the embryos that are less than 5 days old (ie non-protected), indeed we usually use embryos that are less than 24 hours old. We anaesthetise adult fish prior to fin biopsy and take only a small part of the tail fin; the fins regenerate within two weeks and does not cause lasting harm to the animals.

Why can’t you use animals that are less sentient?

The experiments carried out in the project are done on immature life stages, ie embryos less than 5 days old. In order to generate these embryos, we need to use adult fish for spawning.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Zebrafish are monitored for 24-72 hours after fin biopsy to check their recovery, normal swimming behaviour and if there is any infection of the biopsy site. Those that do not recover, which is approximately 1%, are killed by a schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult the most up-to-date scientific evidence for experimental procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We read scientific literature, attend scientific conferences where advances are discussed, and communicate with other local research groups and aquarium staff about the implementation of advances.

18. Role of the inhibitory neurotransmitter naag and its transporter in pathologies involving glutamatergic dysfunction

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Metabolism, Diabetes, Glutamate signalling, Schizophrenia, Prostate cancer

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary aim of this project is to delineate the role of glutamatergic signalling in communication pathways responsible for the regulation of metabolism. Our secondary aims are to characterise the role of the inhibitory neuropeptide NAAG in schizophrenia, diabetic retinopathy and prostate cancer, which have, together with type 2 diabetes, been genetically linked to a transporter protein we study in our lab which is involved in glutamate signalling.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Obesity remains one of the major health challenges of modern times. By the start of this millennium, the WHO reported that the number of obese adults increased to over 300 million with 41 million children under the age of five classified as overweight or obese by 2016. Co-morbidities, such as lifestyle- induced type 2 diabetes and cancer, are on the rise in parallel, and the number of individuals with diabetes worldwide has been rising exponentially in the last 40 years.

Studies on the endocrine cells - and the hormones they secrete - which regulate our metabolism, such as insulin-secreting pancreatic cells or hormone-secreting gut cells, have advanced our knowledge of how the human body maintains metabolic homeostasis. However, in recent years it has become increasingly clear that, although studying metabolic systems in isolation is tremendously useful, it will only ever allow us to view a snapshot of a specific metabolic state or system in time. Furthermore, when investigating human metabolic disorders, such as obesity and diabetes, we need to understand how all the physiological systems modulated by metabolic dysregulation are affected. The metabolic research conducted in this study investigates how glutamatergic signalling modulates the cells that orchestrate mammalian metabolism via hormone secretion.

Our lab has studied a particular protein of interest that transports glutamate and glutamate-containing molecules across cell membranes. Studies showed that increased gene promotor activity, which results in the overexpression of this protein, in subcutaneous adipose tissue predisposes humans to increased weight gain and the development of type 2 diabetes with age. However, although overexpression of this protein was metabolically detrimental, it protected individuals against schizophrenia and bipolar disorder. Our lab has found that when this transporter is genetically absent from mice, it results in a lean and metabolically healthier phenotype (which is exactly the opposite of the human overexpression phenotype). Furthermore, our metabolic studies demonstrated that mice lacking this transporter are hyperactive and may present a schizophrenia-like phenotype; this is consistent with findings that a primary substrate of this protein, N-acetylaspartylglutamate (NAAG), which is an inhibitory neurotransmitter, is highly associated with schizophrenia and bipolar disorder.

Furthermore, this transporter has been associated by genome-wide association studies (GWAS) to diabetic retinopathy, a complication of diabetes in which high glucose damages the retina. Glutamate is the primary neurotransmitter in the retina, and NAAG is also present at high levels, supporting the hypothesis that this transporter may play a role in retinal glutamatergic signalling. Several other putative substrates of this transporter play instrumental roles in the molecular mechanisms underlying the development of diabetic retinopathy .

Interestingly, it has also been reported in human genetic studies that our target transporter is upregulated in metastatic prostate cancer. The substrate of our protein, NAAG, is known to serve as an important energy source for many cancers. Several genome-wide association studies (GWAS) linked our target protein to the development of metastatic prostate cancer and suggest that this transporter could play a central role in the mobilisation of energy sources and subsequent tumour growth and metastasis in prostate cancer.

Overall, little is known about the target protein in this study, and our laboratory will therefore, alongside our primary metabolic investigation, also explore its possible roles in diabetic retinopathy, schizophrenia and prostate cancer.

What outputs do you think you will see at the end of this project?

Our primary goal is to shed light on the cellular and molecular mechanisms underlying metabolic regulation and dysfunction, including a primary complication of diabetes, diabetic retinopathy.

Furthermore, we want to delineate the roles of the transporter protein we study in schizophrenia and prostate cancer. We expect our findings to effectuate peer-reviewed publications that will inform general scientific audiences. Given the undeveloped nature of our projects studying schizophrenia and prostate cancer, we expect preliminary results to serve as the base for grant applications to fund the maturation of these research programmes in our lab. All models developed during the research will be freely available to the scientific community.

Who or what will benefit from these outputs, and how?

Short term outcomes include shedding light on the mechanism of glutamatergic signalling in obesity, diabetic retinopathy, schizophrenia, and prostate cancer. Specifically, we will delineate the role of the inhibitory neuropeptide NAAG and its transporter in these pathologies. These findings will constitute basic research immediately valuable to other researchers in the field.

In the long term, our findings will, first and foremost, advance current knowledge about the pathophysiology of obesity and the dysregulation of appetite and energy metabolism in obese patients in order to help pave the way to suitable treatments for these patients. Secondly, our findings will help us understand the role of NAAG in schizophrenia and will shed light on the use of NAAG receptor agonists and antagonists in the clinic. Thirdly, we will explore the possibility of finding new early markers to predict prostate cancer progression in man. Finally, we will determine if this transporter of interest plays a role in diabetic retinopathy.

How will you look to maximise the outputs of this work?

Our laboratory regularly attends national and international meetings where preliminary data and experimental hurdles from the proposed studies will be discussed with the greater scientific community. Project data will be made available to all interested researchers through open access publications. Our laboratory also collaborates with a multinational pharmaceutical company that is a major developer of treatments for diabetes. Models generated during the course of the study will also be made available to the greater scientific community. There is active engagement at both the home establishment and other establishments with interest in the subject, which involves the discussion of career progression, ethical data management, healthy living, and the prevention and treatment of obesity.

Species and numbers of animals expected to be used

- Mice: 15,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Metabolism is a complex and integrative physiologic process involving all organs, notably the gut, pancreas, brain, and fat depots. Scientific research regularly utilises in vitro models of some isolated aspects of this system, such as gut-derived stem cells or model cell lines for gut or pancreatic cell types, but many questions can only be answered in an intact system where the cross-talk between organs is present. Much metabolic signalling occurs through inter-organ communication via hormones, each of which have distinct inducers, targets, and clearance mechanisms. Mouse and human energy metabolism are remarkably similar, and therefore mouse models are the most appropriate model to answer these more complex systemic questions. As our work focuses on adult metabolism and the development of dysregulated metabolic processes over time, adults will be the most prominent life stage we use in our studies. Occasionally, juveniles will be used when a procedure takes significant time to take effect e.g., the high fat diet induction of obesity where juvenile mice are placed on a high fat diet to mimic human life-style induced obesity; but our target experimental outcomes will always come from adult mice.

Typically, what will be done to an animal used in your project?

Most mice in our project will exhibit a metabolic phenotype, which may be genetic or experimentally induced. Therefore, some mice will need no intervention to produce this phenotype (e.g., knockout mice), whereas others will be fed a high fat diet or injected with a drug (e.g., subcutaneous injection of hormone receptor agonists). Blood samples may periodically be needed, and some mice will undergo mild imaging methods (e.g., EchoMRI to assess body composition). Some mice will undergo 2-4 metabolic tolerance tests, which consist of a fast, injection of a metabolite such as glucose or insulin (intraperitoneal or

oral), and several small blood samples. For our studies on diabetic retinopathy, diabetic mice will undergo non-invasive glucose urine testing regularly to determine onset of hyperglycaemia, after which they will have blood glucose testing regularly; they may experience one intravitreal injection for acceleration of retinal pathology.

Another of our studies focuses on schizophrenia and involves either genetic mouse models with a schizophrenic predisposition or drug-induced schizophrenia. The latter may receive a schizophrenia- inducing drug such as PCP for up to 2 weeks via subcutaneous minipump implantation. All mice in this line of study would undergo non-aversive behavioural testing (e.g., Y-maze, auditory pre-pulse inhibition). A minority of mice we use will instead be genetic models of prostate cancer who will only experience blood sampling and will be euthanised prior to developments of any metastases or cancer complications, such as organ failure.

What are the expected impacts and/or adverse effects for the animals during your project?

A huge majority of our studies have few adverse effects and do not produce long-lasting harm. Mice may experience several instances of substance administration and a finite number of blood withdrawal procedures, none of which causes more than momentary discomfort. complications. Our metabolic studies focus more on obesity than diabetes pathology, so diabetic mouse models will be avoided for these studies. However, the study of diabetic retinopathy necessitates underlying diabetic pathology. To minimise suffering of diabetic mice, they will be killed as early in disease onset as possible to address our scientific outcomes, usually within 3 weeks of glycosuria detection. After glycosuria is detected, blood glucose will be measured to ensure excessive levels are not reached. Our schizophrenia studies are expected to induce abnormal behaviour, but no physical pain or suffering. Mice modelling prostate cancer will be killed before or during early stages of tumour development and will not develop metastases or other cancer-related complications.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: 80%
Moderate: 20%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Metabolism is a complex physiologic process involving all organs, notably the gut, pancreas, brain, and fat depots. Much metabolic signalling occurs through inter-organ communication via hormones, each of which have distinct inducers, targets, and clearance mechanisms. The metabolic physiology underlying glucose homeostasis and energy balance is well conserved in humans and mice, which is not true for non-mammalian species. Therefore, mouse models are the most appropriate approach by which to answer questions involving whole-system metabolism.

Which non-animal alternatives did you consider for use in this project?

We do (and will continue to do) a significant amount of in vitro work using cells lines, including lines modelling gut cells, pancreatic alpha- or beta-cells, and prostate cancers. We also perform experiments in ex vivo models of gut crypts to answer specific questions about hormone secretion in response to certain metabolic stimuli. After preliminary studies in the eye, ex vivo retinal explants can be used to test new mechanistic hypotheses. All of this work is very important for laying the foundation for animal experiments, in many instances serving as a proof-of-concept.

Why were they not suitable?

These in vitro approaches are limited and cannot be used to fully address the aims set out in this project. In particular, it is impossible to mimic inter-organ communication, especially modulation from the brain. It is also impossible to replicate developmental processes outside of an animal that may be important for underlying mechanisms. Furthermore, overall body weight and metabolic health cannot be assessed in non-animal models, nor can behavioural outcomes associated with schizophrenia.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimated number of mice is derived from our previous studies or, in the case of techniques new to our lab, data reported in the literature but modified to fit our specific experimental needs. We study both males and females as independent groups due the known sex-dependent biological differences in metabolism regulation and schizophrenia.

Not only must we consider our primary procedural goals within this protocol of metabolic tolerance tests and metabolic imaging along with the different mouse models we plan to use, we also do extensive post-mortem analyses (such as western blot and histology) necessitating substantial amounts of tissues. Furthermore, we propose a number of non-aversive behavioural tests that, for the sake of experimental integrity, cannot all be performed on the same mice. Many of our studies (particularly those that are neuro-focused) will be greatly enriched by examining mice at different ages.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design is based on the ARRIVE guidelines, with very clear, measurable outcomes and pre-determined power analyses to ensure optimal usage of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use effective breeding programmes based on existing data to ensure we do not produce excess animals. We will always confirm the viability of any new model or drug for our uses by rigorously analysing the literature. When using new techniques, we will use small pilot studies to not only confirm the efficacy of the method but also to ensure that all of our downstream assays are optimised.

Furthermore, we commonly collect samples from other groups in our department that do not need our organs of interest, e.g., we regularly collect gut samples from a group that is devoted to brain research so that we can optimise new techniques. This helps cut down on the number of mice needed from our own protocols for optimisation-oriented tissue assays. We always strive to utilise as much tissue from one mouse as possible - if there is not immediate use for a tissue, we routinely freeze or otherwise preserve samples for later use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For our obesity studies, we will opt for high fat diet-fed mice or ob/ob mice, neither of which develop overt diabetes or diabetic complications, as those aspects are not currently necessary for our metabolic research programme. We will perform metabolic monitoring of

activity and energy expenditure that will be carried out in a housing environment similar to the animal's home cage but with data collection capabilities. This is more refined than canonical metabolic cage systems with wire-grid floors and absence of bedding and enrichment, which are extremely stressful for mice. We will opt for thermal imaging as opposed to internal (anal) temperature readings, as it is sufficient for our purposes.

To minimise suffering of diabetic mice in our retinal studies, we may use a previously published model variant that includes one intravitreal injection into one or both eyes of a diabetic mouse. This results in a significantly accelerated time course for diabetic retinopathy development, meaning that mice will typically endure hyperglycaemia and the associated complications for approximately three weeks instead of the 12 or more weeks natural development of retinopathy would take. Intravitreal injections will take place with use of a stereomicroscope and stabilised syringe to ensure proper needle placement and to prevent damage to the lens.

To determine diabetes onset, we will test glycosuria, as this is a non-invasive procedure that only involves briefly handling the mouse to induce urination and catching a drop on test strips. This method is a very sensitive indicator of diabetes onset and is much more refined than blood glucose testing.

Following glycosuria detection, mice will regularly have blood glucose tested to ensure they do not reach our humane endpoint

Substance administration of the drugs we plan to chronically administer, such as hormone receptor agonists or drugs that induce schizophrenia-like symptoms, can be refined by using osmotic minipumps in lieu of daily injections. Subcutaneous minipump implantation is a simple procedure that is well- tolerated by the mice. This eliminates the use of needles and significantly decreases the amount mice are handled, which can be stressful. Furthermore, when a drug can be administered via multiple routes, we will always choose the least painful option.

Regarding our schizophrenia models, we have opted for drug-induced models as opposed to those involving maternal separation or hippocampal lesioning which inflict more suffering. Our prostate cancer mouse line(s) will not be kept long enough to experience metastases or complications such as organ failure, as we aim to study the molecular events preceding metastasis.

Why can’t you use animals that are less sentient?

Neither fish nor lower organisms, such as the fly, are suitable for these studies, as it is difficult to investigate metabolism in aquatic organisms, fish are not endothermic and their islets are arranged differently, and the fly is too evolutionarily different. The mouse has well-conserved physiology, including multiorgan control of glucose homeostasis, compared with humans. Conservation at the level of the genome is also high.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our animal procedures are quite simple and are well established. In order to minimise the number of injections that a mouse must undergo, we will utilise osmotic minipumps whenever possible and more refined. The few surgical procedures we present are mild, and standards will be guided by animal welfare resources and the expertise of our vets and NACWOs. When we begin using a drug that is new to our lab, we may conduct a small pilot study with subcutaneous injections versus minipump implantation to assess the scientific viability of minipump use. If we learn of approaches to improve animal welfare or data reliability, we will not hesitate to refine our methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the ARRIVE and NC3R guidelines for experimental design as well as best practices recommended by LASA and the Handbook of Laboratory Animal Management and Welfare (2013, Wolfensohn & Lloyd).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institution regularly sends out notices regarding the NC3R's resources and webinars, which we will utilise. We also stay up-to-date on the literature in the field and will observe modifications that can be made to improve our own approaches.

19. Cellular electrophysiology of cardiac arrhythmias

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

antiarrhythmic drug, arrhythmia, cardiac myocyte, ion channel, pacemaking

Animal types	Life stages
Guinea pigs	adult
Rabbits	adult
Mice	adult, juvenile, neonate, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overarching aim of this project is to advance understanding of the cellular mechanisms responsible for controlling normal heart rhythm and the alterations that underlie disturbances in rhythm (arrhythmia). It is hoped that this research will lead to the development of novel treatments, or improvements in existing therapies, for the management of arrhythmia.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The heartbeat arises through the generation of rhythmic electrical impulses that are conducted throughout the heart, causing it to contract in a co-ordinated manner to pump

blood around the body. Abnormalities in the rhythm of the heartbeat (arrhythmias) are a major cause of death and cardiovascular disease. These arise either through the generation of rogue impulses or conduction abnormalities that alter the propagation of the electrical impulse, either delaying conduction or resulting in circuits of propagation that cause a rapid, irregular and un-coordinated heartbeat. Arrhythmias are often treated using drugs or implanted devices that take over the pacemaking function of the heart.

These approaches have limited effectiveness and many anti-arrhythmic drugs also have unwanted side-effects, including causing an irregular heartbeat. The aim of the outlined studies is to advance understanding of the mechanisms underlying the maintenance of normal heart rhythm and to identify novel approaches to improve the treatment of arrhythmia.

What outputs do you think you will see at the end of this project?

The principal output of the work will be novel information about the cellular mechanisms responsible for the maintenance of normal heartbeat and how alterations in these mechanisms disrupt heart rhythm. In so doing the studies aim to identify novel targets for the treatment of disturbances in heart rhythm.

These findings will be communicated through conference presentations, publications in peer-reviewed scientific journals and via Open Access routes so that the results are available without subscription.

Reports will also be generated for the funding bodies. Where appropriate, results may be communicated to the public through press releases and outreach activities

Who or what will benefit from these outputs, and how?

In the immediate to medium term, we expect the outputs to benefit cardiologists, cardiac surgeons and basic scientists around the world with an interest in the mechanisms responsible for maintaining normal heartbeat and the treatment of arrhythmia. In the long term the findings are expected to contribute to the development of improved treatments to restore normal cardiac rhythm to patient suffering from arrhythmia.

How will you look to maximise the outputs of this work?

In addition to the publication of results in peer-reviewed scientific articles, data will be registered on open access data archives.

Species and numbers of animals expected to be used

- Mice: 2,000
- Rats: 250
- Guinea pigs: 250
- Rabbits: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice have been widely used for studying heart function. As a consequence, extensive background literature exists for these species, making them an appropriate model species to achieve the scientific objectives of many of the outlined studies. In particular, rats are an appropriate model for studying arrhythmias associated with the upper chambers of the heart (atria). Mice are readily amenable to genetic alteration. Consequently, they will be used for studies examining the role of specific genes and proteins in the maintenance of normal heart rhythm. However, neither rats nor mice are suitable for modelling the disturbances to heart rhythm that arise in the ventricles of humans.

Therefore, such studies will utilise rabbits, which have a conduction system that closely replicates that of humans. The ionic mechanisms underlying repolarisation of the rabbit ventricle are closer to those of the human than are those of rat or mouse ventricles. In addition, it is easier to identify the relevant structures in rabbits than in smaller laboratory animal species. Furthermore, the larger size of the rabbit heart means it is also possible to obtain atrial and ventricular heart muscle cells from the same rabbit hearts as used for the study of the conduction system [reduction]. Therefore, in so far as is possible, these hearts will also be used to investigate atrial and ventricular cell electrophysiology for the objectives covered by this project. However, the rabbit has limitations as a model for the human in that it lacks a certain component that is important to human ventricular function. Consequently, some studies will be undertaken using guinea pigs as they have the relevant ventricular component missing in the aforementioned species.

Previous studies have shown that the structure of heart muscle and of heart muscle cells is extremely important to the mechanisms responsible for maintaining normal heartbeat and that disruption of these structures can cause disturbances to heart rhythm. As these structures are immature in hearts from very young animals it will be necessary to use adult animals for the outlined studies.

Typically, what will be done to an animal used in your project?

Guinea pigs, mice, rabbits and rats: Animals may be given an injection that causes no more than mild transient pain shortly before they are killed using a non-Schedule 1 method in order to obtain tissues for ex vivo studies.

Mice: Mice may be bred with genetically alterations relevant to the regulation of heart rhythm. None of these animals are expected to suffer any adverse effects as a result of the

genetic alterations. Small biopsy samples (typically ear punches) will be taken post weaning for the purpose of genotyping. This causes no more than mild transient pain.

What are the expected impacts and/or adverse effects for the animals during your project?
All animals: Some animals may experience mild transient pain when given an injection.

Mice: No adverse effects are expected as a result of the genetic alterations however most will experience mild transient pain as a result of biopsy sampling for the genetic screening.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for all animals is mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to study fully the cellular and sub-cellular mechanisms underlying the maintenance of normal heart rhythm, or disturbances to it, without using animals.

Which non-animal alternatives did you consider for use in this project?

A number of non-animal alternatives will be used as part of the outlined studies, including:

- Cultured cell lines engineered to carry a protein of interest, often an ion channel.
- Stem cell-derived cells that have some of the characteristics of human heart muscle cells.
- Computer simulation of the electrical function of the heart that underlies normal heart rhythm (this in collaboration with specialists in biological physics and mathematics).

However, as of yet, such non-animal alternatives do not enable the fundamental questions relating to the cellular and sub-cellular mechanisms underlying heart rhythm to be addressed.

Why were they not suitable?

Cells grown in culture are of limited value in these studies as they rapidly lose the ability to spontaneously generate the electrical signals responsible for heart rhythm and also lack the anatomical and physiological criteria needed to address the fundamental questions relating to the cellular and sub- cellular mechanisms underlying heart rhythm. Data generated from these studies will contribute to the development of computer simulation models however, as of yet, these are not sufficiently advanced to address the fundamental questions that are the focus of the outlined studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animals is based on previous experience and reasonable expectation of obtaining definitive result. The experiments on this project exclusively use either excised beating hearts (ex vivo) or isolated heart muscle or heart muscle cell preparations (in vitro) and do not involve experimental intervention to the animal (such as drug treatment, recovery surgery). Thus, the project objectives are framed within what would reasonably be expected to give a clear result on an important scientific question and be achievable within the time available. The numbers of animals to be used are those required to meet these objectives. In the case of the numbers of mice to be used, this takes into account the breeding of colonies of genetically altered animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

By definition, the process of good experimental design requires the estimation of the minimum numbers of experiments necessary to achieve the study objectives. In calculating the numbers of animals required, we have drawn upon our previous experience using the in vitro and ex vivo approaches that will be used during these studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

From the previous work, we have gained much experience in the efficient management and breeding of genetically altered strains of mice. The laboratory experiments will be coordinated to ensure that the available tissues from each animal contributes to as many different aspects of the study as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals will only be used to provide tissues for studies performed after they have been killed humanely. Suffering will be kept to a minimum and will not exceed that of mild transient pain caused when given an injection or (mice from genetically altered colonies only) collecting a small biopsy sample.

Guidance on the handling of animals and use of anaesthetics are followed to ensure that the techniques used are the most refined possible.

Why can’t you use animals that are less sentient?

The structure and function of heart muscle cells from embryonic or neonatal hearts is immature and unsuitable for these studies as the ultrastructure of mature heart muscle cells plays an important role in the mechanisms underlying normal heart rhythm and in disturbances to heart rhythm. It is therefore necessary to use hearts from adult animals.

Major structural and functional differences exist between the hearts of mammals and lower vertebrates, such as frog’s or fish, including: the number of ventricles, the conduction velocity of the conducting system and the structure and function of the heart muscle cells. Consequently, it is necessary to use mammalian hearts for this project.

Rats and mice are well-established models for the study of heart function and are therefore appropriate for many of the objectives of this project. Mice are also suitable for the study of the effects of genetic alteration on heart function. However, the rabbit and the guinea pig are the more appropriate species for the study of the conduction system and for the study of abnormalities in heart rhythm arising in the ventricles.

Many of the animals used in this study will only undergo tissues harvested under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures on this licence involve no more than mild transient pain associated with an injection or (mice from genetically altered colonies only) the collection of a small biopsy sample. Suffering during these procedures will be minimised by the use of the most refined methods and good animal handling using non-aversive methods. Where animals are injected, new needles will be used on each occasion and needles will be discarded after

use (i.e. needles will be used only once). The welfare costs to the animals will be kept under regular review and any refinements that improve their wellbeing will be implemented.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Local Policy and Guidance on animal use and handling will be adhered to at all times. The injection techniques used will comply with that described in NC3Rs and LAVA guidance documents. Needles will be used only once (no re-use of needles) and non-aversive handling methods will be used.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment administration regularly circulates information, both via email and via newsletters, to PPL holders regarding activities and seminars run by the regional NC3Rs representative. In addition, we receive communication directly from NC3Rs and through the national establishment network. This information is then disseminated to members of the group, encouraging participation and with advice on implementing advances where relevant and appropriate.

20. Development of combined treatments for cancers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, oncolytic virus, immunotherapy, vaccination, drug-resistance

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project is a continuation of our past and current work with the primary aim of finding new treatments for cancer using animal models. Such studies are necessary and important for future testing in cancer patients in clinical trials. Our research is focused on cancers that that are difficult to treat and have poor outcomes such as pancreatic, lung, ovarian, breast, prostate, bladder and brain tumours. Many of these new treatments involve the use of specially modified viruses that kill only cancer cells whilst avoiding normal, healthy human tissue to minimise any unwanted side effects. These viruses will be tested in combination with other anti-tumour drugs, including those that encourage the patient’s own immune system to help further boost cancer cell killing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a major health issue causing much suffering and death worldwide. Despite recent treatment discoveries that improve patients' quality of life, most do not cure cancer. Many cancers become resistant against treatment over time and effectively overcome the initial cancer-killing effects to eventually spread to many sites in the body, at which point the disease becomes even more difficult to control. It is therefore essential to investigate and develop new therapies that tackle these problems.

These will include specifically modified viruses that kill only cancer cells whilst also activating the patient's own defence (immune) system, enabling it to recognise cancer tissue as "foreign material" and destroy it. To identify better treatments, it is necessary to perform animal testing to ensure that the drugs are both safe and effective before evaluation in humans. This project will help us find and develop new ways to prevent and treat cancers, decreasing the suffering in patients.

What outputs do you think you will see at the end of this project?

Short-term: Understanding the mechanisms of action of our novel treatments. We will use our previously developed mouse models of human cancer to determine how our new treatments act on both the mouse and the cancer tissue. These models include mice with and without a functional immune system and mice that have been genetically modified to develop pancreatic tumours. The models are well established and used by research teams world-wide. These models have enabled us to refine treatment schedules and doses of our newly developed cancer-specific viruses. In this project we will use state-of the-art techniques to investigate the role of the cancer-tissue microenvironment (other cells and factors supporting the cancer cells) and the immune system and, how on a molecular level our new treatments can inhibit the growth of cancer tissue. We will also identify biomarkers for both tumour growth and inhibition by our treatments for future clinical applications.

Medium-term: Development of new improved combination-treatments for human cancer. The major goal of our research is to develop novel therapies for cancer, based on a greater understanding of the molecular biology of the disease. The absolute pre-requisite for developing a successful treatment is that it will have anti-tumour activity and safety in live animals (mice). We are continuing our work on understanding how our new biological treatments (viruses) for cancer can improve the effects of currently used cancer drugs. Our findings from the previous project demonstrate that combining our viruses with chemotherapy and/or immune therapies results in greater efficacy than either treatment alone. However, we still need to investigate and determine the optimum combinations, the dosing schedules and the mechanisms underlying the improved effects to create robust therapies with clinical potential. During the past 5 years we have made excellent progress in identifying specific modifications of the viruses and the specific immune-factors that are essential for killing cancer tissues. In this project we will continue to explore the underlying mechanisms to enable future applications in patients.

Long-term: Understanding of the role of the immune system in the activity of our new anti-cancer treatments and long-term protection (vaccine development). In the previous project we demonstrated that oncolytic viruses induce long-term cancer-specific immunity, which is critical for the overall efficacy of the treatment. In this project we aim to gain a good understanding of the factors that are essential for immunological memory to also protect patients from regrowth of cancers after treatment. For example, we will continue to assess the potential of using antigens (whole cancer cells, protein, peptide, DNA or RNA), viruses or immune cells both as treatments for established cancer and for protection for future cancer growth (development of vaccines). Our research is aimed at directing an immune attack on cancer-specific proteins by exploring large scale patient data bases (existing knowledge of cancer specific proteins) for a number of cancers. This will enable us to further optimise our virus-based treatments.

Towards year 3-5 of this work we anticipate to have several publications in press to share our findings with both the scientific and medical communities as well as patient organisations including our Patient and Public Involvement Advisory Group (PPI) at our Institute.

Who or what will benefit from these outputs, and how?

The findings from our studies will guide future research to better target cancers. We intend to publish our findings in professional journals and present all results in seminars for access by other researchers, medical professionals and patient groups, continuously during the 5-year project. We are funded by charities for pancreatic and prostate cancers that both have interactive patient organisations that visit and review our progress. Our Institute also has an active Patient and Public Involvement Advisory Group (PPI) that meets to discuss projects and proposals.

The major benefits of this project are that our findings have the potential to be directly translated into clinical trials for our novel treatments in patients with a wide range of cancers (at the end of the 5-year project).

How will you look to maximise the outputs of this work?

We have ongoing collaborations with both national and international teams focused on cancer research and oncolytic viruses. Through these collaborations we share data including problems, unsuccessful approaches and the development of better in vivo models.

We frequently attend professional meetings to keep up to date and discuss our findings, and we present our work in seminars to other researchers including medical professionals and scientists. We will keep non-experts informed of major findings through online publications and presentations and in meetings with our Charity funders.

Species and numbers of animals expected to be used

- Mice: 6500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice with either normal or defective immune system that are supplied by authorised breeders. Animals with defective immune system will be used for growth of human cancer tissue or cancer cell lines to determine both efficacy and mechanisms of action of our novel therapies. These animals have been established by genetic alterations and do not have harmful clinical effects. The immunocompetent (normal) animals will be used when determining interactions of our novel therapies with the host immune system and whether long-term anti-cancer protection (vaccination) can be achieved. In some studies, we will also use animals that have been genetically modified to develop cancers spontaneously, similar to cancer in patients, such as mice predisposed to pancreatic or prostate cancer. All strains that we use are well established and produce animals without clinical effects. Our studies will only include young adult mice, from 5 weeks of age at the start and most studies ending at 4 months of age. In the long-term protection (vaccination) studies healthy animals may be kept up to 15 months for evaluation without further treatments.

Typically, what will be done to an animal used in your project?

Animals not predisposed to spontaneous tumour development will be inoculated with human cancer tissue, or human and mouse cancer cell lines to establish cancer growth either under the skin or in the relevant organ (for example, the pancreas) or body cavity (for example, peritoneum, bladder). Tumour bearing animals will be treated with anti-cancer agents by direct injection into the tumour or through delivery via oral administration or the blood stream or into the peritoneum. The anti-cancer treatments include our new oncolytic viruses alone or in combination with conventional anticancer drugs (for example, chemodrugs) or immunotherapies (for example, antibodies, cytokines and immune cells). The efficacy and body distribution of our new therapies are evaluated by tumour measurements and imaging of live animals at different time points. These studies are short and will be completed within 1-4 months after the first treatment. We will use imaging whenever possible to monitor treatment success which will reduce the number of animals in each study. During the 5-year period for the project we anticipate the use of less than 6500 mice spread over six protocols.

Some studies require surgical procedures such as injection of cancer cells directly into an organ (for example, the pancreas). For these studies animals will be anesthetised prior to and during surgery and treated with pain relief medication post-surgery. Aseptic

techniques are routinely used at our center and we use approved anaesthetics and pain medication after discussions with our Named Veterinary Surgeon (NVS).

Each animal will be inoculated with cancer cells or tissue once or twice and treatments will not exceed 21 doses in the lifespan of the animal.

What are the expected impacts and/or adverse effects for the animals during your project?

From our past experience we predict that the planned studies will cause only mild or moderate discomfort. In the majority of studies, the animals return to normal activity within minutes after treatments such as cell injections or drug administration. When animals have been subjected to surgery the recovery time is usually longer (2-3h after administration of anaesthesia and pain medication). We are and will be monitoring treated animals daily and do not expect any severe side effects. However, if an animal appears to suffer for example, by loss of weight, not eating or drinking, shivering, not grooming, is lethargic, has a hunched posture or display any other abnormal signs, it will be humanely killed using regulated procedures. At the end of each study when all results have been collected, all animals will be killed by humane and regulated procedures and their tissues used for analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In our two breeding protocol (up to 2000 animals) we do not expect any clinical effects and from experience these protocols are therefore of mild to moderate severity with the majority of animals experiencing sub-threshold severity in the mild protocol, and the majority of animals experiencing mild severity in the moderate protocol.

All other protocols (up to 5000 animals) have either mild or moderate severity. We do not expect any severe effects in our protocols.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

All the new anti-cancer therapies that we plan to investigate in this project have been, or will have been, extensively tested in the laboratory before we test them in live animals. Our laboratory experiments will identify therapies that are most likely to be successful in patients and will supply us with invaluable information. However, laboratory-based models cannot predict how the new therapies distribute within an organism or how they affect a living animal for example, liver uptake, accumulation in normal tissues rather than tumours and activation of the immune system. These aspects can only be assessed in realistic models of cancer in whole animals.

Which non-animal alternatives did you consider for use in this project?

In order to minimise animal usage, we are utilising highly sophisticated in vitro models, including 3- dimensional organoid cultures, 3-dimensional tumour-stromal cell co-cultures (in contrast to routine growth of cells on plastic in 2-dimensions), culture of primary tumour cells from patients and whole tumour ex vivo cultures, and will continue to do so throughout the lifetime of this project licence. We are also integrating our laboratory research with the extensive bioinformatics platforms available at the Barts Cancer Institute that enables us to refine treatments further before in vivo analysis begins. Only new therapies that demonstrate repeated efficacy in the laboratory using these and other models will be further examined in live animals. We have already minimised the number of animals that will be needed by developing these non-animal models and will continue to improve on ex vivo/laboratory models in parallel with this project.

Why were they not suitable?

Although these laboratory-based techniques are the most sophisticated mimics of the tumour and tumour microenvironment that are available, they fail to model critical aspects of the biology of novel anti-cancer agents. These include bio-distribution, pharmacokinetics, pharmacodynamics and interactions with liver, spleen, kidneys and immune systems. These aspects can only be assessed in realistic models of cancer in whole animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on our previous and ongoing studies. We have extensive experience of studying oncolytic viruses in murine models and over 20 years of collected data on suitable models and number of animals per group to generate reliable data. The studies in this project will utilise these models while advancing our work to improve on both

models and therapies. The work is now at a stage where we will need to focus on the interactions of our novel therapies with the tumour microenvironment and the host immune system. These studies require testing in several immunocompetent mice models (mice with active immune system) necessitating the breeding of transgenic animals (genetically modified mice; estimated to 1500) and immune studies (estimated to 4000). The remaining 1000 animals will be sufficient for testing efficacy and bio-distribution of various combination therapies (including novel therapies and conventional therapies). However, these are the maximum estimated number of animals and in each study an exact calculation will determine the numbers to achieve statistical significance. Whenever possible we use data obtained from previously control-treated animals, for example, when a same agent is tested under the same condition and in the same mouse species, this allows for fewer animals in each study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All studies are reviewed by me as Project Licence holder, including statistical assumptions and calculations. We routinely use data from our past studies to estimate the minimum number of animals required to address the stated primary endpoint of the experiment without having to repeat entire studies. We also refer to other available tools such as the Experimental Design Assistant available from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the 'resource equation' based on the law of diminished return and for larger studies the online power calculation tools. By undertaking studies with adequate statistical power, definitive positive or negative data can be generated from a single experiment, thus avoiding repeated small under-powered experiments that may be futile and wasteful. Whenever possible we use data from control treated animals for example, when the same agent is tested under the same condition and in the same mouse species.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The studies will only include agents that have been pre-selected as potential new therapies using our sophisticated in vitro and ex vivo models of cancer as detailed in the replacement section.

We have incorporated in vivo imaging where possible in the majority of our protocols to enable smaller cohorts of animals to be observed prospectively throughout an experiment rather than relying on killing of separate groups of animals at each time point. This is especially true in models of ovarian and pancreatic cancer, where estimation of tumour burden in the peritoneal cavity was essentially impossible in live animals before bioluminescence and Magnetic Resonance Imaging (MRI). Our imaging team has acquired a small animal MRI unit that we are and will use to determine internal tumour growth. We have developed advanced procedures to image bio-distribution of our new therapies by small animal SPECT/CT that significantly limits the number of mice that are

needed for these studies. The use of imaging in our protocols will avoid the waste of entire cohorts of animals.

By first exploring conditions in small pilot experiments the final conditions can be optimised and also reduce the number of animals subjected to unexpected side-effects. When possible, the data from the same groups of control animals (untreated or mock-treated) will be used in several studies to minimise the number of animals. Tissue is and will be harvested from each study for laboratory investigation to collect all available information from each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All experiments will be performed in mice. This is the species on which the greatest amount of information is available. They can be easily genetically manipulated and a vast array of experimental tools (for example, tumour cell lines, antibodies, and genetically altered animals) is available. The models we use in the majority of protocols include growth of cancer cells under the skin of the animal which is minimally invasive and cause limited suffering and distress. When tumours form they are easily visible and can be injected directly with the therapeutics causing only mild to moderate distress. However, we will also use models that better represent human tumour growth. The most simple of these involve injection of tumour cells into the peritoneal cavity; the disseminated growth within the cavity provides an accurate model of human ovarian cancer, with multiple peritoneal and serosal deposits, with formation of ascites. We have also developed orthotopic tumour models, where cells are injected directly into the relevant organ, for example the pancreas. The tumours that develop accurately recreate the complex tumour-stromal interactions seen in the human disease. Although these models require more invasive procedures, the animals recover very rapidly (within hours) and administration of pain relief medication reduces pain and limits distress. Furthermore, results from orthotopic tumour models or genetically altered animals with spontaneous tumour formation will generate more relevant information that in the long-term will reduce both the number of studies and suffering of the animals.

All our studies are classified as mild to moderate.

Why can’t you use animals that are less sentient?

These models are the most realistic available and reflect the most up-to-date information about human cancer biology. More immature life forms are not suitable due to the great differences between humans and for example worms, flies, and fish, and the lack of relevant circulatory and immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In the course of the current project we have significantly refined our procedures with the help of our dedicated Veterinarian, the facility managers and the animal technicians. Further education of animal license holders is an ongoing process with a minimum of one refresher seminar yearly. We now have reinforced daily monitoring of each animal by the responsible person(s) in ongoing studies observing weight and health and making sure that the animals will get used to handling. Surgical procedures and postoperative care including pain management is always discussed with the veterinarian if the study has not previously been performed. We have also moved away from each individual performing advanced procedures such as surgery and have instead dedicated well-trained technical personnel for these procedures. This has greatly reduced the number of animals in each study by decreasing surgical failure and also improved on the generation of reproducible data. Another refinement is the continued and increased use of imaging in our studies that is also performed by dedicated personnel to minimise failure. Using imaging enables us to follow each animal over longer periods of time rather than harvesting tissues from numerous animals at several time points. The use of imaging together with endpoint analysis of tissue enables us to maximise the information obtained from each animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All recent advances and practices on NC3Rs website; https://nc3rs.org.uk The ARRIVE guidelines; https://arriveguidelines.org/resources

The Home Office regulations (online material)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My team is on mailing lists from the 'National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs)' and are regularly informed of seminars and workshops that train users in new techniques, and inform on regulations. Our animal facility managers and our dedicated Veterinarian Surgeon regularly update us on new applications and regulations. All researchers that perform animal studies have a personal licence, are continuously trained and supervised until they have demonstrated the requisite competency and are required to attend yearly update seminars delivered by the veterinarian and our skilled animal technician team. I am, together with my senior managers, attending yearly update courses and refresher modules focused on animal welfare in research and improvement of study design. We discuss the new developments with the veterinarian, animal technicians and relevant personnel to explore if and how we can implement new advances.

21. Control of blood flow and cell function in the brain and other organs, in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Capillary pericyte, Dementia, Stroke, COVID-19, Diabetes

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged
Rats	adult, aged, juvenile, neonate
Hamsters (Syrian) (Mesocricetus auratus)	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how blood flow in the brain and other organs is controlled by different cell types, how blood flow control and tissue cell function goes wrong in disease, and to develop therapeutic approaches to correcting these defects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is increasing evidence that defects of blood flow control contribute to a wide range of disorders. Heart attack and stroke are major diseases where blood stops being provided to the relevant organ. In addition there is increasing evidence that defects of blood flow control contribute significantly to dementia (such as in Alzheimer's disease) and to diseases of peripheral tissue such as the kidneys.
Furthermore brain blood flow falls in patients with COVID-19 and this may contribute to the neurological problems associated with this disease. All of these diseases have massive socio-economic consequences.

What outputs do you think you will see at the end of this project?

We will obtain new information on a range of mechanisms regulating blood flow in the brain and other organs, how this affects the functions of the cells in those tissues, and in particular how this contributes to causing dementia. This information will be made generally available to other scientists in the form of peer-reviewed publications.

Several of our experiments explicitly address potential therapies to reduce the occurrence of dementia, stroke, COVID-19 and diabetes. Depending on how successful these strategies are, it may be possible to develop drug approaches to treating or preventing some of the deleterious effects of these conditions on the brain and other organs.

Who or what will benefit from these outputs, and how?

In the short-term (2-4 years) we anticipate our research feeding into the research of other scientists in order to gain a better understanding of mechanisms regulating blood flow in the brain and other organs, and a better understanding of the causes of dementia. In the medium-term our research should lead to

pre-clinical trials of therapeutic approaches to reduce dementia and other disorders (4-5 years). In the long-term (>5 years) we hope that the research will have led to successful therapies in the clinic.

How will you look to maximise the outputs of this work?

We aim to publish all the results of our research, including negative results if they are important. We disseminate our work as preprints, as published papers, as talks to scientists and interested members of the lay public, on social media and in advice given to bodies such as the Medical Research Council and Wellcome Trust.

Species and numbers of animals expected to be used

- Mice: 6000
- Rats: 3250
- Hamsters (Syrian) (Mesocricetus auratus): 585

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.
Types of animal

Mice are selected because they allow the use of transgenic methods to mimic disease, to identify certain cell types with fluorescent labels, and to manipulate cell function by changing the expression level or function of proteins.

Rats are used when a larger animal facilitates some experiments, typically involving cannulation or occlusion of blood vessels or laser Doppler measurements or some imaging experiments.

Hamsters are used because, unlike rats and mice, they are suitable for experiments investigating the effects of the virus causing COVID-19, owing to the sequence of their ACE2 (an enzyme expressed in pericytes which is the receptor for COVID-19) being much more similar to the human ACE2 sequence than are the rat and mouse ACE2 sequences.

Choice of life stage

Young animals (in the first 4 weeks of life) may be used because developmental processes are occurring then that we may wish to investigate, such as the formation of synapses between neurons. They also offer technical advantages in terms of the optical clarity of the tissue for imaging, and ease of electrical recording. Adult and aged animals will be used in order to investigate diseases of adulthood, particularly those leading to dementia in old age.

Typically, what will be done to an animal used in your project?

Some transgenic animals (i.e. mice with cells labelled with a fluorescent dye for identification purposes, or with protein level altered to investigate its function) will be bred (including clipping their ears for identification purposes) and then will be humanely killed, in order to study their tissues.

Some animals (which may also be transgenic mice) will be bred, and may have dyes injected to label the blood or cell types or drugs injected to try to prevent diseases developing, and will then be anaesthetised and their brain or other organ will be imaged (e.g. through a thinned skull or a hole in the skull) while under anaesthesia (and they will finally be put to sleep while anaesthetised).

A much smaller proportion of animals will be repeatedly studied - using tests of memory and/or by imaging the brain through a thinning of the skull (or a hole in the skull that is permanently covered with a glass window) - as a pathological condition like Alzheimer's disease develops, and drugs will be used to try to prevent the decrease of brain blood flow and changes in nerve cell properties that occur in this disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Many of the procedures that we will use have no significant effect on the animals' lives. This includes routine breeding of animals, and rearing them to an old age; administering harmless dyes or protective drugs to the animal; and assessing cognitive function.

Some animals will have a window implanted into their skulls or will have their skull thinned for imaging, or else will have viruses injected into their brains to change the manufacture of proteins in cells. This is unlikely itself to significantly affect the animal, but a small proportion of animals may suffer ill effects for a few days on recovering from the surgery involved, such as having infection of the wound which will be treated with antibiotics (and in extreme cases if necessary the animal will be humanely killed).

Some animals will be mice that are genetically manipulated to produce a condition that mimics diabetes or Alzheimer's disease, and they will gradually experience, for diabetes, modifications of control of body sugar and an increase in urination, and for Alzheimer's disease, a decrease of their mental abilities - one of the aims of the project is to find ways to prevent this happening.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice

- Mild 85%,
- Moderate 15%

Rats

- Non-recovery 25%,
- Mild 64%,
- Moderate 11%

Hamsters

- Non-recovery 28%,
- Mild 54%,
- Moderate 18%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For the great majority of experiments, when studying blood flow, or interactions between neurons, glia and the blood vessels, it is essential to use tissue in which all the cell types have their normal spatial relationship. Consequently cultured cells cannot be used. For

example it is not possible to grow cultured blood vessels connected to an operating heart that functions as in the real body.

Which non-animal alternatives did you consider for use in this project?

Our main approach to non-animal alternatives is to try to use live human tissue when possible. We obtain such tissue from surgical operations (e.g. on brain tumours) in which some tissue needs to be removed to access an area of interest (e.g. a tumour or epileptic focus). This overlying tissue would normally be discarded, and we are able to use it for experiments (ethical permission is in place for this).

As an alternative non-animal approach we routinely employ mathematical modelling of cell interactions, which we have made freely available to the scientific community on the worldwide web.

Why were they not suitable?

The main difficulty of the human tissue approach is that the tissue is only available in very limited quantities, and furthermore the source of the tissue does not have the same consistency of properties as animal tissue does (due, e.g. to age variations or prior drug treatment). Nevertheless, significant results can be obtained with this approach, and we will continue to expand this approach in our work.

Mathematical modelling can provide useful insight into complex problems, but in general cannot replace actual experiments on biological tissue if it is necessary to learn new facts about how individual signalling pathways operate. Thus, mathematical modelling is inherently limited in scope.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

By estimating:

(3) the number of separate experiments we need to perform (including for exploratory investigation of a scientific area, for pilot experiments to establish effect size, and for experiments testing specific hypotheses),

(2) the number of animals needed per experiment (given hypothesised effect sizes), and

(3) the number of animals we need to breed to produce these animals (e.g. by crossing different types of transgenic mice),

and then subtracting animals that we can avoid using by having different investigators share tissue from the same animal.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The major step is to take into account the sharing of tissue from a given animal between different researchers. This can reduce the number of animals needed for some experiments by a factor of 2 typically. However, it is often not applicable for experiments imaging animals in vivo because having different researchers work on the same anaesthetised animal would prolong the experiment excessively.

In addition, the use of transgenic mice significantly decreases the number of animals needed, because it allows the labelling of specific cell types. This avoids the need to record from cells before knowing their identity and only identify them later using immunohistochemistry, which itself is often unreliable. It thus avoids the need to redo experiments when the cells turned out to be different from what was believed at the time.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

There is a strong culture of reducing animal use in my laboratory.

The major animal reduction measure is the sharing of tissue from a given animal between different researchers. This can reduce the number of animals needed for some experiments by a factor of 2 or 3. However, it is often not applicable for experiments imaging animals in vivo because having different researchers work on the same anaesthetised animal would prolong the experiment excessively.

We also try to monitor closely our breeding colonies of transgenic animals, in order to keep to an absolute minimum the number bred.

We also carry out some experiments on live human tissue when it is available from surgical operations, and perform some ‘experiments’ by computer modelling.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodent models that allow us to image blood flow in the brain and other organs, to investigate how defects in blood flow control lead to malfunction of the brain and other organs. The methods used include making tissue slices from tissue taken from dead

animals, imaging of the brain and other organs in anaesthetised animals, manipulating cell function using genetic or drug methods, and assessing brain function using memory tests.

The memory test used, the Barnes maze, offers advantages over the commonly used Morris water maze in that it does not involve swimming and the potential confounding factors associated with it.

In order to study processes that lead to pathology in diseases of great social and economic impact - such as Alzheimer's disease and stroke - it is impossible to avoid creating some suffering in the animals used, but we strive to keep this to a minimum by using humane killing and general anaesthesia. Thus, many of our invasive experiments are carried out on animals that are terminally anaesthetised or have already been humanely killed to obtain their tissue. At the end of each experiment, or set of experiments, on an animal it is humanely killed.

Why can't you use animals that are less sentient?

Mice, rats and hamsters will be used for this project as they represent the least sentient species appropriate for this type of work.

In addition, decades of research have resulted in highly advanced and efficient techniques developed for rodents as opposed to other species. This includes excellent stereotaxic maps of the mouse brain, allowing accurate targeting of injections to specific brain regions, and the mouse is also high genetically tractable, allowing transgenic identification of specific cell types crucial to the fulfilment of the project .

Many of our invasive experiments are carried out on animals that are terminally anaesthetised or have already been humanely killed to obtain their tissue.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Appropriate anaesthetic/analgesic regimens will be used to minimise pain. e.g. delivery of pre- operative analgesia, as discussed with the NVS and Animal Facility Staff.

Maximum injection / infusion parameters will be strictly adhered to. In the very unlikely case that this is not possible due to extenuating circumstances, any changes will be discussed with the NVS.

Housing cages will be spacious and enriched with e.g. rodent toys, chewable materials such as wood, running wheels, and shelter, unless these interfere with the experimental design. In addition, where possible animals will be group housed post surgery using strategies devised in collaboration with our local NVS and NACWO.

Our behavioural tests will not use food or water deprivation.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Information from the local NVS and NACWO Resources hosted on the NC3Rs website, in particular:

- ARRIVE guidelines on experimental design and reporting results.

- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.
- Rodent housing and husbandry.
- Rat and Mouse Grimace scales.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep in constant contact with the local NVS and NACWO to ensure we are maintaining best practice.

We will liaise with the in-house NC3Rs representative to ensure we are up to date with current best practice.

We will use the resources published on the NC3Rs website to ensure that the group undergoes continuous training and professional development with respect to the 3Rs.

We will follow technological advances in the published scientific literature, allowing more efficient recording and imaging techniques (yielding more data per animal), miniaturising equipment (leading to a refined animal experience) or allowing recording or imaging in more naturalistic settings (for example, via wireless data transmission).

22. Assessment of biological response to novel ocular drug delivery formulations and devices

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Eyes, Drug delivery, Nanomedicine

Animal types	Life stages
Rabbits	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to assess the biological response to novel ocular drug delivery formulations and devices for the treatment of sight-threatening eye diseases. It will assess whether these implanted formulations and devices cause any undesirable response in the eye. It will also assess whether they are able to deliver drugs to the appropriate tissues in the eye at a controlled, predictable concentration at doses that are likely to be clinically effective and over sufficiently long periods of time.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Delivery of drugs by injection direction into the eye is currently the most effective route for treatment for several common, sight-threatening eye diseases, including diabetic retinopathy and age-related macular degeneration. Hundreds of thousands of these injections are done every year in the UK, and patients have them for many years, so numbers are increasing. This creates a significant financial burden to the NHS and impacts negatively on patients, who have to attend clinic appointments and endure an uncomfortable procedure on a regular basis. There are certain patient groups for whom this is even more challenging, particularly the elderly, those in rural areas and those with dementia. In low/middle income countries, where there has been a rapid rise in the prevalence of diabetes, repeated injection is not achievable. Intravitreal injections also have a risk of sight-threatening complications.

The development of drug delivery technology that can reduce the number of injections would have significant clinical, societal and economic benefit. We have drug delivery systems that show promising results in benchtop studies, and now wish to see if these perform safely and can deliver drugs appropriately inside a living eye.

What outputs do you think you will see at the end of this project?

For our silicone oil technology, we will conduct studies to demonstrate that the oils are biocompatible. The outputs will be used by our group and the medical device industry, particularly our collaborators, to develop silicone oil-based medical devices that can deliver drugs. They will also be used to produce scientific publications and inform future research projects.

For the nanomedicine and hydrogel formulations, we will generate data on the biocompatibility and, in some cases, intravitreal release behaviour of various formulations. We will also gain insight into whether the drugs leave the eye and enter the rest of the body; this is an area in which knowledge is lacking. It is likely that these data will be used as part of the case for supporting protection of Intellectual Property.

Who or what will benefit from these outputs, and how?

The outputs from silicone oil studies will be used by our group and the medical device industry to develop silicone oil-based medical devices that can deliver drugs. These will be used as they become available. They will further add to the academic group's position as world-leading in the development of novel tamponades. Subsequent clinical trials would likely be carried out with local clinical partners, providing benefit to the reputation of that establishment, but also to its patients, who would have the opportunity to be the first to receive new treatments.

The outputs from nanomedicine and hydrogel studies will help clarify whether these new technologies are suitable in this application. They will help us to screen out certain formulations and accelerate development of those with the most potential to be developed

into a clinical product. We will also use pharmacokinetic data in development of our in silico models, in order to accelerate development of future formulations, and to reduce animals required for their testing by screening out unsuitable formulations. The outputs will, therefore, be used immediately. Our team includes academic clinicians, who will generate and understand data that will allow them engage directly with patients' concerns over nanomedicines.

New technologies for ocular drug delivery will benefit patients by providing a means of long-acting release formulations that can reduce patient discomfort and inconvenience and bring treatments to new patient groups. At the same time, healthcare systems will gain a cost-effective means of delivering treatment and improving clinical outcomes. Drug delivery systems could also be useful in veterinary applications, as diabetic retinopathy and uveitis are significant causes of sight loss and frequent intravitreal injection causes distress. These benefits are likely to be realised in ten-fifteen years.

How will you look to maximise the outputs of this work?

The UK is already a leader in both nanomedicine and ophthalmic biomaterials and, through publication of the data generated within this project, it is anticipated that we can strengthen this position and develop collaborations with national and international research groups. Protection of intellectual property will be sought where appropriate, to increase the chance of commercial development of the technology and, thus, the likelihood of it reaching patients. Dissemination of materials, techniques and skills will occur as appropriate. The demonstration of proof-of-concept of safe and effective drug delivery platforms could lead to collaboration with other partners with biological assets, potentially current clinical drugs where reduced frequency of intravitreal injection could improve clinical burden and patient welfare

Part of the existing funding for this project comes via a scheme specifically designed to progress technology towards generating clinical impact. As a consequence, there are detailed plans to maximise outputs. Existing collaborations with both a clinical partner and two industrial partners, built in to the funding, will be used to maximise the outputs. One industrial partner has a track record of commercialising silicone oil technologies developed in universities, and this partnership provides a proven route towards achieving healthcare and commercial impacts from the technology. Their close involvement with the formulations/device design will also help de-risk the next stage of investment. The clinical partner will have the opportunity to input into the project, which will lead to more rapid development of effective treatments for his patients and, if the technology progresses to clinical studies, increase institutional prestige. The clinical partner will also facilitate patient involvement will benefit the project team, and connect patients to research. Interaction with patient groups will increase patient knowledge of advances in treatment, and may encourage their engagement in their own treatment and inspire lobbying for the funding of eye research.

Species and numbers of animals expected to be used

- Rats: 60
- Rabbits: 120

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Pilot studies for nanomedicine and some hydrogel formulations will initially be conducted using adult rats. The use of rodents for these studies is well-established in toxicology, and will allow us to follow guidelines for best practice in design and conduct of the studies, and to take advantage of publishes data to use the smallest number of animals possible.

Studies of how the drugs move in the eye will be conducted in adult rabbits. It is well-established that rabbit is clinically predictable animal model for how drugs move in the human vitreous

Vitreous replacement studies will be conducted using healthy adult rabbits. There is no disease model that can be used. Rabbits are considered an appropriate laboratory model for assessment of how well these devices will be tolerated, as their eyeballs, although smaller than humans, and with a relatively large volume being taken up by the lens, are large enough for performing the required surgery without a high complication rate. A healthy, adult rabbit model has been chosen because it is the lowest species with eyes of appropriate size and structure. This will allow implantation using surgical techniques to be applied that are directly transferable to human eyes. These techniques are well-established, and have a low complication rate.

Typically, what will be done to an animal used in your project?

This project will involve implanting, under anaesthesia, and usually by injection, devices and drug formulations into the eye. These will be left in the eye for up to 12 weeks. The eyes will be studied regularly throughout the experimental period using non-invasive imaging and measurement techniques that will allow assessment of the response to the implanted device/formulation, as well as to assess welfare. Standard welfare checks to assess the general health of the animals will be performed throughout. In some experiments, an invasive imaging technique will be used to assess the function of the retina, which will help with the assessment the response to the implanted devices and formulations. For this, animals will be anaesthetised and have small electrodes placed on the eye and head, which will record the response of the eye to flashes of light.

What are the expected impacts and/or adverse effects for the animals during your project?

Experiment	Animal	Likelihood	Impact/ adverse effects	Duration

All	Rat, rabbit	Low	Post-operative infection Animal showing swelling, redness or discharge at the operation site or reluctance to move, vocalisation when handled or posture suggestive of pain.	The animal will be killed if no improvement is seen in the first 24hrs of treatment or if its condition deteriorates before then.
All	Rat, rabbit	High	Short periods of restraint There may be initial agitation, but the methods of restraint are standard to the handling of rabbits and are well-tolerated by the animal	The periods of restraint will be relatively brief (about 10 minutes maximum)
All	Rat, rabbit	High	Vision loss Surgical implantation of the experimental devices and formulations will have an immediate effect on the animals. It is invasive surgery that will result in some vision loss in one eye. Devices and formulations that cause an adverse tissue response may result in increasing loss in vision that may be permanent.	The vision loss may persist for the duration of the experiment (up to 12 weeks)
Drug loaded	Rat, rabbit	Low	Systemic toxicity due to transport of drugs outside of the eye.	The animal will be killed if signs of systemic toxicity formation are observed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that all rats and rabbits will experience moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals to assess the biological response of our devices and drug formulations in the target organ. In particular, we will be assessing safety and drug release from our devices over several weeks. Prior to the commencement of any animal studies, we will use a range of non-animal techniques to assess our formulations and devices. In order to assess the biological response fully, and meet our scientific aims, we need to study how our formulations and devices behave in a complete, living eye, and see how that eye responds to our formulations and devices.

Which non-animal alternatives did you consider for use in this project?

We have already established a range of in silico (computer), in vitro (benchtop) and ex vivo (tissue from dead animals) models that will be utilised during this project to optimise formulations and precise delivery method (e.g. length and gauge of syringe) prior to animal work. This includes protocols for studying release of drug from silicone oil in ex vivo porcine eyes obtained from abattoirs. We have also developed in vitro and in silico models that model drug release from silicone oil and the transport of model compounds across permeable barriers in a flow environment to mimic the outer blood-retinal barrier (a key part of the tissue in the eye that affects how much drug stays in the eye). We have established an ex vivo model for testing aggregation of nanomedicine formulations in porcine vitreous pig eyes and the release of model drugs from these aggregates into the vitreous part of the eye. This is important as it is known that nanomedicines move differently in vitreous than standard drug formulations.

Why were they not suitable?

There are limitations to the in silico, in vitro and ex vivo models we will use in earlier parts of the project. In particular, they suffer from the inability to: -simulate tissue sub-compartments to see how the different of the eye responds faithfully simulate human biology and the processes that are involved in the absorption, distribution, metabolism and excretion of drugs faithfully simulate the in vivo immune response. Available models do not include all the cell types or immune molecules that may have an important impact on the response relationships.

As a consequence, the scientific aims may only be fully met by utilising in vivo models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experimental and statistical design has been conducted following consultation with biostatisticians, and will we consult further with them as required, and as pilot data becomes available. We have used published data from similar studies where possible to help inform our estimations. These have given us an idea of what size of effect we might expect to see from our formulations, as well as the complication rate. Where there is not enough data available, we will conduct a pilot study to produce data to allow us to make better estimations on the number of animals required for a main study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs Experimental Design Assistant (EDA) has been used to plan workflow and will be further utilised once data from preliminary in vitro, ex vivo and pilot studies are available. We will alter the length of studies if later time points do not provide any additional information. This will reduce the number of animals that are required. The use of non-invasive ophthalmic imaging means that the number of animals required overall is reduced, as multiple measurements can be collected from a single animal throughout the study. Furthermore, each animal has an experimental and a control eye, meaning that the number of animals required for controls will be reduced.

Prior to starting work with live animals, we will conduct a series of in vitro studies to screen out unsuitable formulations. These studies will include tests suggested in ISO 10993-5 (Biological evaluation of medical devices — Part 5: Tests for in vitro cytotoxicity) and ISO 16672 (Ophthalmic implants — Ocular endotamponades), which are relevant to the devices and formulations we are designing.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A likely source of variability is differences in surgical procedure. We will use ex vivo tissue, including tissue from abattoirs and from the establishment tissue bank, in order to optimise and standardise surgical technique prior to using live animals. We follow, as closely as possible, techniques that are well-established in human clinical practice.

Where insufficient data is available, particularly for novel formulations, we will use in vitro methods to attempt to define exposure-response relationships, then conduct pilot studies to generate data to allow us to design subsequent, main studies optimally.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use adult rats and rabbits during this project. Rats will be used for preliminary dose studies for novel formulations. Rabbits will be used for the majority of studies. The size of the rabbit eye makes it amenable to the application of specialist surgical tools and techniques used in human ocular surgery, which should minimise the complication rate and increase the chance of the scientific aims of the project being met. It is possible that surgery may result in post-operative infection or significant tissue inflammation; in these cases, animals will be killed for welfare reasons. Small gauge instrumentation will be used where possible, in order to reduce pain and minimise the chance of post-operative infection

The process of implantation may cause partial or complete sight loss in the operated eye. A key part of our study is assessment of tissue response to the implanted device, so keeping the animals with this inevitable sight loss is required. To reduce animal distress, only one eye will be operated on, leaving sight in the remaining eye.

Why can't you use animals that are less sentient?

Less sentient species, such as rodents, have eyes that are too small for accurate surgical implantation of silicone oil tamponades. Furthermore, the highly-specialised surgical instrumentation required cannot be used in small eyes.

For nanomedicine and some hydrogel studies, we will use adult rats for pilot studies. Smaller rodents, such as mice, have eyes that are too small for such studies. Use of rats will help us screen out formulations in pilot studies. Published data on dose scaling between rats and rabbits are available. For longer term studies, rabbits will be used for technical reasons (it is difficult to isolate rat vitreous) and scientific reasons (rodents have been shown to have low predictive value for certain classes of drug, and their eye is too small for a translatable tolerability study, and published data demonstrating that rabbits are a clinically predictable animal model for intravitreal pharmacokinetics for a range of different drugs).

We need to assess the response to our novel formulations over several weeks, so we cannot use animals that have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use our effective, established protocols (developed in our current work, which involves similar surgical procedures to those that are required in this project) to minimise welfare costs for the animals. These protocols include pre-, peri- and post-operative screening for general and ophthalmic health, and an effective pain relief procedure. One advantage of the eye is that it is possible to see inside it; we will use real-time imaging of

operated eyes in order to identify problems with the eye that would mean that the scientific objectives of the experiment could not be met, and humanely kill animals if this is the case.

Animals will be closely monitored throughout all the studies and pain relief will be given to animals showing any signs of pain and/or distress. We will seek advice from the Named Veterinary Surgeon (NVS) and Named Animal Care & Welfare Officer (NACWO) where appropriate. Any animals whose symptoms cannot be relieved will be humanely killed using a Schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use NC3Rs best practice guidance where applicable. In particular, we will use:

- the rat and rabbit grimace scales to detect the presence or absence of signs of pain or discomfort.
- LASA/NC3Rs Guidance on dose level selection for regulatory general toxicology studies for pharmaceuticals (for guidance - although our studies are not for regulatory purposes, many of the best practice elements will be the same)
- LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery
- LASA Good Practice Guidelines - Collection of Blood Samples

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My team and I will continue to attend local and online NC3Rs events and in-house training to learn about 3Rs best practice and innovations. This also facilitates access to the NC3Rs Regional Programme Manager. I will also maintain my subscription to the NC3Rs e-newsletter and Tox News. We will also continue to attend specialist ophthalmic research conferences, in order to stay informed about field-specific advances (e.g. imaging techniques) that could have 3Rs benefits for this project. We will discuss these advances with the local facilities team in order to ensure the feasibility and benefit of any proposed changes, as well as maintaining compliance with licence conditions.

23. Provision of services to investigate novel health technologies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

translational, biocompatibility, safety, surgery

Animal types	Life stages
Rats	juvenile, adult
Mice	juvenile, adult
Rabbits	juvenile, adult
Animal types	**Life stages**
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to provide research services to enable the assessment of novel health technologies. These include:

safety and biocompatibility assessments of novel materials,

safety or efficacy assessments of substances delivered to the eye,

devices or substances to treat conditions related to gastrointestinal surgery, bowel anastomosis and chemotherapy delivery.

devices to treat conditions related to the eye

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The models and protocols described in this project are intended for research into surgical and interventional sciences, and will be applicable across a range of clinical conditions which require surgery.

What outputs do you think you will see at the end of this project?

Outputs of research conducted under this licence may include: publications, patents, product development, product registration, commencement of clinical trials, new products.

Who or what will benefit from these outputs, and how?

In the long-term this research will benefit patients with various diseases or conditions: the impact of this work is applicable in multiple treatment fields.

For research Sponsors, data can assist with decision making, for instance elimination of unsuitable candidates and selection of more suitable candidates, prior to further costly development, and further animal research.

Research models using smaller mammals are useful to refine and develop techniques and can generate data upon which further investigative studies can be based, either in clinical trials or in vivo trials. Research models using larger animals are useful to simulate, refine and develop surgical techniques and strategies.

How will you look to maximise the outputs of this work?

Whilst publication of results would not be discouraged, it is expected that in most cases publication or dissemination will not be possible as the research will be conducted as a commercial service to companies.

Species and numbers of animals expected to be used

- Mice: 250
- Rats: 250
- Rabbits: 450
- Pigs: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages

Biocompatibility of materials (Rats & mice)

Rats and mice are used as models for assessing material biocompatibility as materials can be placed sub-cutaneously, relatively simply and safely in a short surgery time (compared to larger animals).

Their smaller size enables the inclusion of larger group sizes or collecting more datapoints more easily in terms of handling and husbandry, improving data reliability, as well as enabling multiple tissues to be assessed post-mortem more easily compared to larger animals. This is an efficient way to investigate or compare new treatments or multiple candidate materials quite quickly. Juvenile or adult animals would be used depending on the Sponsor's requirements, e.g. body weight, growth rate, size of implant/material to be placed, or the intended life span of the implant/material or length of study.

Ocular dosing and ocular tissue regeneration (rabbits)

Rabbits are frequently used for ophthalmic research as the size of the eye is more comparable to humans compared to smaller animals (e.g. mice or rats) and the stem cell regeneration of the epithelium is more similar to humans compared to mice. Substances can be relatively easily delivered into the rabbit eye, compared to smaller or larger animals.

Bowel anastomosis and drug delivery

Larger animals (in this case, pigs) are useful to evaluate products in the final stages of pre-clinical development, or devices which have been scaled up to a representative human size, or procedures intended for human surgery. Larger animals are often used for testing medical devices due to their physiological similarities to humans: devices and implants of a similar size to those which would be used in humans can be applied; in comparison to smaller mammals (mice and rats) there is a larger blood volume and the response to treatments can be evaluated over a longer period of time. In particular, gastrointestinal anatomy is more comparable to humans, compared to sheep for example, making pigs a useful and clinically relevant model for gastrointestinal and abdominal procedures.

Typically, what will be done to an animal used in your project?

Biocompatibility of materials (Rats & mice)

Most animals will undergo surgery, under general anaesthesia, to place up to 4 samples of materials under their skin. Some animals may not receive the implant or may receive an alternative or control material. Depending on the nature of the implant, it may be injected subcutaneously rather than surgically implanted (e.g. pastes or gels): this would not necessarily need to be performed under anaesthesia.

Ocular dosing and ocular tissue regeneration (rabbits) Ocular injury and tasorrhaphy

For most animals, an injury will be created on the epithelium of one eye, either by physically scraping or cutting the epithelium, or by applying a chemical to it (e.g. ethanol). This would always be performed under general anaesthesia. A loose, temporary suture (tasorrhaphy) would be placed to keep the eye closed for some or all of the follow-up period, but would allow observations to be made during this time.

Application or delivery of substances

Substances or treatments may be applied to the eye. These could be as drops or gels, as physical devices such as a contact lens (which may contain test substances). The substance could be delivered directly to the ocular surface with the animal restrained, or it may need to be injected into the eye, in which case the animal would be anaesthetised. The substances may be administered alone or in combination, at multiple times during the study, or may be slow-release substances/devices, releasing the test material over a prolonged period of time. The substances could be applied for experimental purposes (e.g. new treatments) or for monitoring or imaging purposes (e.g. dyes to view different parts of the eye).

Bowel anastomosis and chemotherapy delivery (pigs)

Bowel anastomosis and device placement

The bowel will be cut in up to 4 places and put back together (using stitches, or staples or glue etc). This would always be performed under general anaesthesia. Devices for drug delivery may also be applied to the bowel or surrounding tissue: e.g. sponges, patches etc. These would need to be attached by a suture, clip, glue or another type of fixing.

Application or delivery of substances

Substances or treatments may be delivered to the bowel or surrounding tissue either during surgery or after surgery via an extension tube. Devices applied during surgery may already contain the substances to be delivered over time. The substances may be administered alone or in combination, at multiple times during the study, or may be slow-release substances/devices, releasing the test material over a prolonged period of time. The substances could be applied for experimental purposes (e.g. new treatments) or for monitoring or imaging purposes (e.g. dyes to view blood flow or bowel obstruction, or labelled cells to assess tissue healing).

Treatment of eye conditions (rabbits)

Device placement

Most animals will undergo surgery, under general anaesthesia, to place a device into the eye.

Application or delivery of substances

Substances or treatments may be applied to the eye. These could be as drops or gels. The substance could be delivered directly to the ocular surface with the animal restrained, or it may need to be injected into the eye, in which case the animal would be anaesthetised. The substances may be administered alone or in combination, at multiple times during the study. Some substances may also be applied for monitoring or imaging purposes (e.g. dyes to view different parts of the eye)

Blood sampling (all animals)

If repeat blood sampling is required for the experiment, up to two (usually one) indwelling catheters may be inserted and tunnelled through the skin. This would be done under general anaesthesia.

Alternatively, if blood samples are only required occasionally, they may be taken directly from a blood vessel while the animal is restrained. It may be necessary and less stressful to briefly anaesthetise larger animals to take occasional blood samples.

Control groups

All steps are optional within each protocol: this is to allow the inclusion of control groups where they are required, such as administering substances without creating an initial injury. "No treatment" control groups are very rarely used for biocompatibility studies and the inclusion of these groups in a study would need to be approved by the Institute's ethical review body (AWERB).

End of experiments

Animals will be killed at the end of the experiments. This would usually be by an overdose of anaesthetic, but occasionally we would place the animals under general anaesthesia and retrieve blood and/or organs before killing it.

What are the expected impacts and/or adverse effects for the animals during your project?

Surgery & injuries (general, e.g. placing indwelling catheters, creating eye injury)

There is likely to be pain and some discomfort, and possibly localised inflammation, originating from any injuries created, the surgical incisions and extension tube for blood sampling, if placed. This would be managed with pain relief and dressings.

Wound opening (all protocols, all animals)

Occasionally, surgical wounds may open during the recovery period. This could happen if the animal interferes with the wound (scratching, overgrooming) or if there is an infection. In the cases, where there is no infection (or minor infection) the wound could be re-closed (usually under anaesthesia).

Infection (all protocols, all animals)

Infection is a possible adverse effect for any surgical procedure. This would be managed with antibiotics and dressings.

Creating eye injury (rabbits)

There is likely to be pain, inflammation and discomfort originating from eye injuries and associated suture.

Collars (mice, rats, rabbits)

To prevent animals interfering with wound sites or dressings, collars can be used. However, continuous use of a collar will interfere with the animals natural behaviour, e.g. unable to groom properly, unable to express coprophagy behaviour, leading to digestion problems). The impacts of continuous use of collars should be weighed against the benefit of preventing the animal interfering with the wound and hurting themselves. This would be assessed on a study-by-study basis. Continuous use of a collar can also rub against the skin, sometimes causing sores, pain and discomfort - this is checked regularly and creams or ointments can be applied, where this does not interfere with the study in progress.

Blood sampling

The animals may be averse to repeat blood sampling procedures which we will attempt to alleviate with habituation, training and enrichment during the acclimatisation period. The animal would need to be restrained whenever a blood sample was to be withdrawn. When taken from an indwelling catheter, the time of sampling should be shorter, with relatively less discomfort, than if the sample was to be taken directly from a vessel. In both cases, the impact would be mild and short-term

Application of substances

Occasionally there may be swelling or discomfort from implants placed under the skin. Following e.g. delivery of substances to the eye, or intraocular device placement, there may be pain, discomfort, irritation or inflammation. There is also the possibility of materials or substances causing some toxic effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 50% mild; 50% moderate

Rats: 50% mild; 50% moderate

Rabbits: 100% moderate

Pigs: 100% moderate

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use anials to achieve the aim of your project?

The models and procedures described in this project licence are intended for research of new healthcare approaches, treatments or devices, with a particular focus on injuries, trauma, or conditions requiring surgery. In many cases, treatment of a condition requires multiple approaches including surgery and drug therapy. The aim of this licence is to provide research as a service which reflects these multiple approaches and adequately tests new technology for healthcare. The range of potential fields that could benefit from this research covers the majority of medicine. It is expected that new technology is tested first in computer models or laboratory settings, but before technologies can be tested in, or applied to, humans, there must be some evaluation of the potential safety and benefit of doing so. To do this adequately usually requires evaluation in a living model - this includes multiple processes occurring simultaneously including breathing, blood circulation, the nervous system, hormonal effects, metabolism, excretion, growth, interactions with surrounding tissue, healing over prolonged periods of time. The safety and effectiveness of a technology would be affected by all these processes, and it is almost impossible to adequately recreate them in a computer or laboratory test.

Which non-animal alternatives did you consider for use in this project?

Where possible we make use of human or animal cadavers to do the initial stages of research, or basic research.

We also expect the research Sponsors to have completed intitial stages of research in non-animal models before commencing animal research.

Why were they not suitable?

Living processes (breathing, circulation, bleeding, metabolism, growth etc) are not present in cadavers. Non-animal computer or laboratory models cannot adequately present the multiple physiological processes involved in recovery from injury, trauma, surgery or disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated animal numbers are based on examples of likely study designs and timespans, for instance:

one study a year using 5 groups of 10 animals per group (<250 total) 6 studies a year using 8 animals (250 total)

2 studies a year using up to 24 animals of each sex (<250 total) 5 studies a year using 6 large animals (<150 total)

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures, before commencing larger studies - where possible, pilot study data will be included in the main study.

Where possible, multiple materials could be placed for biocompatibility studies.

Where possible, control materials or devices as well as test items can be placed in the same animal which could eliminate the need for a separate control group.

Wherever possible we make use of non-invasive or non-terminal endpoints such as non-invasive imaging or repeat blood sampling, to eliminate the need for additional study groups for different timepoints.

We frequently recommend cadaver studies to Sponsors, and use cadavers for model development and training opportunities.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures, before commencing larger studies - where possible, pilot study data will be included in the main study.

We routinely harvest tissues and organs from experimental animals for research and training purposes.

We work with Sponsors to ensure that the number of animals is enough to generate good quality data and reliable statistics.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocol 1: Biocompatibility
Mice, rats
Surgical placement of implants placed under the skin
Surgical placement of a catheter for blood sampling, and tunneled under and then through the skin
The surgery is always performed under general anaesthesia with pain relief alongside. The skin thickness is thinner in rodents compared to larger animals and surgical placement of materials subcutaneously is relatively simple in rodents and the animals recover relatively quickly (ie. usually within minutes following inhalational anaesthesia, compared to hours for larger animals). The surgical site is on the animal's back so the risk of interference and subsequent wound dehiscence is low.

Catheters would be placed if blood samples were required frequently: this would cause less distress than repeated handling, restraint or anaesthesia to withdraw a blood sample. Medicine to relieve pain would always be administered for a few days after the surgery, and longer if needed.

Protocol 2: Ocular injury and delivery of substances

Rabbits
Surgical placement of a catheter for blood sampling, and tunneled under and then through the skin
Creation of an injury on the eye, with a stitch to close the eyelid loosely
Delivery of substances or devices (e.g. contact lens) to the eye
Delivery of substances to look at the eye (e.g. dye)

The surgery is always performed under general anaesthesia with pain relief alongside. Catheters would be placed if blood samples were required frequently: this would cause less distress than repeated handling, restraint or anaesthesia to withdraw a blood sample.

Medicine to relieve pain would always be administered for a few days after the surgery, and longer if needed. Antibiotics can be administered directly to the eye if they were needed.

Only one eye would be damaged in each animal, and applying ethanol to the cornea in a well helps to control the injury size. The chemical injury is less severe than cutting. The animals are all acclimatised to the staff for handling, which makes the observations and administration of substances easier and less stressful after the surgery. The eyelid of the injured eye would be loosely sutured so that it could be opened briefly to administer substances as drops directly to the eye - this would not usually require anaesthesia.

However, for some observations and measurements, it could be necessary to anaesthetise the animal to administer dyes and shine different coloured or fluorescent lights onto the eye. Doing this under anaesthesia would cause less distress than if the animal was awake and restrained.

Protocol 3: Bowel anastomosis and drug delivery

Pigs
Surgical placement of a catheter for blood sampling, and tunneled under and then through the skin
Injuring the bowel, including completely transecting the bowel and re-connecting it ("anastomosis") in up to 3 places.
Placing a device onto the bowel or other associated tissues (for example the stomach, pancreas, abdominal wall).
Tunneling an extension line through the skin connecting to the device, to allow delivery of substances directly.
Delivering substances, such as chemotherapy, to the injured tissue, or to a device.
Looking at the injured tissue or body using CT or ultrasound, and delivering substances to assist with imaging, such as dyes or fluorescently labelled cells.

The surgery is always performed under general anaesthesia with pain relief alongside. The surgery would be performed by a competent surgeon, which could be a practicing medical surgeon or a competent and appropriately trained research scientist, veterinary surgeon or research surgeon.

Catheters would be placed if blood samples were required frequently: this would cause less distress than repeated handling, restraint or anaesthesia to withdraw a blood sample. Similarly, a tube for infusion can be connected to an internal device to avoid having to anaesthetise or restrain the animal to administer a substance. Medicine to relieve pain would always be administered for a few days after the surgery, and longer if needed. Antibiotics would also be administered if needed. The animals would be monitored closely after the surgery with particular emphasis on any signs of bowel problems or infection. Before and after the surgery, the animals could be provided with a different diet to soften the stools and make gut transit easier. They can also receive flavoured rehydration treatments to drink (which pigs quite enjoy).

Protocol 4: Treatment of eye conditions

- Rabbits
- Surgical placement of a catheter for blood sampling, and tunnelled under and then through the skin
- Surgical placement of devices (e.g. stent) into the eye
- Delivery of substances to look at the eye (e.g. dye)

The surgery is always performed under general anaesthesia with pain relief alongside. Catheters would be placed if blood samples were required frequently: this would cause less distress than repeated handling, restraint or anaesthesia to withdraw a blood sample. Medicine to relieve pain would always be administered for a few days after the surgery, and longer if needed. Antibiotics can be administered directly to the eye if they were required.

Only one eye would have a device implanted in each animal. All animals may experience some post-operative pain or discomfort because of the surgery. The animals are all acclimatised to the staff for handling, which makes the observations and administration of substances, as drops, easier and less stressful after the surgery - this would not usually require anaesthesia. However, for some observations and measurements, it could be necessary to anaesthetise the animal to administer dyes and shine different coloured or fluorescent lights onto the eye. Doing this under anaesthesia would cause less distress than if the animal was awake and restrained

Why can't you use animals that are less sentient?

The choice of animal is based on using the least sentient animal which is most clinically relevant and representative of a human and physiological processes, or most appropriate to represent the intended clinical setting.

Mice and rats are well characterised models for biocompatibility studies and are less sentient than larger animals (e.g. rabbits). Rats are usually preferred for this model over mice due to their larger body size, organ size and blood volume, enabling easier placement of materials and placement of multiple materials where appropriate.

Rabbits are frequently used for research into conditions affecting the eye as the size of the eye is more comparable to humans compared to smaller animals (e.g. mice or rats). Where recovery from injury and repair is to be investigated, the regeneration of the rabbit eye tissues is well characterised and is more similar to humans compared to mice.

Some translational studies require appropriately sized animals which are comparable to humans in order to be clinically relevant. The body size, blood volume and growth rates of larger animals are useful for these types of studies, and the ratio of body weight:blood volume is closer to humans than smaller mammals. The bowel of the pig is deemed more representative of the human than the sheep. Also, new procedures, instrumentation and devices may be designed for humans and a representatively sized animal will therefore have to be used.

We frequently recommend cadaver studies to Sponsors where this would meet the study aims, however studies including a recovery period are necessary to evaluate physiological, biochemical and histological responses to treatments. Larger animals are more appropriate for evaluating techniques and devices over longer treatment or recovery periods (weeks-months) compared to smaller mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely provide post-operative pain relief and antibiotics, and are prepared to extend the provision of these where necessary. All animals are closely monitored immediately after surgery, and then observed closely in the days and weeks after surgery, for instance their mood, grooming, movement, weight, eating and drinking, how the wounds look.

For recovery studies, all the animals arrive to the facility at least two weeks before studies start (for non- recovery studies, this can be one week, allowing time for physiology to return to normal levels and for any stress associated with the animal's arrival to diminish). During this time staff can start to train the animals if this will be needed for the experiment, for instance to be restrained (small animals) or stand still (pigs) for blood sampling.

Smaller animals (mice, rats and rabbits) will also be handled frequently before the study to get them used to staff and being handled.

All animals are provided enrichment whilst in the facility, such as chew sticks or treats and raised tunnels for rats; raised steps, a hiding place and dietary enrichment for rabbits; chains, balls and bars for pigs to chew.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our facility is GLP-certified and experiments can be performed to GLP-certified standards where required; non-GLP studies are performed to the same standard operating procedures.

The PREPARE guidelines cover many topics that are usually discussed between the research team and Sponsors whilst developing protocols, and an adaptive approach to these will be useful for planning specific studies and continuing the project.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our research staff actively seek opportunities for training and continuing professional development. We circulate the NC3Rs newsletters and take part in IAT and LASA activities. We communicate openly about animal welfare and suggestions and ideas for improvements are welcomed from all staff members.

24. Induction of anti-tumour immunity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunotherapy, White Cells, Carcinogen, Blood Vessels

Animal Types	Life Stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to improve our understanding of the relationship between the immune system and cancer and to use this information to design new immunotherapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To enable the design of new immunotherapeutic approaches to be tested in patients with cancer.

What outputs do you think you will see at the end of this project?

The design of new immunotherapeutic approaches to be tested in patients with cancer.

Who or what will benefit from these outputs, and how?

The main output of the study described herein is a better understanding of the reciprocal relationship between tumour blood vessels and anti-tumour immune responses. The findings will be shared as quickly as possible with the scientific community via open access publications and through talks at conferences and seminars. As mentioned throughout this application, there is a great deal of interest in developing blood vessel targeting agents for cancer immunotherapy. The findings of this study will be directly relevant to these efforts and as such, will be used to inform the design of new early phase studies in patients with cancer.

As well as the expert audience, we will also communicate our new findings to patients and the public. This has previously been done through lab visits for charity supporters, patients and their families, hosting coffee-shop evenings and speaking at public events. We also interact with schools and are specifically involved in projects aimed at helping young people understand the complex relationship between the immune system and cancer.

How will you look to maximise the outputs of this work?

Knowledge gained through work conducted on this licence will be shared with:

Cancer Immunology Researchers: Despite the success of novel cancer immunotherapies, the fact remains that for most cancers and the majority of patients, these therapies do not work. Currently, there is a large emphasis of combination therapies whereby a dual approach of e.g. priming the immune system with radiotherapy, chemotherapy, administration of oncolytic viruses etc is followed by or used concurrently with inhibitors of immune checkpoints. This project will examine the impact of combining treatment targeting blood vessels and immune cells thereby contributing knowledge to the design of novel immunotherapies.

Clinical Academics: This research will identify novel immune intervention which could be tested in early phase clinical studies.

Immunologists: Whilst the focus of this study is entirely on cancer, it is clear that the knowledge gained will also contribute to our understanding of immune responses to infection and especially of immune responses generated in the context of autoimmune disease. Thus, the findings of this study will be of interest to the wider immunology community, interested in understanding how to control of infection and/ or exacerbating or limiting autoimmune disease.

Collaborators: This study will extend our ongoing collaborations with multiple groups around the world. Our key contribution will be in imaging and we will aim to share our

methodological expertise with others. A large part of the process of collaboration is discussion of unsuccessful approaches and how this can be tackled. Thus, the progress we make will accelerate research in our group and beyond.

Species and numbers of animals expected to be used

- Mice: 15,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this study we will use adult mice in which tumours will be induced through injection of a carcinogen or through injection of cancer cells. One purpose of the work is to understand how the mouse immune system responds to the growing cancer. The second purpose is to test new therapies based on manipulation of the immune system. The mouse provides an excellent model in which to study the relationship between the immune system and tumour growth, since mice are well characterised immunologically and several key features of the mouse immune system resemble those of humans.

Moreover, many genetically modified mouse strains are available which will enable us to examine which components of the immune system help control cancer growth. Use of the mouse models described will also enable us to assess and visualise cancer cell and immune cell movement in the body. This is important as it enables us to work out how cancer cells avoid the immune system and how we can prevent this from happening. Currently there are no lab-based techniques which can recapitulate these processes.

Typically, what will be done to an animal used in your project?

Animals used in experimental procedures will be handled frequently (approximately three times per week). During these times animals will be injected and / or monitored for tumour burden (typically takes less than 30 seconds). In order to mimic the situation for patients with cancer, it will be necessary in some cases, to surgically remove tumours before novel therapies are administered. For this purpose, animals are anaesthetised for around 10 minutes. As well as for surgery, some animals will be anaesthetised in order that their immune cells and / or cancer cells can be visualised using imaging techniques. Typical imaging experiments require that animals are anaesthetised for around 1 hour.

What are the expected impacts and/or adverse effects for the animals during your project?

Many of the mice in this study will have a tumour generated either through injection of carcinogen or through injection of cancer cells. Both methods will result in development of the tumour at the site of injection. In the case of the carcinogen, this is on the hind leg

whereas cancer cells are implanted either under the skin or in the colon. In all cases, tumours are readily visualised either by eye or using an endoscope (colon tumours). Mice will be monitored for tumour burden frequently and tumours will be scored for size, position and, in the case of tumours implanted under the skin, redness and/or irritation.Through good handling techniques, distress caused to the animal from being restrained will be minimised in terms of time and discomfort. Should tumours limit mobility, appear inflamed or reach a maximum permissible size, animals will be killed using an appropriate humane method. In the case where surgery is performed, appropriate analgesics will be administered to control pain. Score sheets are used in all experiments to record signs of distress and weight loss. Appropriate remedial action will be taken immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on working with mouse models of tumour growth since 1999, it is expected that for the majority of animals used in procedures in this project, the severity level will be "Moderate".

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Interactions between the immune system and developing tumours depend on the integration of signals from a number of immune cell types and immune mediators. With this in mind, an animal model is necessary as there is currently no way to recreate these in vivo conditions in an in vitro setting.

Which non-animal alternatives did you consider for use in this project?

Some non-animal alternatives are used in this project. We are currently using organoid cultures in our laboratory which grow in 3-dimensions and which resemble the complex cellular heterogeneity of tumours growing in animals. These are useful for examining the direct effects of drugs on cancers and to examine how immune cells interact with cancer cells. However, their use remains limited by a lack of blood supply to the organoids which limits our ability to study cancer and immune cell movement.

Why were they not suitable?

An animal model is necessary as there is currently no way to recreate these in vivo conditions in an in vitro setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experimental designs to be utilised are simple and have been used, with slight variations, in our laboratory for a number of years. For most experiments, little optimisation of regimes required, keeping the number of animals required as low as possible. As the aim of this research is to identify immunological effects that are both reproducible and unambiguous, most experiments will include both positive and negative control groups. This is important as it enables us to ensure that a given experiment is working (positive control group) and that any effects observed are due to the intervention being tested (negative control group). In the case where a pilot experiment is conducted e.g. to determine the feasibility of an experimental technique or to set imaging parameters, no control group will be required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All PhD students and post-docs in the lab will have performed a course on use of statistics in biology and will be well versed in use of "power calculations". This means that they will be able to use "power calculations" to work out what the minimum number of animals is needed in order for a given experiments to produce a meaningful (statistically significant) result. This is important, not just for making sure that no more animals than necessary are used, but also because using too few mice means that it might not be possible to draw a conclusion from the experiment.

Members of the lab also use a set of guidelines called "ARRIVE" guidelines found on https://arriveguidelines.org/. These are an extremely useful set of recommendations which are designed to help researchers ensure that they perform their animal work in the most robust way possible. The purpose is to enhance the quality and reliability of the findings of individual labs in order that their work can be more easily reproduced by others. These principles form the cornerstone of animal work performed in our lab.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Several measures are taken to optimise the number of animals used:

1. This project will make use of a number of different imaging modalities for measuring tumours which are not visible to the naked eye. This will enable us to carry out longitudinal analyses of tumour growth in individual mice thereby significantly reducing the numbers needed to assess the impact of a given immunotherapy on tumour growth over time.

2. Where possible we will try and use the same control group for multiple experiments – this requires coordinating the activities of different members of the lab in order that experiments can be synchronised. Regular small-group lab meetings are held where researchers working with mouse models present their experimental plans for the month ahead. This information sharing enables the design of experiments where control mouse groups can be applied to different (but obviously related) experimental questions. This is a very powerful way of reducing mouse numbers and increasing the quality of the experiment beyond what one individual researcher can achieve. This approach also facilitates greater oversight of the animals involved in the study with shared responsibility amongst researchers.

3. Randomisation is also used to ensure validity of results. Due to the nature of the tumour models that are used, whereby tumours arise at different times in individual animals, experiments are often performed in sub-groups (enabling randomisation within blocks). This approach builds additional robustness to the experimental findings as any conclusions drawn come from findings which have withstood the natural variation occurring within experimental units.

4. Variation amongst mice / experiments is kept to a minimum by conducting procedures at a similar time of day, using uniform and well validated techniques and equipment. In all cases individual mouse variation e.g. body weight, tumour size etc, are taken into account.

5. Where possible, experiments are performed in a blinded fashion. Animal samples taken to the lab will be coded and key measurements conducted by a researcher who is blinded to the experimental code e.g. measurements of immune cells in tumours. Tumour volumes are measured by technicians who are not aware of what (or whether) mice received interventions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse provides an excellent model in which to study the immune system. Mice are well characterised immunologically, and their immune systems closely resemble those of humans.

Tumours will be induced either through injection of a carcinogen in the hind leg, tumour cell lines in the skin or in the colon using an endoscope. Both procedures involve minimal restraint and little discomfort to the animal. Tumours are monitored frequently either by imaging or palpation allowing us to kill animals by Schedule 1 methods before tumours cause pain / discomfort.

Why can't you use animals that are less sentient?

This work evaluates the dynamic interactions between blood vessels, tumours and the immune system. These interactions, which encompass complex cellular heterogeneity and which require the need to analyse cell behaviour in their natural environment must be performed in an adult animal with similar biological systems to those in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All new techniques (or combination of techniques) are subjected to scrutiny with respect to harms to the individual animal. Score sheets are updated to reflect any relevant observations relating to animal welfare. We also work closely with the animal technicians and NACWO to ensure that all parties are aware of potential adverse effects and how to respond accordingly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE Guidelines are the most useful for this purpose.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay informed about advances in the 3Rs (reduction, refinement and replacement) through published literature. An example of a transformative step is the development of cancer "organoid" technology. Organoids are three dimensional structures which can be grown from both mouse and human cancers in the laboratory. They retain many of the features of cancers growing in the body and can therefore sometimes be used for testing e.g. new drugs in the lab without the need for an animal model. For this reason, we are currently developing a bank of human breast cancer and colorectal cancer organoids which will allow us to perform at least some experiments to examine the interaction between immune cells and cancer. Students and post-docs in the lab also attend workshops which are run by the "National Centre for Replacement, Reduction and Refinement of Animals in Research" - this provides the lab with the opportunity to learn about the latest innovations (such as use of organoids as described above) which help

reduce the need for animal models or which improve experimental designs such that fewer animals are needed.

Refinements in imaging procedures have been continuously adopted during the course of our studies. This is important because our findings are otherwise limited to static snapshots of how cells of the immune system interact with cancer cells. Imaging techniques enable us to see how cells move and interact with each other over time. This means that substantially more information can be gained from individual animals. These techniques are usually non-invasive thereby offering a significant refinement to traditional methods.

25. Immune regulation at mucosal and barrier surfaces

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Microbiome, Mucosal surfaces, Inflammation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate and understand the interplay between the host immune system and colonising microbes, and how breakdown of interactions between them can lead to the onset of inflammatory diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding fundamental cellular and molecular pathways underpinning inflammatory diseases at barrier surfaces has already led to new treatments effective in the clinic, many

of which target common pathways to inflammation at several sites, including the intestine, skin and joints. However many patients show little response to current treatments, or response declines over time, meaning that additional treatments are required to suppress pathological immune responses or to induce protective immunity against intestinal pathogens. These studies may aid the development of new antimicrobial approaches and vaccines for treatment of infectious disease as well as identification of new therapies for a number of chronic inflammatory disorders in addition to IBD, psoriasis and arthritis, including type 1 diabetes and multiple sclerosis. Our work is relevant not only to human health as chronic intestinal inflammation is also a problem in the livestock industry, and IBD affects domestic animals including cats and dogs.

What outputs do you think you will see at the end of this project?

The overall aim of our project is to understand how microbes and the immune system interact in health and what goes wrong in disease. We are particularly interested in inflammatory diseases such as inflammatory bowel disease, arthritis and psoriasis, in addition to colorectal cancer, which are increasing in prevalence. Our works aims to understand how these diseases arise and how to better treat them. Outputs may include the identification of both common disease pathways and novel treatment targets. This information will be used to design interventions to promote health, which may be translated to human disease through collaborations with industry partners. A greater understanding of the role of intestinal microbes in disease onset, promotion and protection may also lead to more targeted interventions and design of synthetic microbes as an avenue for treatment. All of this work will be published in peer-reviewed publications, and disseminated to the broader scientific community through conferences.

Who or what will benefit from these outputs, and how?

Inflammatory bowel disease is a chronic debilitating inflammatory disease of the gastrointestinal tract that affects around 0.2% of western populations. Disease affects young people in their prime and current therapies do not cure disease and can lead to systemic immune suppression, leaving patients susceptible to infection over decades. Five years after diagnosis, it is estimated that between 15-20% of patients are disabled to some degree by their disease. Our programme of work which involves fundamental basic science is to identify key immune and tissue pathways that control the host environmental interface at barrier surfaces such as the skin and intestine, and non-barrier areas such as the joints in health and how these change during disease. Based on the success of our previous programmes we anticipate these studies using pre-clinical models of disease will identify new prognostic and therapeutic biomarkers including microbial mediators for IBD, arthritis and psoriasis.

Epidemiological studies indicate that IBD patients, particularly those with UC, have an increased risk of developing colitis- associated colon cancer (CAC). Therefore, the development of improved therapies for IBD is likely to result in decreased incidence of CAC.

How will you look to maximise the outputs of this work?

The outputs from this work will be maximised through the dissemination of our findings in publications and conferences. In addition, we will continue to publish our negative results (when relevant) in the hope of minimising redundant work.

We also have a number of successful collaborations in both academia and industry.

Species and numbers of animals expected to be used

- Mice: 59,100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the most appropriate species for our studies because the mouse models that we will utilise are the best characterised models of gastrointestinal infection and inflammatory diseases, and they show the main features of human disease whilst being the lowest neurological sensitive species that does so. Most of our experiments will be performed on adult mice, but as microbial colonisation starts at birth and significantly changes in early life, we may alter microbial colonisation in juvenile mice. Very rarely we will use neonatal mice, where we need to alter development of the immune system before it is mature.

Typically, what will be done to an animal used in your project?

Many of the animals in this project will have an inflammatory disease induced, that will lead to inflammation in the colon, liver, joint or skin. Some animals will also develop colon cancer in the presence or absence of other inflammation. Disease induction usually involves injection or oral dosing of bacteria, bacterial parts, or a chemical, usually up to three times, but in the case of skin inflammation, daily application for up to 10 days at a time up to three times. Inflammation can take days or weeks to develop, depending on the model, but most experiments will be terminated within 2-6 weeks. Colon cancer takes months to develop so mice may be kept for up to one year to allow for tumour formation.

Prior to or during inflammation mice may also be injected with other substances such as blocking antibodies, antibiotics, or fluorescent dyes. Occasionally mice will be subjected to whole body irradiation followed by injection of bone marrow cells in order to understand the role of different genes and cell types. Animals will be allowed to recover for at least six weeks after this process before inflammation of any sort is induced.

What are the expected impacts and/or adverse effects for the animals during your project?

Following bone marrow transplantation, mice are expected to lose body weight and to experience general discomfort leading to symptoms such as temporary reduced social behaviour, loss of coat grooming and partial hunched posture. These symptoms are expected to last 3-5 days, depending on the treatment. However, full recovery is expected to be achieved within 7-14 days.

Injections are expected to cause local temporal pain, with no longer term effect.

Induction of inflammation is expected to cause inflammation at the site (intestine, joint or skin) leading to general discomfort. Mice can develop loose faeces, and lose body weight. Following onset these symptoms are expected to last 1-2 weeks in most cases. Mice that develop cancer (either spontaneously or following colitis) are expected to lose weight and may show temporary reduced social behaviour, loss of coat grooming and partial hunched posture. We do not expect tumours to reach a size where they impede normal biological functions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols we expect the majority to experience subthreshold severity (approximately 70%), and a small number to experience mild severity (approximately 20%) and less than 10% to suffer moderate severity.

For the mice on experimental protocols, we expected the majority (approximately 90%) to experience moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Intestinal physiology and disease involves complex interactions between host genetic factors and the environment and these cannot be reproduced in vitro. A mammalian species is required to permit the study of the innate and acquired immune mechanisms that contribute to the development and control of intestinal infection and inflammation, and it is not possible to replicate the complexity or dynamics of these host-microbe interactions in vitro. Furthermore, the intestinal anatomy in which these host- microbe interactions occur cannot be reproduced in vitro.

Which non-animal alternatives did you consider for use in this project?

Where possible, some in vivo assays are replaced by in vitro assays to analyse immune cell function. For example, T cells can be grown in vitro under different conditions to manipulate their cytokine production and measure responsiveness to various stimuli. We have also established a 3D organoid culture model whereby different cellular populations are grown together in a gel matrix to re-create certain parts of the intestinal structure in vitro. This allows us to grow, manipulate and analyse some rare intestinal cell populations in the dish.

Why were they not suitable?

Although we are able to culture immune cells and bacteria in vitro, the conditions and media used to culture mammalian cells and intestinal bacteria are often mutually incompatible, meaning it is not possible to study interactions between them in a dish. Three-dimensional and co-culture systems are not yet advanced enough to replace all animal work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers of mice to be used are based on our experience running an integrated project over the last 25 years. The large numbers of mice for breeding genetically modified or harmful mutant mice reflects the use of these mice as donors of immune cells as well as hosts for immune cell transfer or infection. There are several very complex genetic crosses that mean that many mice need to be bred in order to get sufficient numbers with the right genetic mix, and we have accounted for this in our breeding estimates. In addition, to reduce the possibility of genetic drift arising due to inbreeding, where impact would be significant we will backcross genetically modified strains to the parent strain approximately every 10 generations. This will generate an increased number of animals to re-cross to a homozygous background.

We have also estimated the statistical power and frequency of our experimental set-ups to calculate the number of mice we will use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In experiments designed to test whether a particular manipulation has led to a reduction in the severity of disease compared to the control group, the number of animals in each group has been calculated to ensure a 90% chance of detecting a change that is statistically significant at the 5% level. For example for categorical data where the probability of mice in the control group getting colitis is 0.8 and where we would like to be able to reliably detect a reduction in the test group to 0.3, power analysis indicates a group size of 20. This group size, taken together with the number of different types of manipulation has been used to estimate the number of animals to be used.

Age and sex-matching within experiments will be used to reduce inter and intra-group variation, thus reducing the numbers required to generate statistically meaningful results. Where possible we co- house experimental groups in the same cage to reduce variability further, but this is not always possible when investigating the effect of intestinal microbes, as each mouse in a cage will share a very similar set of microbes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Every effort will be made to reduce the number of mice as follows:

- Use of pilot experiments with up to 5 animals per group for dose determination or model development, and up to 10 animals per group to determine intra and inter group variation.

- Inclusion of colonoscopy allows individual mice to be followed throughout disease development, both for IBD and cancer studies. This will reduce the number of mice required to look at disease kinetics and tumour progression.

- Maximal use of harvested cells and tissues. For example, spleen cells isolated from genetically modified mice may be used as a source of immune cells for in vivo transfer as well as for biochemical analysis in vitro.

- Mouse requirements will be reviewed regularly to avoid unnecessary breeding and breed only the animals that we need.

- Use of cells and tissues from shared control animals by multiple researchers.

- Archiving of frozen tissue samples to permit analyses of novel factors without additional in vivo experiments. We are creating a tissue bank of 10 different tissues from experiments using rare strains or mice lacking all microbes.

- Embryo freezing of strains not in current use.

- For xenograft experiments we will inject control cells and tumour cells into different flanks of the same mouse to allow an internal control and halve the number of animals that need to be used for each experiment.

- Where possible both genders will be equally used across experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse models to assess the immune-microbial interactions that occur during infection and inflammation. We will therefore infect mice with microorganisms including bacteria and parasites, some of which will cause pathology in the gastrointestinal tract. We have carefully selected models of inflammation (in the intestine, skin and joint) that most closely mimic human disease whilst being minimally invasive to induce. Most of our models last 1-6 weeks, although our cancer models can last up to a year as it takes time for tumours to develop. For most experiments we are investigating the immune-microbial responses during inflammation, so once inflammation (or tumours) have developed our experiments end within 1-2 weeks. Occasionally we are investigating the repair response, as the diseases we are modelling are relapsing-remitting. In this case once inflammation develops we wait for spontaneous repair, which can start to happen within 2-3 weeks. We only perform repair experiments in models where we know that disease will self-resolve within 2-3 weeks.

As far as possible we have chosen models where we do not expect inflammation in any location other than the one of interest, e.g. a model of intestinal inflammation should not lead to concomitant joint or skin inflammation. One model of joint inflammation does also cause intestinal inflammation in a subset of mice (similar to human patients where a subset of ankylosing spondylitis patients develop additional intestinal symptoms), and understanding why this is the case and why it does not affect all animals is part of our scientific project. Many of our experiments are designed to assess the role of specific microbial or immune functions on disease outcome, and we expect that addition or removal of specific factors will in general ameliorate disease relative to controls rather than enhance it.

Why can’t you use animals that are less sentient?

The mouse is the most appropriate species for our studies because the mouse models that we will utilise are the best characterised models of gastrointestinal infection, human

IBD and cancer, and re- capitulate the main features of disease. The mouse is the lowest neurological sensitive species that shows similar intestinal and skin disease to the human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To investigate the role of different cells and factors in intestinal inflammation and immunity, it is necessary to allow intestinal inflammation to develop to a moderate degree and the different disease characteristics mean that the end points will differ in different models. We have established refined monitoring schemes tailored to different procedures to assess the extent of clinical signs of IBD and to detect any adverse effects in experimental animals. We have shortened our models to reduce suffering to the shortest possible time, and our monitoring schemes allow us to end experiments as soon as practically possible after disease has developed. To accelerate tumour development, we will inject mice with the carcinogen azoxymethane (AOM), which does not impact on the induction of chronic intestinal inflammation, but accelerates tumour development allowing these experiments to be terminated earlier.

We use environmental enrichment and reduce social isolation of mice to a minimum by co-housing wherever possible. We make every effort to keep the number of procedures each animal undergoes to a minimum, for example by combining injections wherever possible. We also carefully consider the route of injection and where multiple routes are possible we use the least painful and invasive.

When possible and necessary, we use anaesthetics to reduce temporary discomfort during a procedure. Our preferred choice of anaesthetic is inhalation, which we use whenever possible. The equipment we use is very reliable to ensure the appropriate level of anaesthetic is delivered. When surgery is involved, we use appropriate aseptic techniques, monitor the animals before during and after the procedure. Most of our surgery will be performed under a terminal anaesthesia.

When using live pathogens, we use species that primarily infect the gastrointestinal tract, and avoid the use of species that cause more systemic disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We make use of the ARRIVE guidelines both for planning and reporting experiments, and we will also make use the NC3RS Experimental Design Assistant (EDA), G*Power2 and other online tools to assist with calculating appropriate experimental group sizes. If experiments are more complicated and require more specialist input we will seek support from statisticians local to our institute.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly attend animal welfare meetings. When utilising new treatments or models we will seek the advice of experts in the field to ensure that we are using the most appropriate techniques and monitoring. We use the NC3Rs website to keep up to date on more general advances in the 3Rs (https://www.nc3rs.org.uk).

26. Neuron-glia biology in neurodegenerative disorders

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Ageing, Alzheimer's disease, Inflammation

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the role of glia and neuron-glia interactions in neurodegeneration, particularly in Alzheimer's disease

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Alzheimer’s disease accounts for around two thirds of all dementia cases (around 33 million people worldwide) with a complex cellular response and no treatments that can stop, slow or prevent it.

Understanding the biological mechanisms behind the disease is essential to finding ways to treat it.

What outputs do you think you will see at the end of this project?

The project comprises basic scientific research that will increase our understanding on the role of glia (support cells in the brain) in Alzheimer's disease and neurodegeneration in general. The outputs will primarily take the form of publications in peer-reviewed journals, but will also be disseminated at academic conferences and to the lay public via popular science initiatives. Materials, data and methods may, where appropriate, be disseminated online.

Who or what will benefit from these outputs, and how?

By understanding the role different brain cell types play in neuroinflammation we can begin to dissect out the different stages in Alzheimer's disease progression. In the short-term, the primary beneficiaries will be other scientists working in the field of neuroinflammation, ageing and Alzheimer's disease. In the medium term to long term, the basic science knowledge gained may have the potential for clinical translation. For example, understanding key pathways in disease progression may identify new targets for developing new pharmaceutical or therapeutic interventions in Alzheimer's disease.

How will you look to maximise the outputs of this work?

We will share data, analysis tools and resources between other members of our research community and this will reduce the number of replicated experiments in the field and the number that we need to do in our laboratory. In addition, we will disseminate our research by publishing results in peer reviewed journals. We aim to publish all results, including those that do not confirm our hypotheses. We will also present our work to academic peers at scientific conferences (national and international), and engage with public partners to disseminate our results.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will do these experiments in mice because of the number of available mice that are genetically suitable and the comparison with previous studies in the scientific literature. Using transgenic mice has the distinct advantage that we can use mice that express diseases, such as Alzheimer’s disease. We will use adult and aged mice, since these ages represent the most relevant for the study of age-related neurodegenerative diseases.

Typically, what will be done to an animal used in your project?

Some animals will be bred, and may have dyes injected to label the blood or cell types or drugs injected to alter the function of some cell types, and will then be humanely killed in order to study their tissues.

Some animals will undergo a surgery, where a small part of their skull is replaced with a glass coverslip to give us repeated optical access to the brain. Adverse effects after the surgery may reach moderate levels of severity for a short period of time, but all animals receive pain relief and are closely monitored until they recover completely. After that time, they will have a number of non-painful behavioural tests, some of which will also involve measuring from the cells in their brain using light. These tests may be repeated several times. At the end of these behavioural measurements, the animals will be humanely sacrificed and their brain tissue may be used for post-hoc analyses.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will undergo surgery of moderate severity. This means that the mice will be quiet and move less for a day or two after surgery. The animals will be given painkillers after surgery. Animals might lose a bit of weight, but will typically regain that weight within two to three days. Some animals will also be allowed to age (up to 24 months) meaning they may experience certain discomforts associated with the ageing process. At the end of experiments, or if mice show signs of ill health, distress or suffering that are not improved or resolved within a timeframe approved by the veterinary surgeon they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

30% of mice will experience a severity category 'Mild'

70% of mice will experience a severity category 'Moderate'

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice will be used in this project. Studying the cellular mechanisms involved in dementia and AD is extremely complex and involves understanding the interactions between different systems in the body (e.g. nervous, immune, and vascular). It is very difficult to mimic such complex interactions ex vivo, and whole animal in vivo experimentation is therefore vital in order to obtain a greater understanding.

The proposed studies could not be undertaken in lower species because they do not show such similarities to humans (e.g. they do not have similar glial cells), and in vitro experiments do not allow the study of interactions between different body systems (i.e. immune and vascular), which are critical for this project. Thus, the questions and hypotheses to be addressed cannot be fully studied in vitro alone and require in vivo studies.

Which non-animal alternatives did you consider for use in this project?

This project will be done in parallel to studies using non-animal alternatives such as Human post-mortem and brain biopsy studies.

Induced pluripotent stem cells (iPSC) Brain organoids

Why were they not suitable?

The use of non-animal studies will provide us with useful information that can be used to design our animal experiments. However, in vitro experiments (e.g. using induced pluripotent stem cells or brain organoids) do not allow the study of interactions between different body systems (e.g. immune, vascular and nervous) which are critical for the understanding of the physiological changes occurring in Alzheimer's disease. The use of human post-mortem and brain biopsy tissue, while helpful, will only provide us with a snippet of the cellular states at the later stages of the disease, but in order to understand disease progression we need to be able to study the brain at multiple timepoints during disease development in a living organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on previous experience when dealing with complex genetic crosses in mouse breeding as well as estimates on the number of experimental animals required based on expected effect sizes from the literature, past work, and in vitro pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Several factors lead to a reduction of animal numbers, including reducing variation and good experimental design involving the use of appropriate statistics. In particular statistical tests will be used to ensure that we use the minimum number of animals possible to reliably interpret our data.

We will design our mouse breeding strategies carefully to minimize the number of generations necessary to reach the desired endpoint (i.e. desired combination of transgenes/ mutations), and to cut down the number of unwanted offspring. Where appropriate, we will use otherwise unwanted offspring for negative control experiments.

In our experimental design, we always collect as much data as possible from each animal. With longitudinal experiments, we repeatedly measure the same structures or cellular activity over a long period of weeks. This approach allows us to directly compare the structural/functional plasticity in the same synapses, cells and animal before and after sensory deprivation or alterations in behaviour.

Furthermore, in each animal, we can collect data from many cells, increasing the amount of data from each animal used and reducing the overall animal number necessary.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding and holding lines as frozen down embryos and sperm will be used to minimise the number of mice being produced for these studies. Genetically modified lines will be sourced from repositories to avoid remaking of lines whenever possible. Any excess stock will be offered to other researchers to minimise wastage. Pilot studies will be undertaken to ensure the correct time course and experimental paradigms for our experimental purposes before larger scale studies. Tissues sampled from the animals used in this project will be shared with other researchers and the data produced linked to that generated by the project, to maximise long-term utility.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents have been chosen for this work as the least sentient species to mimic the human nervous system well enough for our work to be relevant to understanding of human brain function and disease. Mice are essential because the experiments require the use of the latest and most refined transgenic technologies to identify and label cell subtypes, to allow cell specific knock-in and knock-out approaches, to express genetically encoded indicators and optogenetic modulators and to model human diseases (e.g. Alzheimer's disease). These mouse models are not expected to exhibit any harmful phenotype.

We will be using chronic imaging in combination with cranial window surgery preparations, which allows us to follow the same cells over a period months. This preparation is ideal for examining how the same cells are changing their structure and function over time during disease progression. Cranial window surgery is necessary to allow us to image individual cells at a resolution that will allows us to draw meaningful results. This protocol minimizes suffering, as the initial surgery is the only one in which any pain may occur. All imaging sessions afterwards will only require light anaesthesia and no surgical intervention. For the surgical step appropriate anaesthetic/analgesic regimens and post- operative care will be used to minimise pain. Any surgical procedures will undergo regular review to identify further refinements to minimise animal suffering including optimisation of implants and anaesthesia/analgesia regimens.

In addition to chronic imaging, we plan to extract tissue from mice for in vitro downstream applications. These terminal experiments will take place entirely under anaesthesia and therefore will have minimal suffering. We plan to use these experiments to test a number of potential mechanisms before testing them in vivo, which will help reduce the number of animals undergoing the in vivo paradigm and that may suffer as a result.

Why can't you use animals that are less sentient?

Rodents will be used for this project as they represent the least sentient species appropriate for this type of work. Other species which are less sentient (such as invertebrates) cannot be used because they do not show such similarities to humans (e.g. they do not have similar glial cells which form the basis of this proposal). Mice which are genetically tractable, allowing transgenic identification and manipulation of specific cell types and there are a significant number of well characterised transgenic mouse lines available to model disease.

Animals at a more immature life stage cannot be used because this work focuses on the cellular physiology of ageing and age-related disorders and as such, we need to work in adult animals.

A number of our experiments are done in animals that have been euthanised or are terminally anaesthesised, but in order to look at long term cellular changes throughout disease progression we need to carry out some chronic experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animal facility staff run a comprehensive health-monitoring programme whereby animals health and welfare are checked and recorded on a daily basis. The animals will be maintained under conditions where their health status can be protected as far as is reasonably practicable. We use refined holding techniques for the animals, as well as group housing and enrichment. We use appropriate anaesthetic/analgesic regimens (including pre- and post-operative analgesia) to minimise pain and will refine these with advice from the NVS to ensure that we are using the best possible option given our experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Resources hosted on the NC3Rs website, in particular:

- ARRIVE guidelines on experimental design and reporting results.
- PREPARE guidelines for planning animal experiments
- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.
- Rodent housing and husbandry
- Rat and Mouse Grimace scales

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs from several sources:

- Liaison with our animal care staff and NC3Rs representative
- Technological advances in the published scientific literature
- The NC3Rs website

27. Immune-based treatments for cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Therapy, Immune, Microenvironment

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will characterise the immune cells found in cancers and study how immune pathways can respond to cancer treatments. This will help to identify new ways of treating cancer by working out which types of cancers or which treatments respond best to immune-based cancer treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding how cancers and immune cells interact has led to the biggest breakthrough in anti- cancer treatment in recent years. Despite this, most people with cancer don't

benefit from these treatments because they only work for a minority of cancers. It is interesting that most cancers where immune-based treatments don't work well are the same cancers which are caused by long-term inflammation. We have previously found immune pathways involved in inflammation to be active in aggressive cancers. We can alter these pathways using lab techniques or using treatments, and then study how cancers change their behaviour in response to these alterations using mouse models. Using mouse models means we can study these pathways in cancer in the context of an active immune system and response. This is very important as many different aspects of the immune system influence how cancers behave, which we can't model using cells in the lab. There are already drug treatments available targeting some of the pathways we are interested in, and knowing who could benefit from these treatments is important.

What outputs do you think you will see at the end of this project?

Cancers that are aggressive are typically inflamed. This makes them resistant to current cancer treatments. We have identified some ways in which this inflammation could be tackled by studying immune pathways in cancer cells. In this project we want to further development understanding into the role of inflammation in cancer development, spread and response to treatment.

We already work with international groups (in the US and Europe) in this area. We anticipate this work will be published in journals freely available to the wider community (called "open access"). We will also present this work at national and international scientific meetings. We work with patient groups to inform our research and make sure it stays relevant to patients and their needs.

We anticipate we can identify new treatments as a result of the work described in this licence. We also expect we can improve our understanding of which kinds of cancers respond best to combination treatments. Promising results from this work identifying new combinations or ways to tailor treatments will be brought forward to clinical trials.

Who or what will benefit from these outputs, and how?

In the short term, the scientific community will benefit from deeper understanding of inflammatory pathways in cancer. These short term outputs will primarily be publications and presentations within the scientific community.

In continuing our collaborative approach, we anticipate an ongoing acceleration in sharing techniques and refining approaches between our group and others.

In the longer term, we anticipate impact in new combination treatments or better selection of patients for existing anti-cancer treatments. These may not be evident in the five year span of this project as typically these treatments and selection techniques can take up to 10 years to get to the clinical setting.

How will you look to maximise the outputs of this work?

The licence applicant has demonstrated a collaborative approach in the development of this planned project, and has established collaborations both locally and internationally which will accelerate the development and strengthen the analysis of findings from this project.

Findings will be shared using open-access papers. Any negative data will be published to prevent unnecessary duplication of approaches taken during this project.

Species and numbers of animals expected to be used

- Mice: 3750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have demonstrated from human studies the profound effects of tumour-driven inflammation on the immune response to cancer, and effectiveness of anti-cancer treatments. We will use adult mice to study these pathways in established cancers and in cancer spread. By using mice, we can manipulate these pathways in the lab prior to injecting cells to better understand the impact of immune pathways on cancer development and spread. We can also use adult mice to study responses to cancer therapy and in particular, immune responses to specific treatments. We use mice with an active and intact immune system in this project to help us answer these important questions. We use adult mice as they have a mature immune system.

Typically, what will be done to an animal used in your project?

We will inject cancer cells in the mice, sometimes just under the skin and sometimes through a vein that results in lung disease. In some cases we will inject cancer cells directly into the abdomen. Using these approaches allows us to represent human cancer in the mouse. We can then use genetic alteration of immune pathways, or immune or anti-cancer treatments, to study the effect on tumour growth. We can specifically study immune cells in the tumour to under this better.

Other injections animals might receive include injections into a vein to allow us to take images of tumours using a scanner. They may also receive injections in the stomach, into the veins or under the skin which are anticancer treatments. In some cases we will inject these directly into the tumour.

Surgical procedures on mice will not be conducted in this work.

When we take images of the cancer, we will usually give the mouse a mild inhaled anaesthetic, which we expect will keep them still and comfortable without causing distress.

We may take very small amount of blood samples from the mice, usually from the tail vein, up to a maximum of 4 times.

Most experiments in this project could be measured in terms of weeks - we do not expect we will have mice on treatment for more than 3 - 5 weeks in total. In some cases, where mice recover fully from the cancer as a result of treatments given, these mice may stay alive for another few weeks to allow us to check the immune system responses to cancer. This involves an injection of cancer cells to the back or side of the mouse which will be permitted to grow to only a small size.

What are the expected impacts and/or adverse effects for the animals during your project?

Most mice on this project would be expected to develop cancers. They may have this cancer as a lump on the skin or breast area, or in the lungs, for a number of weeks. We expect most animals will not experience serious discomfort. In the protocols described in this project we have identified conditions that would mean that we end the experiment early to prevent the mice experiencing suffering.

Some mice may receive additional injections of anticancer treatment, injections to enable imaging of the cancer, or radiotherapy treatment. We have carefully controlled the dose or number of treatments a single mouse would receive. Mice receiving these treatments would only receive them for a few weeks in total.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most protocols in this licence are of moderate severity as they involve the induction of tumours and study of cancer. Out of all the animals on this licence, most would experience a moderate severity as they would develop a tumour, undergo imaging and receive treatment; or receive an intravenous injection of tumour cells which results in tumours in the lung; or receive radiation or systemic anti- cancer treatments. For all mice, we expect 75% on protocol 1 will experience moderate severity, up to 95% on protocol 2, up to 98% in protocols 3, and 4 and 40% on protocol 5. We would expect other animals to experience a mild severity. No protocols on this license are "severe". Typically induction of a tumour and receiving a treatment are considered "moderate".

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While we can study some pathways and effects using cells in the lab, the immune system in particular is complex and cannot be recapitulated outside of an animal model. A cancer is composed of multiple cells types - cancer cells, immune cells, blood vessel cells, fibrous cells and the extracellular matrix or secreted substances. All these factors within a tumour contribute to the immune response, and currently it is not possible to model this complex interaction outside of using an animal model such as mice.

Cancers often spread in humans, and this is ultimately what causes death from cancer. Using animal models to study this spread is very useful in trying to develop techniques and treatments to prevent this spread, and therefore aim to reduce deaths from cancer.

We do extensive work on the lab bench, using cells and co-culture models (where we grow two or more different cell types together such as immune cells and cancer cells) to make sure our experiments in animals are streamlined. We wish to use a minimum number of animals to answer what are essential questions about how cancers and immune cells interaction.

Only the use of mice will allow up to study the multiple features of cancer and allow the capacity to test potential future treatments.

Which non-animal alternatives did you consider for use in this project?

A literature review of current immunology methods was performed, with a focus on up-to-date development of human explant and organoid cultures. Explants and organoids are examples of techniques that take tumour samples donated from patients and grow them in the lab setting. We can also use blood samples from volunteers. In addition, we are studying the immune cells in cancers by using specific markers to stain and measure them. Where possible we will use these donated samples. Where these do not address important questions, we will use animal models to study more complex questions.

Why were they not suitable?

These human samples of tumour do not contain the full components of an immune system (for example, lymph nodes) and are unable to bring new immune cells in to the cancer. These human samples can typically only be maintained for 2 weeks, and don't permit the study of cancer spread or meaningful response to treatment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimations are based on our previous knowledge on the variability of the outcomes of interest, for the specific animal models used in our lab or from collaborators.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use a variety of strategies to ensure that the minimum number of mice necessary are used in each experiment. We use the NC3Rs experimental design guidelines to design our experiments, for example by ensuring randomization and blinding to avoid bias and increase reproducibility. We use data from small pilot experiments to help calculate animal numbers.

We use standard operating protocols in the lab, meaning that we expect that our care of cells in the lab, the injection of cells, the preparation of drugs and administration of these drugs to mice, all meet the same standard and are consistent. This means that we can design robust experiments using the minimum amount of animals.

We use appropriate controls - for example, control animals do not receive the anti-cancer treatment but receive an injection of fluid so that nearly every condition is the same. By changing only one condition in each group of animals, we can study the effect of that one condition closely.

We house and handle animals using standards that are consistent. We use appropriate animals housing, appropriate protective clothing, and ensure consistency in our approach.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For clinical interventions, such as testing anti-cancer agents, pilot experiments will help us to gain understanding of the response to therapy and statistical variability.

The minimum number of mice that will give a meaningful result will be determined using power calculations. For each animal treated or included in an experiment, we will harvest tissues and blood from the sample animal to obtain as much information as possible. By using imaging, we can follow the same animal over time, which gives meaningful results and reduces the need for additional animals to be studied.

Experiments testing novel treatment combinations will be randomised to ensure variability in tumour growth does not affect experimental outcome.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The least sentient mammalian species that is appropriate for this work, namely mice, will be used for this project. The availability of gene knockout and transgenic mice as well as the ability to manipulate mouse cancer cells in the lab using gene editing techniques gives a great deal of usefulness to the study of cancer in mice. We use good laboratory practice, high standards of training and project management to ensure we continually review our procedures and keep up to date with available refinements.

Why can't you use animals that are less sentient?

In order to study the interaction between a mature immune system and cancer, adult mice are the preferred model. Mice are the most commonly used species for the types of studies we are proposing in this project. Mouse models have been extensively used in the development of a wide range of chemotherapies and immunotherapies alone, and in combination with radiotherapy. They are classified as the lowest order species in which we can study tumour growth and adaptive immunity in a way relevant to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For each step in the protocols we have introduced monitoring and controlling measures to minimise the harms for each animal used in this licence. Some of the most significant ones are specified below:

Tumour induction and growth: Tumour induction will be performed under brief recovery anaesthesia, which allows precise injection of tumour cells to minimise the risk of cancer cells invading muscle.

Tumour cells will first be tested in a small number of animals to analyse expected growth curves and optimise conditions of tumour formation. Only tumours models which are useful and appropriate will be used in further experiments.

Administration of substances: We will typically use substances that are known to be non-harmful at the appropriate dose.

Radiation: Radiation will be applied locally to the superficial tumour, under anaesthesia. Damage to non-target tissues is minimised by the use of lead shielding or focussed

radiation (including imaging) and precise positioning under anaesthesia, or by the use of a linear accelerator (FLASH-RT) that spares normal tissue. We will use FLASH-RT as a means to reduce the side effects of irradiation on normal (non-cancer) tissue. This is in part due to a reduction of the time needed to deliver the irradiation, from minutes (X-ray radiation) to fractions of a second (FLASH-RT).

As a general measure, we will continuously revise our methodology and adapt it according to new policies, technologies and approaches aimed at minimising welfare costs. To achieve this, we will attend the seminars provided by the NC3Rs, keep up to date with NC3Rs recommendations via its website and communicate with the Regional Programme manager for advice to improve the 3Rs in our experiments. Together with the University 3Rs Committee we will diffuse our particular advances on the 3Rs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

A number of approaches will be used throughout the project to minimise adverse effects. Published guidelines for best practice will be followed: for example, Laboratory Animal Science Association Good Practice Guidelines Series 1/Issue 1) October 1998. Administration of Substances (Rat, Mouse, Guinea Pig, Rabbit) and Collection of Blood Samples (Rat, Mouse, Guinea Pig, Rabbit).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Those licensed to work on this project will sign up to the 3Rs mailing lists (if not already signed up). To expand our knowledge on advances in the 3Rs, we will keep up to date with 3Rs newsletters, prepared by the University 3Rs subcommittee and by attending the 3Rs Research day. We will also attend the seminars provided by NC3Rs, keep up to date with NC3Rs recommendations via its website and seek advice to improve the 3Rs in our experiments.

28. Cell fate determination and morphogenesis during early mammalian development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

embryo development, cell movements, stem cells, cell differentiation, morphogenesis

Animal types	Life stages
Mice	embryo, pregnant, adult, juvenile, neonate
Rats	embryo, pregnant, adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our broad aim is to understand at the cellular and genetic level how embryonic pattern is specified. We seek to clarify which cells give rise to various organs in the embryo, how cell movements generate the shapes of these organs and how genes control these events during early embryonic development. We will achieve this by:

Characterising the movement and fate of cells of the embryo, from pre-implantation to early organogenesis stages

Elucidation of the molecular and cellular control of embryonic morphogenesis

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Large-scale cell and tissue movements play a major role in shaping the mammalian embryo. For instance, the embryonic region that gives rise to the heart actually starts out in front of the region that forms the brain. Little is currently know about how the movement of cells and tissues is coordinated to give the intricately shaped structure of the body and how our genes control these complicated movements.

These questions are intrinsically interesting as they address the issue of how we (with a distinct front and back, organs of various shapes etc.) develop from a fertilized egg that is roughly spherical and has no features distinguishing any one region from another. They are also medically important as congenital abnormalities such as various heart defects, cleft palate, spina bifida etc. are the result of improper cell or tissue movements during development. Understanding which populations of cells give rise to different portions of these organs may help in preventing or treating such disorders. This knowledge may also identify stem-cell populations in the embryo or adult that could be used treat various conditions in humans.

What outputs do you think you will see at the end of this project?

Publications, that will advance our understanding of the molecular and cellular mechanism that control embryonic development. All publications will be open-access. The findings in these primary publications will in time be included in text-books and therefore contribute to teaching material in the biomedical sciences.

Public repositories of data that will be of use to other scientists, and occasionally, to the lay public. This will include, but is not limited to: single cell transcriptomic data; single cell epigenomic and genomic accessibility data; time-lapse movie repositories of embryonic development

New methodologies and software for analysing data, both nucleotide sequence as well as image data. The former might include approaches for interrogating transcriptomic data and the latter will include tools for automatically detecting cells outlines. These computational tools will be made publicly available on repositories such as GitHub.

My group is active in outreach activities. For example, we have participated in the annual Science Festival for the past five years. We incorporate our research findings into our outreach material.

We use time-lapse recordings of embryonic development to explain our research to members of the public. We also use our high resolution confocal image volumes of embryos to print 3D models of mouse embryos and embryonic hearts, so that the public can appreciate the remarkable similarities between mouse and human embryos. This new

findings resulting from this project will similarly contribute to addition material to enhance our outreach efforts.

My group is active in public engagement activities where we work closely with non-scientists over a longer term. For example, we have collaborated with a dance group, that uses dance as a medium whereby disabled young people can express themselves. The young dancers used our time-lapse volumes of heart development as inspiration for the dances they designed. the dances they designed. Similarly, the research outputs of this PPL application will be used as inspiration in our future engagement with other artist and members of the public and will likely result in the production of works of reflection, self-expression and art.

Who or what will benefit from these outputs, and how?

In the short-term:

The scientific community will benefit from the knowledge we generate. It will help advance or collective understanding of fundamental cellular processes relevant not only to the embryo but also the adult.

Other scientists will be able to use the knowledge we generate to design their experiments to advance their areas of study.

Other scientists will benefit from the data (e.g., transcriptomic and epigenomic data) we generate, which they will be able to directly interrogate or compare with data from their system.

Researchers working in the area of directed in vitro differentiation of stem cells will particularly benefit as the understanding of normal cell specification that we generate will enable them to design a rational approach for generating in vitro different cell types of choice.

These outputs will be used by other scientists in their research and will therefore potentially contribute to the development of regenerative approaches to treat ailments.

Lay members of the public with an interest in science will benefit from those aspects of our research findings that we disseminate through our public outreach and engagement activities. This will help sustain public curiosity in fundamental research as well as well as respond to curiosity around the fascinating process by which we are shaped in the womb.

In the longer-term:

Our work focuses on fundamental biology. It provides the foundations on which new therapeutic approaches can be developed for clinical impact.

Understanding how normal development occurs will enable us to understand how congenital abnormalities arise. In the longer term, this will help us to avoid or, potentially, even treat them.

How will you look to maximise the outputs of this work?

All our publications will be in Open Access journals, of be made Open Access

We will deposit pre-prints of our manuscript on bioRxiv prior to submission to journals for peer- review.

Where possible, we will create easily usable web-sites that others can use to interrogate our data with minimal technical background. As an example please see: https://marionilab.cruk.cam.ac.uk/heartAtlas/

We will make computation tools we develop easily accessible, either through GitHub or through university repositories. As an example of this, we developed a tool for quantifying protein levels from image data of mouse embryos. This tool is freely available from https://process.innovation.ox.ac.uk/software/p/13299a/silentmark-academic/1

We will publicise our results at conferences through oral presentations and posters.

Species and numbers of animals expected to be used

- Mice: 35,600
- Rats: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodent embryogenesis is similar to human embryogenesis at the genetic and cellular level, and therefore represent a viable model for experimental studies of human embryogenesis. The knowledge we gain from experiments on mouse embryos is essential in understanding the development of human embryos.

Large-scale cell and tissue movements play a major role in shaping the mammalian embryo. For instance, the embryonic region that gives rise to the heart actually starts out in front of the region that forms the brain. Little is currently know about how the movement of cells and tissues is coordinated to give the intricately shaped structure of the body and how our genes control these complicated movements. The aim of this project is to understand at the cellular and genetic level the movements that shape the body. We seek to clarify which cells give rise to various organs in the embryo and how cell movements generate the shapes of these organs.

We will use rodents (mice and rats) as a source of embryos for the experiments we need to perform to address the above questions.

Typically, what will be done to an animal used in your project?

The majority of animals produced under this licence (no more than 36,300) will be used for breeding to maintain strains with specific genetic characteristics and for embryo production. Up to 1% will be recorded as having experienced a mild procedure. All other animals will experience little or no effects from the breeding programme, referred to as sub-threshold.

A number of animals will undergo surgical procedures. No more than 1000 female mice will receive embryo transfers and no more than 100 male mice will undergo a vasectomy. These animals will undergo one procedure with full recovery expected without incident. The surgical procedures are needed to produce new genetically modified mouse lines.

A number of females (no more than 2000) will be used for the production of early embryos using a hormonal injection procedure termed super-ovulation. This is performed to obtain embryos for experimentation or for long-term storage/archiving (cryopreservation).

A number of animals will receive one or more injections of substances that induce an effect in the cells of that animal, or in the cells of embryos females are carrying (no more than 5200).

What are the expected impacts and/or adverse effects for the animals during your project?

Since we study embryonic development, the vast majority of our animals (~90%) are used primarily as a source of embryos and therefore are simply maintained, mated and then killed so as to collect their embryos for experiments.

We will breed and maintain wild type and genetically modified animals. The vast majority of mutants will have nil or minor/transient adverse effects. Genetically modified animals of greater severity (e.g., mild limb defects such as digit duplications, tail defects such as short or entirely absent tail, tooth defects such as loss of specific teeth) will be bred on a separate moderate protocol.

The only procedure the majority of our animals will be subject to is an ear biopsy and/or an injection, which is of mild severity.

Superovulation procedures are expected to result in no more than transient discomfort and no lasting harm.

Surgical procedures will be carried out aseptically. In the unlikely event of post-operative complications, animals will be killed. In the case of wound breakdown, uninfected wounds may be re-closed on one occasion within 48 hours of the initial surgery. Animals are expected to make a full recovery from the anaesthetic within two hours.

For any application of substances done under protocols in this license application, any transgene inducing agents normally have very little or no adverse effects on the overall welfare or health of the animals. In extremely rare cases, adverse effects may arise in the mother from the expression of genes in her foetuses, induced by the administration of substances. There is a very low risk of harm to the mothers from the method of delivery of substances (<1%).

The majority of animals will be killed humanely at the end. Those that are not killed will be transferred to other authorised scientists who might be interested in studying them.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Subthreshold 89%
Mild 1%
Moderate 10%

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of this proposal is to further our understanding of mammalian embryonic development. Since so little is known about this process, it has to be directly studied in embryos from mammals.

Amongst mammals, research using the mouse comes with a relatively low ethical cost. The mouse is also the most appropriate mammalian model due to the well-established molecular genetic technologies available for experimentation.

The majority of developmental stages that we focus on in this project are early enough to not be covered by ASPA. Our use of the embryo to model basic cell biological processes that are also important in adults, such as cell migration, can be considered replacement as otherwise, one might have to use protected animals to study these processes.

Which non-animal alternatives did you consider for use in this project?

Mathematical models
Tissue and cell culture models

Why were they not suitable?

Mathematical models of development cannot entirely replace experiments on embryos since the models are themselves founded on experimentally obtained knowledge and are only as good as the information that went into building them. Therefore, while computational models can help identify the most plausible of several hypotheses for testing experimentally, they are limited in their ability to tell us completely new things about embryogenesis. Therefore, to understand the processes outlined in this project, we need to perform experiments on actual embryos.

Well-constructed models however show 'emergent' properties that were not explicitly programmed into them. We have a continuing collaboration with a group of mathematicians to use mathematical models of cell movements in our studies. This will enable us to use the model as a replacement for embryos in specific initial experimental investigations. It should be noted however that results from the use of mathematical models will invariably have to be verified using actual biological samples.

The specific tissue interactions during embryonic development cannot be accurately recapitulated in cell culture. In recent years, several in vitro 'embryo-like' models derives from ES cells have been developed. Comparison with known developmental events suggest that these do not faithfully recapitulate known aspects of in utero development, particularly with respect to the role of extra-embryonic tissues in patterning, which is a major component of the research in the project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate of animal numbers is based on the following considerations:

the number of embryos we will require to address the objectives of this project and the average yield of embryos at various stages from females of a variety of backgrounds (including, but not limited to CD1, C57Bl/6, 129 and Balb/c)

a forecast of various genetically modified mouse lines that we will need to generate, and the numbers of animals required to generate such transgenic lines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to reduce animal use, we are developing mathematical models that will help us to rule out certain experiments using computer simulations.

A thorough literature search is conducted to ensure that experiments that are undertaken do not duplicate reliable data that is already published or present in data/resource repositories.

Principles of experimental design are applied in order to minimise the number of experiments required to achieve reasonable statistical significance and data reproducibility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When setting up crosses to produce embryos, where possible we use males homozygous for the reporter so that all the resulting embryos carry the reporter gene and are usable.

Where possible, instead of establishing permanent transgenic lines and maintaining a colony, we will use high-efficiency CRISPR technology to create ‘transient transgenic’ lines that will produce enough mutants for our experiments with fewer mice. This may include the administration of transgene inducing agents to pregnant dams that have undergone an embryo transfer in protocol

Protocol 1 and 8 allows us to produce a greater number of viable embryos from a single dam.

Where possible we will import previously generated GM mouse lines from colleagues/collaborators/resource centres.

Stock levels of mouse strains will be set to minimise animal breeding whilst at the same time ensuring that given strains are not lost. Trained animal house staff will carry out the majority of breeding and maintenance, constant contact and instruction will ensure the colonies are maintained at the correct levels.

To avoid unnecessary breeding/maintenance of strains we will archive (embryo/sperm cryopreservation) when no longer needed, where we can access them at a later stage. We will supply cryopreserved embryo/sperm to other investigators on request in order to reduce duplication of animal experimentation.

Where possible, we will use embryonic stem cell derived ‘embryoid bodies’ (EB) as a replacement for actual embryos. Our preliminary experiments suggest that we may be able to test hypotheses initially in EB before verifying results in actual embryos. This will lead to a reduction in the total number of embryos (and therefore animals) used.

Tissues/embryos, DNA/RNA and protein samples obtained from experimental animals/embryos are preserved, usually by storing in liquid nitrogen or at -80c, to allow where scientifically justified, use in other experiments by ourselves or other scientists who may request such reagents.

Where possible, we will harvest rat serum for embryo culture from our rat colony. Such serum will be used to verify the suitability of commercial serum for embryo culture. This will enable us to ensure embryo culture conditions are robust, thus ultimately leading to a reduction in the total number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project focuses on understanding mammalian embryonic development. The genetic basis for the development of mouse embryos is sufficiently similar to that of humans for it to be a viable model of human development. The majority of mice will be used only as a source of embryos, and therefore will not suffer any experimental procedures. The mice will be killed humanely in order to recover embryos from them.

Regarding specific procedures:

Vasectomy – Animals are expected to suffer no more than moderate harm due to the nature of the scrotal sac method which is the most refined method for this procedure. When available, we will acquire genetically altered or naturally sterile males that don't require vasectomy.

A surgical procedure termed laparotomy is routinely carried out on pseudo-pregnant recipient female mice (after mating with sterile males) for the implantation of embryos during production or rederivation of genetically altered animals. The procedure can be performed on one (unilateral) or both (bilateral) sides of the abdomen depending on the number of embryos requiring implantation, the stage of development at implantation and the number of pseudo-pregnant recipient mice available. An alternative non-surgical procedure termed transcervical transfer can be carried out but only on embryos at a specific late stage, referred to as blastocyst.

Superovulation by hormone injection is the standard method to collect the most oocytes and zygotes from the least amount of females. The appropriate concentration of hormone is age, weight and strain dependent, having been optimised in studies over many decades.

Under breeding and maintenance of genetically modified mice, most animals are not expected to suffer any more than mild pain. Expected actual severity is sub-threshold. Some animals are bred under a moderate severity and although not expected to show a harmful phenotype this is always a possibility. Adults that do show any harmful effects will be culled.

Administration of substances will be carried out by the most refined method available.

Why can't you use animals that are less sentient?

Non-mammalian species such as the zebrafish are not suitable for this work as they do not show several features of development seen in mammals (such as implantation in the womb, or a four- chambered heart). Moreover, mice are the lowest mammalian species in which it is relatively easy to make the genetic modifications required for this project.

The genetics of mouse development have been long studied, providing a good foundation for our work. Mice are the most suitable mammalian species of the lowest sentience that it is relatively easy to make transgenic modifications in. Technologies exist for knocking out gene functions, and chemically inducing gene expressions. The vast majority of the mutants we work with are recessive, i.e., they suffer no physical changes when kept as breeding colonies. In the homozygous condition they are generally embryonic lethal, so in general we do not maintain homozygous affected individuals for the majority of our mutant lines.

The genetic basis for the development of mouse embryos is sufficiently similar to that of humans for it to be a viable model of human development. Furthermore, the early mouse embryo is a powerful model for studying basic cellular and genetic processes that operate in adult contexts, both in healthy and pathological situations. One of our main research questions is how cell migration is controlled in epithelia. The early post-implantation mouse embryo is a good model for characterizing such movement by volume imaging as it is small and the epithelial tissue of interest on the surface of the embryo. It is also a good model for addressing the mechanistic control of cell migration, as it is amenable to manipulation in culture and various mutants with defective cell migration exist. In order to perform comparative studies on the influence of basic physiological processes on embryological patterning (e.g., initiation of cardiac contractile activity), we will occasionally use embryos from Rats, that are a well-established model system, particularly for cardiac physiology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We make use of all method which allows us to have a higher efficiency of targeted homologous recombination (e.g. CRISPR 2C-HR) during microinjection.

We will keep up to date with all surgical procedures and their refinements and will attend any relevant workshops.

Laparotomy surgery will cause moderate suffering. Non-surgical implantation through the cervix may cause distress if the handler is not as proficient but is not expected to cause harm. Animals are expected to make a rapid and unremarkable recovery from the implantation procedure.

Analgesic agents will be administered.

Animals to undergo surgery are given at least 7 days to acclimatise before procedure starts.

We will ensure that embryo culture condition are optimal at all times. To this end, if required, we will produce our own rat serum.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.

Code of practice for the housing and care of animals bred, supplied or used for scientific purposes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By regularly attending the NC3Rs days organised at the University.

Regular contact with transgenic groups within our institution allow us to update each other with advances in techniques and training.

Departmental animal welfare meetings held termly allow us to communicate any 3Rs implemented within our group and invited members including NACWOs and NVS ensure that any new advances are disseminated.

Attending the termly Gold Standard and Animal Welfare meetings during which advances in the 3R are frequently discussed.

29. Synapses in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Alzheimer's disease, Synapses, Microglia, Immune response, Genes

Animal types	Life stages
Mice	neonate, juvenile, adult, embryo, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how risk-factors modify neuronal and glial phenotypes throughout the life span of models of Alzheimer's disease in relation to normal function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The leading cause of death in the UK is now dementia, the most common form being Alzheimer's disease, accounting for 12.7% of all deaths registered in 2018 (i.e. the most

recent data available at the time of preparation;
https://www.ons.gov.uk/peoplepopulationandcommunity/healthandsocialcare/causesofdeath/articles/le adingcausesofdeathuk/2001to2018). Alzheimer's disease is characterised by increasing deposits in the brain, both inside cells (tau tangles) and outside cells (amyloid-beta plaques).

There are no effective treatments for the disease. Those that are currently in use only temporarily alleviate the symptoms, probably by increasing general awareness and concentration but do nothing to slow the insidious development of tau tangles and resulting cell death.

A large hole in our understanding is how the initial triggers of Alzheimer's disease, raising Amyloid-beta and its subsequent deposition, lead to tau tangles and neuronal cell death. Mouse models of the disease have been very successful in modelling the early Amyloid-beta component but they do not develop tangles or substantial neurodegeneration, unless the link is bypassed by the introduction of changes in the tau gene. However, such changes in the gene for tau have never been identified in Alzheimer's disease (but are relevant to other related diseases).

Our previous work indicates that mice have a very strong immune response, involving many of the genes associated with Alzheimer's disease. While in humans these are typically changes that cause loss-of-function, in the mice the expression of these genes is increased. We therefore believe that one reason for mice failing to develop the late stages of the disease is this strong immune response and we therefore intend to employ models that compromise this response by introducing changes into immune genes and also to combine other high-risk-factors, like obesity.

By studying such models, we will gain invaluable information on how the immune system interacts with neuronal function; how obesity interacts with neuronal and immune function; how obesity interacts with the immune system to affect neuronal function; and, crucially, how all these combinations interact in ageing and Alzheimer’s disease. This information is gained irrespective of whether combining these factors leads to the ambitious aim of developing a ‘Gold Standard’ model, whereby mice develop all stages of the disease but in the absence of changes in tau.

What outputs do you think you will see at the end of this project?

The outcomes of the project cover several levels from, 1. synaptic transmission and study of neurones (nerve cells) and glia (the immune cells of the brain) within brain tissue to 2. measurement and localisation of brain proteins and gene expression and 3. behaviour. Moreover by using the same mouse brain for several different tests the data can be correlated and the number of mice used minimised. Our key outputs are thus run in parallel, allowing us to study the brain from genes to cognitive function. Specifically, we examine gene expression (neuronal and glial gene specific; or using a genome-wide approach), neuronal and glial protein expression, synaptic function and behavioural

outcomes. We will study these in a number of mice that will reveal how risk-factors interact to modulate disease and normal function. Importantly, the results of one section is not dependent on the success of other sections and, therefore, the chances of useful data that advance our knowledge is increased.

1) Alzheimer's disease is usually a disease of old-age. However, this crucial aspect is often overlooked, with many studies focusing on young adult or middle-aged mice, at oldest. This project includes animals right up to end-of-life and will therefore inform us about neuronal and glial function in both normal ageing and its interactions with Alzheimer's disease.

2) TREM2 is a microglial gene with rare gene variants that substantially increase the risk of developing Alzheimer's disease. One such variant is a loss-of-function mutation, TREM2R47H which increases the risk of developing Alzheimer's disease by more than 3-fold; a similar increase to that caused by more common APOE4 variant. Studying the TREM2R47H variant in knock-in mice will allow us to understand how compromised microglia affect disease-related effects.

3) Obesity is a major risk-factor for developing Alzheimer's disease. Feeding wild type mice a high-fat diet will allow us to understand the effects of obesity throughout life within the wider population. Feeding the Alzheimer's disease model mice a high-fat diet will offer insights into how obesity exacerbates disease. It is important to include the WT group to assess whether any changes seen in the APPKI mice are simply additive or are interacting with the Alzheimer's pathology. It should be noted that feeding wild type mice a high-fat diet does not induce Alzheimer disease-like pathology; this was established under our previous PPL and at time of application, a manuscript reporting these findings is in preparation. Conversely, we may employ dietary restriction, which has been shown to improve both life-span and quality of late life.

4) A key step in disease progression which is missing from mouse models of Alzheimer's disease is the development of tau tangles. One explanation for this is that human Amyloidβ may not interact with mouse tau in vivo in the way that occurs in Alzheimer's disease We therefore will examine whether humanising the tau gene (Mapt) affects neuronal function in otherwise normal mice and then whether humanising Mapt results in progression to Tau tangles in Alzheimer's model mice.

5) All interactions of the above will also be combined. We will thus study obese Alzheimer's model mice with humanised tau, compromised microglial function (TREM2R47H).

Each stage of these experiments will inform us about those functions and their subsequent interactions. We may also find that this combination of risk-factors results in mice developing tau tangles and neurodegeneration without the introduction of mutations in tau. Such a gold-standard mouse would be crucial for the wider research community, allowing elucidation of how raising Amyloidβ levels and its deposition into plaques results in tau

tangles. It would thus also provide a much improved model in which to test potential therapeutics. However, this would indeed be the 'icing on the cake' and the proposed outcomes above are not dependent on the development of tangles, nor indeed of changes observed at any one stage of the project.

All the results from the experiments will be published in open access format in high profile journals as well as being presented at conferences to maximise the benefit of our findings to the wider scientific community.

Who or what will benefit from these outputs, and how?

While unlikely to be achieved within the lifetime of this project, the ultimate beneficiary is the community at large. With Alzheimer's disease already the leading cause of death and the incidence rising along with the ageing population, it is crucial that we understand this disease. While the health benefits are arguably the most important, the economic costs to the taxpayer should also be considered. The annual costs for caring for people with dementia is more than that for cancer and cardiac disease combined.

The broader neuroscience and Alzheimer's research communities, both at a basic and clinical research level, will also benefit. At the basic level, understanding how risk-factors interact will inform further research in the field. Along-side the Alzheimer's field, the research will inform physiological research: how does ageing affect neuronal function and brain’s immune responses? How does obesity affect these responses? If the combination of risk-factors successfully results in generating the 'gold-standard' mouse model, then all subsequent basic research will also benefit from having a much improved model. Moreover, this model would then be available to benefit clinical research, as confidence in the animal research would be much improved and lead to better translation to the clinic.

How will you look to maximise the outputs of this work?

The lab is highly collaborative. Many of our publications are from authors of multiple institutions both nationally and internationally. Active collaboration that are currently in place include co-supervision of a PhD student, funded by the Swedish Alzheimer’s Foundation; a long-standing active collaboration with a world-renowned geneticist from our institution; ongoing interactions with other local dementia researchers; and interactions with clinical research staff.

All research is published in peer-reviewed and open access journals. We also have a freely accessed web-based database, allowing anyone to search for genome-wide expression data from 5 different transgenic mouse models and across the lifespan. This will very soon be updated to include data from the improved APP knock-in mice.

Publication of unsuccessful approaches has been notoriously hard to achieve and is fraught with problems with assessing the cause of the failure: inexperience, incompetence, poor specificity of the reagents used, lack of power to detect small effects, or indeed that there is a genuine lack of effect. However, our recent funding to develop organotypic brain

slice models of Amyloid β plaque development has failed to reliably produce plaques and we are aware that other groups have similarly failed, making it likely that the results (or lack there-of) are real. We are therefore investigating the feasibility of a group publication, using the independence of the groups and differences in approaches as a strength to support the idea that organotypic brain slices do not make a good model for Alzheimer's disease and thus prevent further ongoing attempts (and use of animals), unless someone can see where our previous combined attempts may have failed and improve on those.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice offer the best model for Alzheimer's disease: one that provides an in vivo mammalian central nervous system without using non-human primates. We have explored using rats as a better model, but these offer little if any further correlations to the disease than mice do, but have some extra welfare requirements. Conversely, invertebrate models such as flies and worms (which have their appropriate place in neuroscience and Alzheimer's disease research) fail to provide the similarities to humans, particularly in terms of brain structures and mechanisms of synaptic transmission. Importantly, mice are very amenable to genetic manipulation and reach old age within the life span of typical research grants (mice typically live to 24-36 months of age; a typical grant is 30 (or rarely up to 42) months).

By the very nature of Alzheimer's disease, typically a disease of old-age, we need to study adult and aged-adult animals. However, there are situations when using tissue from embryos or neonates is appropriate. When such situations arise, we indeed use these and they are included in this licence application.

Typically, what will be done to an animal used in your project?

The vast majority of animals undergo no interventional procedures such as surgery or substance administration. They are, however, bred carrying genes that in humans cause familial forms of Alzheimer's disease. Once they are weaned from the mother at 3-weeks-old, they are group housed with their littermates in a slightly enriched environment (bedding, chew toys, houses) and aged to an appropriate age (anything from weaning through to end-of-life at 24-36 months-old), until they are removed from the cage to the laboratory and killed humanely.

Once the animal is dead, the brain is rapidly removed to keep the tissue alive and submerged in artificial cerebrospinal fluid. We can then cut the tissue and keep brain slices alive for the remainder of the day, allowing us to make electrical recordings from either single or populations of neurones. From the same brain, we can also get immunohistological (information about distribution and amount of specific proteins) or genetic data, allowing us to correlate all of these.

The aim of this project is to combine risk-factors for Alzheimer's disease, investigating either their singular or combined effects. Specifically, we will compromise the function of microglia (the innate immune cells of the brain) and/or make mice obese by feeding them a high-fat diet. This may exacerbate the Alzheimer's disease phenotype, providing crucial information on how these risk-factors modulate the disease and potentially offering therapeutic targets by which we can hopefully slow the progression of disease. Conversely, we may employ dietary restriction, which has been shown to increase life span and, moreover, quality of extended life.

A small subset of animals may undergo surgical procedures from which they recover. This is to enable us to delivery substances to the brain to modulate neuronal (or other cells) function. Such procedures can either be short (e.g. injection under anaesthesia) or long-term in which we fit a small slow-release pump, designed to fit under the skin at the back of the neck of a mouse, and will release substance over the following month.

Some of the animals that have been on a high-fat diet or have undergone the surgeries described above, may undergo behaviour testing. This is usually reward-based testing. For this, the animal has food withheld overnight so that it is motivated to retrieve a food or liquid reward, typically sweetened condensed milk. Animals then explore an open arena or a maze, and are assessed on their ability to remember either previously encountered objects or previously visited areas of the arena or maze. We usually opt for single-trial tests that last for 30 minutes at most but are typically a couple minutes in duration and include habituation to the arena as part of the test on the same day. Following testing the animal may then be returned to the home cage for further similar testing later in life or be killed for the above described experiments examining neuronal function, genetics and immunohistology.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals, even ones that possess genes that cause Alzheimer's disease and have been combined with risk-factors, never develop to stages where they display clinical symptoms . However, one of the aims of the project is to exacerbate the progression of these models and we would therefore predict that some of the animals in the study may develop a neurodegeneration that presents with the animal having slow responses, moving little in the cage with a hunched posture, piloerection as well as loss of weight. This is distinct from the general slowing seen as animals age. If this phenotype becomes apparent, the animal is always killed on that or the next day and the brain used in the

described experiments. Importantly, a collaborator has used in-cage behavioural monitoring to assess some of the crosses we will use, aiding us to monitor clinical signs prior to likely onset. Feeding mice a high-fat diet offers further considerations. We have experience of this procedure from our previous PPL and have an established monitoring regimen to check weights, blood tests for diabetes and body condition to ensure that animals are able to move properly.

Contrary to perceived outcomes, dietary restriction is not detrimental to animals. 60% food intake provides sufficient vitamin and mineral intake and actually increases life-span and, moreover, quality of that life (Fontana and Partridge. Cell 161:106-118, 2015).

Following surgery, we have excellent recovery rates. However, interactions with the Alzheimer’s disease phenotypes could add unforeseen complications. We have in place an established monitoring system to ensure that mice recover, both immediately from the surgery and are not developing unforeseen adverse effects caused by the administered substances.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

While our protocols have either mild or moderate severity limits, most of the animals (>90%) will not develop clinical symptoms and would have a severity rating of sub-threshold.

Some of the Alzheimer's model mice (~10%), particularly those that also have compromised microglia and are fed high-fat diets, may start to show some overt traits such as diabetes and may reach a mild severity. A very small proportion (<1%) may show neurodegenerative-like symptoms and be considered as a moderate severity.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While there are certain questions that can be answered very well using either computer modelling or cell cultures, these do not replicate the complex interactions of an intact

animal. Understanding how the brain's immune system, particularly microglia and astrocytes, interact with neuronal cells requires an intact brain, which cannot be modelled in vitro or 'in silico'. If we then bring in how Amyloidβ modulates these interactions and their effects on the brain, such modelling is nigh-on impossible. Using rodent models is the best option, as they offer a mammalian brain that in many aspects is similar to human (same neurotransmitters, analogous brain structures), are readily amenable to genetic modifications and allow us to perform other interventions that would otherwise not be achievable ethically in human studies. Importantly, being able to kill the animal and remove the brain at variable stages prior to natural death permits high-resolution analysis that cannot be achieved with the current technology for live patients.

Which non-animal alternatives did you consider for use in this project?

Cell cultures.

Induced pluripotent stem cell (iPSC) cultures from patients.

Computer modelling.

Why were they not suitable?

At the time of our previous PPL application, there was limited evidence that a 3D mouse neuronal culture could replicate some of the pathological features of Alzheimer's disease, however this not been reproduced by others, or indeed the same group.

iPSC cultures do, to some extent, achieve the pathological features of Alzheimer's disease. However, adult levels of Alzheimer's-relevant proteins such as mature forms of tau are not present until 2 years in culture (it is an admirable feat to maintain such cultures for so long!) and, importantly, these cultures still fail to retain the complex in vivo interactions of CNS immune cells, sensory inputs or other peripheral inputs.

Moreover, to date, there are no reports of them having developed tau tangles as a result of APP mutations and thus present with the same key limitation of the animal studies in addition to the limitations discussed above.

Computer modelling again is very limited in relation to Alzheimer's research. Indeed, it is limited for understanding normal function where the types of interactions between different cell types and proteins are only just being identified and cannot therefore be factored into simulations. However, we are currently exploring modelling Amyloidβ plaque growth to understand different deposition patterns.

In addition, in our last licence, we explored using organotypic brain slices, which maintain the basic neuronal connectivity of the hippocampus and retain all the cell types normally present. However, similar to independent trials by other groups, we were unfortunately unable to reliably model Amyloidβ deposition. Organotypic brain slices do, however, have

an ongoing role within the lab in understanding certain neuronal functions, particularly related to normal function.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we propose to use were determined by power analyses based on a mixture of experience with previous experiments that indicate expected variation and effect sizes, thus numbers of animals required to reliably detect a real effect. Importantly, the numbers of litters we will need in order to supply the sample sizes we need were calculated using our local Biological Services Unit animal costs calculator.

The sample sizes identified from such analyses are then scaled up by the number of different experiments we intend to perform. We also factor in attrition, particularly when we are studying the oldest ages.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The design of the experiment has been peer reviewed several times (e.g., for our previous PPL 70/8999, for successful grants and for peer-reviewed publications.). Important factors we consider include: the random assignment of cages to different treatments (for example control versus high-fat diet); performing experiments blind to genotype/treatment wherever possible and always analysing blind to genotype or treatment group; ensuring that the appropriate sample sizes have been attained for replicates within a given experiments; avoiding pseudoreplication, which is a common error in electrophysiology whereby multiple cells are recorded from a single animal and then treated as independent samples; we have a degree of repeating experiments by independent operators or blind- reanalysis by two independent operators; wherever necessary, covariates are factored into the statistical analysis so that the influence of other different factors can be considered (it should be noted that, using genetically identical mice raised in identical conditions, rules out many of the confounding factors that are common to human studies.)

Wherever possible we breed mice in colonies that limit the number of unusable genotypes. For example, when homozygous and wild type mice are required, we try to avoid using heterozygous x heterozygous crosses as 50% of mice will not be useable (other than for replenishing breeders). We would therefore have three colonies: two larger colonies, one with homozygous x homozygous mice, the other with wild type x wild type; and a third, smaller colony of heterozygous x heterozygous mice, which enables us to confirm that there are no differences in development and rearing of young between mutant and wild type mice. Thus, we largely avoid producing animals with unusable genotypes.

We have also started using both female and male mice whenever possible and this is the case for most of our experiments. There are some cases, however, where the female oestrous cycle causes substantial variation which can confound the experiment. One example is densities of hippocampal dendritic spines, the sites of many synapses on neurones. There is a >15% variation in density between pro-oestrous and oestrous phases and thus we would identify potential phenotypes in males first for these types of experiments and later determine whether a repeat using female at known stages of oestrous is required. While it is of course extremely valuable to understand the role of the oestrous cycle and to tease out effects that may be dependent on these variables, this is a subject in its own right, requiring many more animals and substantial additional time and resources. Interestingly, however, for many of the variables we are testing we find little if any difference between male and female mice and generally use both. Indeed, all female mice that are bred (and are of usable genotypes) are now used in experiments rather than culled and sex is used as a factor in our multivariate analyses.

The tissue from all animals are used in multiple experiments. A single brain is bisected into its two hemispheres, which then are processed in at least two, sometimes three ways. One hemisphere can be fixed for immunohistological examination (visual examination of the distribution of particular proteins), the other frozen for other protein or genetic analyses.

Alternatively, one hemisphere is sliced for live recording using electrophysiology, the slices from which are often shared between multiple experiments, increasing the output; with the other hemisphere fixed for histology. It is possible to snap freeze one hemisphere, slice the other for live recordings and also drop fix one of these slices for histology. Importantly, this approach not only reduces the number of animals but also increases the power of the experiments as we can correlate the different types of results within a single animal (see next section).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As discussed above, breeding regimes try to limit the numbers of unusable genotypes. Staff members involved in setting up breeding have attended accredited courses aimed at improving and optimising breeding regimes for mutant mice. Breeding records are maintained within a shared online system such that pedigrees can be traced and future generations planned.

Using both male and female mice means that the overall numbers of mice used in a given experiment is higher (but not double) than if only males were used. But, we now have the data to determine if males and females respond differently and, if not, a higher statistical power once the data are combined.

Also discussed above is that tissues are shared between multiple experiments. This sometimes extends beyond our lab, with us having, in the past, used brain tissue from rats intended for a cardiac experiment and others having come to collect peripheral tissues when we harvest brain.

If we embark on a non-standard experiment, pilot studies using small numbers of animals are always performed. We can thus determine whether the drug is tolerated or having the expected (or unexpected) effects before scaling up to full numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The choice of using rodents has many-fold advantages. Firstly, they are mammals and therefore share many of the features of humans (although consideration of their differences should be made). Secondly, they prove very amenable to genetic modification, making expression of genes associated with dementia more practicable than many other mammals. Thirdly, they are easily housed in animal units and do not require much specialised care beyond food, bedding and minimal enrichment within the cage.

Importantly, we have moved away from using transgenic mouse models of Alzheimer's disease, which have generally fallen out of favour with the research community as they overexpress amyloid precursor protein (APP), resulting in many off-target effects. Instead, we use APP knock-in mice which were recently developed that avoid this overexpression artefact and also ensures expression of the proteins at the right time and place.

A further advantage of moving away from the transgenic models that we have previous employed is that the incidence of seizures in the transgenics is relatively high. Our previous licence indicated that up to 25% of the so-called TASTPM transgenic mice die suddenly from a severe tonic-clonic seizure; a phenotype shared by several other models. Having moved to the more refined knock-in models, this phenotype is no longer common and occurs no more frequently than in the in-bred background strain (i.e. very rarely).

Our aim is to combine factors to exacerbate Alzheimer disease-related phenotypes in order to produce better models of disease and thereby further our understanding. To this end we will take the best available models available at the moment (discussed above), which currently are the NL-F mice from RIKEN (https://doi.org/10.1038/nn.3697) and cross these with mice that have a genetic risk factor for the disease, for example the R47H mutation of the microglial gene TREM2. Alone, this mutation causes little effect, at least at the level of welfare of the whole animal. However, when crossed with the APP knock-in mice we hypothesise that the disease symptoms will be exacerbated. On top of this genetic risk, we will incorporate an environmental risk for the disease, obesity, by feeding mice a high-fat diet. Our choice of diet is such that it represents a more typical Western diet than many high-fat rodent diets available – for example, many contain 60% fat, while we will use a 40% fat diet that is much closer to the content of, for example, a typical hamburger. As we are trying to model neurodegenerative disease, some of our mice will develop a harmful phenotype. However, upon the onset of clinical symptoms, animals will be killed humanely for use in experiments. Generally, however, most experiments are aimed at the stages leading up to neurodegeneration and therefore most animals will never reach this stage.

However, particularly with new models additional checks are taken to ensure that unexpectedly or unusually rapid development of potentially harmful phenotypes are not occurring.

Where surgeries are employed, every care will be made to minimise pain and distress. Anaesthetics will be used during the sterile procedures and analgesia provided peri- and post-operatively. Animals are then closely monitored during the initial stages of recovery until we are confident that recovery is proceeding appropriately and monitoring can be reduced.

Why can't you use animals that are less sentient?

We always use the animals of least sentience that is suitable for the question asked. However, in modelling a human disease of old-age that largely affects cognition, we cannot avoid using an appropriately sentient mammal for many of the experiments proposed here. Most of our experiments do not involve animals that have undergone surgery. Most are bred and then remain in their home cage until they are killed for tissue harvest, the only scientific procedure being that they are genetically modified (although this genetic modification can be harmful in that it causes an Alzheimer's disease-like phenotype).

If appropriate, we use organotypic slices that are prepared from 5-day-old pups, prior to much postnatal development. These cultures develop to mature neurones and retain the typical hippocampal trisynaptic connectivity and importantly are readily amenable to manipulation in vitro. However, their major limitation is that they are no longer in an intact animal and therefore influences of the rest of the brain and periphery are no longer present. However, on some occasions the initial effect of a manipulation and assessment

of dosage can be ascertained in an organotypic slice before being applied to a more relevant system. It also allows serial observation of effects over time without repeated intervention for an animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our protocols are designed to enable us to use the most appropriate drugs and methods. So, should new anaesthetics or analgesics become available and recommended by the NVS or NACWO, we can readily change to these.

We have recently increased the frequency of post-operative monitoring to ensure that recovery proceeds as expected.

Housing very aged mice is not typical for many colonies. In terms of monitoring for welfare purposes, mice are changed to a different protocol aimed at care of aged animals from the age of 15 months. This protocol provides frequent monitoring for weight loss and frailty, identifying fatty lumps versus tumour growth, deterioration of eyes and potential behavioural phenotypes associated with neurodegeneration. If any signed are detected, daily monitoring is instigated and declines in health causing undue suffering would mean that the animal is killed for experimentation immediately.

Our institutional standard is to provide some environmental enrichment. All home cages are supplied with nesting materials, a shelter, a cardboard tube and wooden chew toys. As discussed, single housing is avoided wherever possible so that mice have a social structure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have several hard copies of Wolfensohn & Lloyd, Handbook of Laboratory Animal Management and Welfare 3rd Ed, which we always direct new PIL holders to and also reference anything we would like further clarification of.

Current best practice according to the Report of the BVAAWF/FRAME/RSPCA/UFAW Joint Working Group on Refinement, 2001 (https://doi.org/10.1258/0023677011911345) is referenced in this PPL and should always be referred to for procedures involving administration of substances.

The UFAW handbook on the care and management of laboratory and other research animals, 8th Ed edited by Robert Hubrecht and James Kirkwood, is also available as an e-resource via the Library to complement the above.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institutional Biological Services offer courses related to the 3Rs, alongside literature and email notifications of advances. When regulations or best practice changes, we readily adopt them to improve the welfare of our animals.

The bottom line is that for the welfare of our animals but also for the most reliable and translatable results of our experiments the aim is to have the healthiest and least stressed animals possible within the contstraints of the experiment.

30. The nervous system influences on pancreas development and physiology

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

pancreas, islet of Langerhans, diabetes, development, in vivo imaging

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to assess the cellular and molecular pathways used by the central and peripheral nervous system to regulate pancreas development and pancreas function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pancreatic islets of Langerhans are made up of different cell types, including the endocrine hormone producing cells, blood vessel cells, and nerve cells. Of the five endocrine cell types, the most well known are the insulin producing beta cells that lower blood glucose levels and glucagon producing alpha cells that raise blood glucose levels. Release of

these hormones from the pancreas needs to be tightly regulated, and changes in this balance could result in diabetes. While communication between different endocrine cell types have known roles in regulating pancreas function, the role of nerve cells has been debated. This is in part due to the limitations in our ability to study endocrine cell activity in living mammals upon changes in nerve control. The goal of this proposal is to use the zebrafish as a model to study the role of nerve cells in the development and function of the endocrine pancreas. Given their optical transparency and rapid development, the zebrafish can be used to visualize and track the developing nervous system in the same animal. Furthermore, we can dissect the impact of different nerve cells on the pancreas. This work is critical for understanding diabetes onset and progression given the changes in nerve networks are observed in patients with different types of diabetes.

What outputs do you think you will see at the end of this project?

This work is expected to provide new knowledge about the nerve signalling pathways that regulate pancreas development and function. The primary expected benefit is publications of new scientific knowledge about how specific nerve cell types improve pancreas development and function.

Who or what will benefit from these outputs, and how?

The data produced in this project will be presented at national and international conferences and published in academic journals. Additionally, the results of this research will be shared with the general public through outreach/public engagement activities, including the department's Diabetes Specific Patient and Public Involvement Group. The new information will allow for the better understanding of how nerve signalling regulates pancreas development and function, from how single cells behave to how they are organized to form an efficient organ.

Changes in the nerve network in the pancreas has been observed in post-mortem human pancreas samples from patients with diabetes. Yet, our knowledge on whether these changes are a cause or consequence of the disease is very limited. This project will provide important insights into the role of nerve cells in the development and function of the pancreas, which in the long-term could help our understanding of diabetes onset and progression and advance therapeutic developments for the treatment of diabetes.

How will you look to maximise the outputs of this work?

The findings will be made available through publication in open-access journals and presentation at scientific meetings. New genetically altered animals generated will be valuable and made available to other scientists interested in studying organ innervation and/or pancreas biology. The findings will also be shared with the general public through outreach/public engagement activities, including the department's Diabetes Specific Patient and Public Involvement Group.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 12500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

There are several advantages to using zebrafish to study how the nerve cells and the pancreas communicate. (1) The eggs are fertilized externally, (2) the embryos develop quickly, and (3) the embryos and larval zebrafish are transparent. All together, these advantages allow us to execute detailed and non-invasive live animal imaging to study organ development and function. The metabolic and signalling pathways controlling the zebrafish physiology and cell behaviour are very similar to mammals, which makes the zebrafish a good model for studying human diseases.

Genetic engineering techniques can be used to make genetically altered zebrafish to carry out these studies. This includes inserting new genes not normally found in the zebrafish or introducing mutations that alter the expression or function of a gene of interest. By inserting new genes, we can make genetically altered zebrafish that can light up specific cell types or change cell behaviour by turning on the expression of specific proteins. To make these genetically altered animals we need to first inject the genetic material into zebrafish embryos, grow up a batch of ‘potential founders’ to adult stages, then screen for fish that have inserted the genetic material into the sperm/egg cells. Not all of the ‘potential founders’ will have the genetic material inserted in the sperm/egg cells and the efficiency of this process is dependent on several factors. Once a good ‘founder’ is identified, the genetically altered zebrafish will be maintained through mating the adult zebrafish and growing up their offspring, a process termed ‘rederivation’. Since zebrafish can give offspring up to 18 months of age, new generations of genetically altered lines will have to be started prior to 18 months.

These genetically altered adult zebrafish are critical for the outlined studies because they provide the offspring for our non-invasive live imaging in embryos and larvae. Prior to 120 hours post fertilization, the pancreas of the fish already has a structure that is more like adult mammalian pancreas and the cells in the pancreas can produce hormones (including insulin and glucagon) to help control blood glucose levels. Importantly, a rich nerve network is present in the pancreas and our data suggest that this nerve network is important for pancreas function.

Typically, what will be done to an animal used in your project?

We will be generating, breeding, and maintaining genetically altered zebrafish that are not expected to display adverse effects in adult stages (including weight loss, tumors, and abnormal feeding/swimming behaviour). These genetically altered animals will supply the offspring that will be used in the project studies.

The genetically altered animals will be housed in standard conditions and routine welfare assessments will be conducted.

What are the expected impacts and/or adverse effects for the animals during your project?

The adult genetically altered zebrafish are not expected to display any adverse effects during the project.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The highest severity that all animals could experience in this protocol is mild.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

One cannot study the dynamic role of nerve cells on pancreas development and function by simply culturing the cells in a petri dish. First active blood flow influences the development of the pancreas and second there are different types of nerve cells in the pancreas. It is difficult to recreate the exact network of nerve cells and blood vessels in a cell culture setting. We therefore need animals to understand what happens to the different cell types in the pancreas as we model the role of nerve cells.

Which non-animal alternatives did you consider for use in this project?

In vitro cell culture studies of pancreatic tissue obtained from human cadaveric donors with nerve cells could serve as a complimentary non-animal alternative for this project. Once we have narrowed down the specific pathways, we will assess the impact of selected proteins on cell behaviour using cultured pancreatic cells/tissue slices and pancreatic cell lines.

To advance scientific knowledge, computer modelling will be used to predict the changes in how pancreas cells communicate upon alterations in nerve activity.

Why were they not suitable?

In vitro cell culture studies will not fully re-create the complex network of different nerve cells in the pancreas and the active blood flow that exists in a live animal. In order to study how the nervous system influences organ development and function we need to first conduct studies in live animals where the structure and function of the nervous system and the pancreas are intact. The data generated from these studies are required for the generation of computer models and the design of specific in vitro cell culture studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on our work using genetically altered (GA) fish lines for the past 6 years, we estimate that 12500 animals will be needed. This estimated number of animals is based on the number of genetically altered lines that will provide the offspring required to complete this project. All of the studies will be conducted on embryos prior to being capable of independent feeding, which will allow us to reduce the number of protected animals used. We will obtain established GA fish lines whenever possible.

Approximately 75% of the studies will use GA fish lines that are already established. During the course of this 5 year project, we plan to establish 20 new GA lines, based on our current number of preliminary targets and the number of inducible tools not yet established. From our experience, the efficiency of finding a good founder when generating new GA lines can range between 1 in 20 to 1 in 150 adults. For new GA lines, we will start by growing 50 fish for the first round of screening. More fish will be grown and screened if the initial screening does not produce a good founder. We estimate an average of 100 potential founders will be grown per line. All newly generated and imported GA lines will be frozen (with sperm collection form 4 different males per line).

50 GA lines will be housed at any given time to provide the offspring for all the studies conducted on embryos prior to being capable of independent feeding. Adult zebrafish can be maintained for up to 18 months of age; therefore, a maximum of 5 generations of rederivation over five years will be required to maintain the GA lines. Based on our experience, a maximum of 40 GA fish will be maintained per GA line. This will ensure that the animals are housed in a socially enriched environment and enough number of adults will be available to provide the offspring for the proposed studies. Although adult zebrafish can provide approx. 200 embryos per round of breeding, following selection of the transgenes and/or mutations of interest, the actual number of embryos we can use is lower

depending on the number of simultaneous readouts. For example, in an experiment requiring pre-selection of 6 GA combinations, 10 mating pairs will be required to provide enough offspring per experimental group. All unused offspring will be euthanized prior to being capable of independent feeding.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3R's Experimental Design Assistant and the ARRIVE guidelines have been used to reduce the animal numbers. All of the studies will be conducted on embryos prior to being capable of independent feeding, which will allow us to reduce the number of protected animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use genetically altered animals that can provide multiple readouts (including cell identity and cell activity) and implement computer modelling at later stages once a robust dataset has been obtained.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically altered zebrafish lines that will provide the offspring required to complete this project. All of the studies will be conducted on animals prior to being capable of independent feeding; thus eliminating the requirement of conducting studies on protected adult animals that are expected to experience greater distress. The offspring from the genetically altered zebrafish lines will allow us to visualize the experimental readouts with non-invasive microscopic imaging.

Why can’t you use animals that are less sentient?

The adult genetically altered animals are required to provide the offspring for the experiments on the larval animals. It is not possible to conduct our studies in species that are less sentient, including fruit flies and worms, because they do not have a pancreas. However, all of the studies will be conducted on animals prior to being capable of independent feeding, where we would expect less suffering in comparison to studies on

adult animals. To study the nerve-pancreas cross-talk, we need to be able to control the activity of the nerve cells in live animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Routine welfare assessments on the animals will be conducted. Animals will be monitored for their growth pattern, swimming behaviour, and feeding behaviour. Genetically altered animals will be grown and maintained until they reach a maximum of 18 months of age. Fish exhibiting any unexpected harmful phenotypes will be killed, or in the case of individual fish of particular scientific interest, advice will be sought promptly from the named veterinary surgeon and assigned Home Office Inspector.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow published guidelines issued by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will stay informed by reading scientific articles and published guidelines by the NC3Rs, attending zebrafish and other research conferences, and liaising with the named veterinary surgeon, named animal care and welfare officer, named information officer, and named training and competency officer.

31. The pathogenesis of a neglected tropical skin disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Neglected tropical skin diseases (skin NTDs) are a group of skin infections caused by different types of organisms. These diseases, defined by the World Health Organisation, affect the world's poorest people and are an important factor in trapping communities in a cycle of poverty and disease due to their association with stigma, disability and mental health problems. The aim of this project is to better understand the processes that occur for one particular skin disease caused by a bacterial pathogen. By understanding the disease better, we can achieve our long-term goal of designing better treatments that might help the infections heal more quickly. At the end of this project we aim to have identified at least one drug, ideally already licenced for other diseases (so-called "drug repurposing"), that could be tested in the future.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Skin NTDs include diseases that can cause extremely serious skin ulcers that may grow to cover large areas of the body, such as an entire arm or leg. Affected individuals are usually found in remote farming communities in developing countries, where access to healthcare is difficult. Current treatments take several months, may require hospitalisation and often leaves patients with large wounds that need either skin grafts or even limb amputation. Better treatments that improve wound healing are urgently needed as this will reduce the burden on patients (reducing deformity and long-term disability) and their families (since many patients are young teenagers requiring treatment far from home). This project will contribute to a fuller understanding of disease development and allow better treatments to be found.

What outputs do you think you will see at the end of this project?

The main outputs of this project will be increased knowledge of how skin disease caused by this organism occurs. This is very important as relatively little is known about NTDs. Outputs will mainly be in the form of peer-reviewed scientific publications and conference proceedings.

Who or what will benefit from these outputs, and how?

In the short- and medium-term, the expected beneficiaries of this programme will be different parts of the academic community such as those working on the skin NTDs, and scientists interested in how specific genes are involved in disease formation. It may also be of benefit to those involved in drug development or the pharmaceutical industry as our findings could lead to the identification of new uses for existing drugs, or new drug targets for the disease.

In the long term, this project will benefit the populations living in regions where skin NTDs are found. This includes many countries of West and Central Africa, as well as other parts of South America and Australasia. These benefits are only likely to be seen some time after the project is complete.

How will you look to maximise the outputs of this work?

We will pursue an active publication strategy. New knowledge will be widely disseminated via publication in open access journal articles. Less impactful findings will also be published in Wellcome Open Research, a dedicated open access platform for results of this nature. We will frequently share our results with collaborators and results will also be disseminated at conferences, particularly the World Health Organisation's biennial meeting on skin NTDs.

Species and numbers of animals expected to be used

- Mice: 4300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult mice rather than neonates in this project because their skin is most similar to the human skin that we need to mimic. Mice are a well-understood model of bacterial skin infection for skin NTDs, and have been successfully used to develop treatments that are now given to patients. Inbred mice are also available, which helps by greatly reducing the number of variables that could influence the outcomes of our experiments making our results more reliable. Furthermore, mice can be genetically engineered to remove or alter the expression of genes that are also found in humans, therefore genetically modified mice can be used to study the role of these genes in the disease. The genetic models we will use have previously provided important insights into other medical conditions. Mice are the lowest sentient species we can use to achieve our scientific aims.

Typically, what will be done to an animal used in your project?

There are two types of experiments in this project, and each mimics a skin NTD by injecting material into the skin. The first type involves infecting the skin with a small amount of bacteria, by giving one injection either into the base of the foot or into the tail. These experiments last several weeks, up to a maximum of approximately 11 weeks, because the bacteria grow very slowly. The second type of experiment involves giving one injection of a purified bacteria-derived compound that is important for the development of disease, either into the tail or the ear. These experiments are shorter, lasting up to a maximum of approximately 2 weeks. These injections are given while the mouse is asleep, under a general anaesthetic.

In both cases, some of the animals might first be given a drug that causes the cells of a genetically modified mouse to change their DNA content. Alternatively, some of the animals might be given drugs that we think will change the ways the skin will respond to the injected material. The drugs will be given to the mice in a variety of different ways, and sometimes we might surgically implant a device that automatically delivers the drugs, if a vet thinks this will be less stressful to the mice overall.

We will carefully monitor the injection site and might sometimes use a medical device similar to an x- ray machine or an ultrasound, or other “imaging” device to see what is happening inside the skin. We will make sure the mice are asleep when we do this, so that it is less stressful to them.

At the end of the experiment, we will kill the animals at pre-determined points, while the animals are no more than moderately affected by the disease, in line with the severity limits of each protocol. We will kill them by a humane (Schedule 1) method. In some cases, we want to study whether the blood vessels are working properly, and these animals will be given a general anaesthetic first so we can inject a dye into their blood stream.

What are the expected impacts and/or adverse effects for the animals during your project?

In all Protocols we will carefully monitor changes in the general condition of the mice that might indicate that they are affected by the injected material. We will also look for potential side effects of anaesthetics, drugs given and/or the genetic modifications present. However, we are not expecting the mice to show any signs, like weight loss or indications that the animals are in pain, during any protocol. This is because the bacteria make a substance that is known to acts like a painkiller. We know that mice that have had material injected into one footpad may experience changes in the way they move about due to their foot swelling up. However, they will still be able to move around the cage without distress. We are expecting changes in the appearance of skin around the site of injection, but this is necessary to understand the disease. We will monitor all animals carefully to ensure that any harms are kept to a minimum and, if they occur, dealt with promptly.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for the mice used in this licence is expected to be mild or moderate. Overall, considering all Protocols except the breeding of genetically modified mice, we expect 70% of the mice to experience a cumulative severity of moderate, with the remaining 30% of the mice experiencing a cumulative severity of mild. For the breeding of genetically modified mice, we expect 99% of the mice born on the Protocol to experience mild severity, with a low risk of one of the 10 genetically modified mouse lines we will breed showing moderate severity in 10% of the animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal use is needed to understand the disease in the context of a living being, and in particular live tissues with blood flow and an immune system. Two other important reasons are that the bacteria grow very slowly (much slower than the speed at which human cells divide in the laboratory) and the optimal growth temperatures are different (29-33°C, much lower than human body temperature of 37°C).

Moreover, revealing the role of individual genes and/or pathways requires the use of genetically modified mice in which these genes and/or pathways are changed so that we can study them. Finally, pre-clinical screening of compounds that might make good treatments is necessary in live animals before testing in humans can be considered. This is because a “fully body system” is needed in which the drugs are given in the context of a body’s metabolism as well as the immune system and blood circulation. None of these can be completely substituted by other techniques that don’t use live animals.

Which non-animal alternatives did you consider for use in this project?

This project involves a range of non-animal alternatives that run alongside animal use. For instance, we test cells isolated from donated excess human skin in laboratory assays, and examine skin biopsies from patients. This has allowed us to develop ideas about how the infections take hold. We also carry out basic biochemical assays on purified components of cells, in which we can investigate fundamental cellular processes. We have also considered developing a system in which a whole piece of donated skin can be maintained in the lab for several days/weeks.

Why were they not suitable?

The laboratory studies are informative, but tell us about cells bathed in nutrients in artificial conditions, rather than in their natural context. The clinical studies are informative, but present a snapshot at quite a late stage in disease which can mask the molecular "trigger" for the symptoms the patient experiences. The skin explant models do not survive for long enough for infections to establish, and also suffer from the temperature barrier, since they must be maintained at 37°C (not suitable for the bacteria causing this neglected tropical skin disease).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals used are estimated based on the experimental design within each protocol. For pilot studies we used a so-called Resource Equation to determine groups

sizes according to the law of diminishing returns. Data available from the scientific literature, or these pilot studies, are used to perform power calculations to determine appropriate group sizes for definitive experiments. We then estimated the total number of animals by adding up the number of animals used for pilot studies, the number of mice needs to perform studies that follow the evolution of the disease as it progresses, and the number used in definitive experiments. In each case this assumes a defined number of experimental endpoints, and that the experiment will be performed for 10 candidates over the course of the licence.

One Protocol describes the breeding of strains of genetically modified mice for use in other Protocols. We used calculators published in the scientific literature to estimate the minimum number of breeding pairs/trios would be required to obtain the required number of animals, and well-established general principles of animal husbandry to estimate the size of the colony needed to maintain this number of breeding pairs/trios for the minimum possible time to meet our scientific aims.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase, we took advantage of the NC3R's Experimental Design Assistant tool to consider all aspects of the experimental design. This included performing power calculations for group sizes, blinding and randomisation strategies, and statistical methods for the analysis of the data. This tool was extremely useful to ensure that the experiments will be performed in a way that reduces animal wastage by ensuring that the experimental data collected is robust and reproducible. Advice has also been sought and taken from a statistician on the design of all experiments in this license, and this will be an ongoing process throughout its lifetime.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wild-type in-bred animals will be supplied by registered breeder such as Charles River. Only the correct number of animals will be purchased. We will also breed genetically modified mice which will be used in the project. Where possible these will be bred as homozygous lines, and compared to wild type animals of the same strain supplied by registered breeder such as Charles River, in order to avoid wastage by breeding excess animals. We are aware of the issues around genetic drift, and will take this into consideration while maintaining any colony of genetically modified mice. Breeding of these animals is controlled by a breeding plan, devised by the NACWO, NVS and the research team, to minimise animal wastage. Wherever possible, we will re-use tissue that has already been collected in exploratory studies to investigate candidate pathways before embarking on definitive experiments.

Moreover, tissue will be shared within local and collaborating research groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use established models of a skin NTD in mice that involves injection of bacteria, or material derived from them, into the skin. This is necessary to mimic how the disease appears in patients. The injection sites are chosen based on established knowledge about how to model human skin diseases in mice. The footpad, tail and ear are all sites with characteristics most similar to human skin, and this means our results will be scientifically meaningful.

In both models we will perform pilot studies to compare within these injection sites to determine the approach which tells us what we need to find out about the disease, whilst causing the least distress to the animals. We will do this by taking measurements in the skin tissue after the mice have been killed, or by using imaging techniques on live mice, and compare them to our findings in patients. Like the infections in humans, these models are extremely unlikely to cause pain to the animals. Since the skin condition will deteriorate the longer the infections last, we have clearly defined humane endpoints to ensure that the animals never experience more than moderate severity. We will also use pilot studies to determine the earliest possible point in the experiment that answers our scientific questions so that these harms are minimised.

In order to test our ideas about the involvement of certain genes in the development of neglected tropical skin diseases, we will use two alternative approaches. These are either genetically modified mouse lines, or drug treatments known to reduce the activity of these genes. Since the genes we are interested in are also involved in other non-tropical diseases, they have been studied previously. This means we have been able to read these previous studies and select strains and/or drugs that cause the least harm to the animals.

Why can't you use animals that are less sentient?

Skin is a complex organ which has changed throughout evolution, and is very different between mammals (such as humans and mice) and lower vertebrates or invertebrates. Therefore, skin diseases in general require mammalian models. For skin NTDs in particular, some mammals (but not lower vertebrates or invertebrates) have been found to get similar diseases, especially when the infection is picked up from an environmental source that they are exposed to. In addition, mammalian skin changes before and after

birth, including changes to the way the blood flows and immune system works. This means that immature life stages are not appropriate for this project. The length of time taken for the infections to develop means that experiments under terminal anaesthesia cannot be used.

Therefore, an adult mammalian model is required to replicate clinical skin infections, and mice are the lowest sentience to meet the scientific aims and get results we can use to develop treatments for people in the longer term.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In order to minimise the possible harms, mice will be monitored with health checks that have been tailored specifically to them, and the protocol being followed. We will use anaesthesia and/or painkillers as advised by a vet to prevent and control any potential adverse effects (including stress or pain). We will implement additional care should specific animal husbandry be advised due to the models (for instance, the use of soft bedding/nesting material). We will perform pilot studies that will enable us to further refine doses, injection routes and the length of experiments so that we can use the most refined protocols. Where possible, we will preferentially use the model involving injected purified components, rather than infection with live bacteria, as these experiments are shorter. Our results will be reviewed regularly and integrated with new knowledge/experience/other publications.

In order to reduce the stress to animals, and hence the need for restraints, during the taking of animals' measurements we will previously undertake regular familiarisation handling of the animals and will use positive reinforcement. For instance, we aim to use refined handling techniques such as tunnel handling or cupping to reduce stress. We will also minimise the number of times each animal is handled by combining techniques where possible (such as measurements and drug administration if required on the same day), and using anaesthesia/sedation should this be advised by the NACWO/NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidelines from the NC3Rs and the Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes. We will follow the PREPARE guidelines and checklist when planning our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The 3Rs are regularly discussed and best practice shared during the User Forum for the unit, which the research team attend and participate in regularly. Members of the team also sit on our institution’s AWERB. These animal welfare meetings, advice disseminated by the NACWO/NVS/NIO, and accessing regularly updated on-line sources of information

about the 3Rs (such as NC3R, Norecopa, Frame), will allow us to keep up to date with advances in the 3Rs and implement them in this project.

Throughout this PPL, we will review our results regularly and integrate any new knowledge/experience from other publications and collaborative network.

32. Understanding and treating preterm birth related pregnancy disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pregnancy, Preterm labour, Ascending infection, Cervix, Neonatal infection

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to understand why preterm labour occurs, and how it can be treated or prevented.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ultimately we hope to be able to identify new treatments or tests for preterm labour.

Around 50,000 babies are born preterm in the UK each year – these babies are at increased risk of premature death and of disabilities in later life. This work will improve our understanding of why preterm labour occurs as well as developing and testing potential preventative treatments.

What outputs do you think you will see at the end of this project?

Our work aims to benefit women who are at risk of- or have had a preterm birth. Over 50,000 women and their babies experience preterm birth per year in the UK, with major cost to the NHS and to society as a whole. Preterm birth is associated with serious neonatal morbidity and mortality, particularly for those infants born before 32 weeks gestation. Preterm birth is the single largest direct cause of neonatal mortality in the United Kingdom and worldwide, being responsible for more than 1 million neonatal deaths globally. There are 54,000 cases of preterm birth per year in England and Wales, which accounts for approximately 8% of all live births and a quarter of these are associated with preterm deliveries before 32 weeks gestation.

Our goal is that our work will lead to clinical trials of novel agents and interventions for the prevention of preterm birth and the adverse neonatal effects of preterm labour, such as death and disability due to brain and other organ damage caused by infection/inflammation.

This programme of work is designed to establish detailed mechanistic pathways leading to interactions between the cervix in pregnancy and ascending infection which may contribute to premature delivery. Furthermore, it will enable identification of novel biomarkers with the potential for development of preventative therapies in women at high risk of preterm birth.

Within the next 5 years we hope to make significant scientific contributions to the field and within the next 5-10 years we hope to be able to translate some of these findings to clinical use. Given that our group has vast experience in running pregnancy-related clinical trials, we feel these are realistic timescales.

Who or what will benefit from these outputs, and how?

The main beneficiaries of the programme from scientists to policy makers, and the public are outlined below:

- The scientific community involved in preterm birth research: This research will benefit those academics who are carrying our similar or related work in the field of preterm birth and will bring us closer to full understanding the mechanisms behind premature birth.

- Scientists investigating mucosal immunity. It will also benefit those working in mucosal immunology.

- Scientists, clinicians in the field of public health investigating the consequences of preterm birth, and the potential lifelong impact on the child. Interest in defining preterm birth risk using biomarkers (including specific dominant vaginal microbiota communities) has expanded rapidly in the past few years. Furthermore, recent research has also focussed on the potential lifelong impacts of prematurity on the affected child. Our

research will help inform those working on large mother-child cohorts of novel associations worth investigating amongst women at high-risk of preterm birth.

• Translation to Clinical research: We have the potential to highlight mechanisms that may be manipulated by clinicians and pharmaceutical companies. Therefore, this work may lead to generation of biomarkers or drugs for medicinal purposes to prevent premature birth.

• Health professionals and policy makers responsible for the care of women who deliver their babies preterm and their children. It is our ultimate aim that this research will have a lifelong benefit for the health of pregnant women and their children. We already have established several channels of dissemination to health care providers and policy makers, and expect that the proposed programme of work will inform Policy and public health practice within the lifetime of the PPL.

• The lay community, especially pregnant women and their children. As a Tommy's Baby Charity Research Centre, we communicate closely with Charity's press officers, in order to disseminate research findings to the lay public.

How will you look to maximise the outputs of this work?

We hope that our animal studies will contribute to the development of a novel diagnostic test for preterm labour with the next 5-10 years. Even if we are unsuccessful in this aim, we will add to the sum of knowledge on the mechanistic pathways of preterm parturition. Our department has an excellent track record in publishing our research, and in training the next generation of researchers; so that the academic community and individual students will also benefit from this work. We plan to present our results from our animal studies through both publications and presentations at local and international conferences to share the knowledge we gain with others in the medical and scientific community.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the minimal species required to address our research questions, and its biology is sufficiently similar to the human for it to give us helpful information. We monitor all animals carefully throughout the entire duration of the experiments. Where more refined approaches become available during the studies, we will adopt them.

We will use the following mouse strains:

Conventional strains (CD-1, BALB-c/, C57BL/6, C57BL/6N-Tyrc-Brd)

Mucin homozygous knock out mice (Muc5ac-/-, Muc5b-/-) and heterozygous mice (Muc5ac+/-, Muc5b+/-)

The above knock out mice will be used so that we can manipulate the cervical mucus plug which is central to understanding preterm birth mechanisms in humans.

Adult male and female mice will be used for breeding in Protocol 1.

Non-pregnant (controls) and pregnant adult female mice will be used in Protocol 2. Pups born to these dams will also be used for imaging purposes under this protocol.

Neonatal pups and then post-weaned adult male and female mice will be used in Protocol 3.

Typically, what will be done to an animal used in your project?

These studies involve trying to understand and prevent preterm labour. The majority of animals will have an induction of preterm labour (for example, by injecting inflammatory or anti-progesterone substances). We will also test preventative therapies for the prevention of preterm birth and then monitor for improvements in outcomes in the mice and offspring as a result of preventing preterm labour.

Typically, mice bred in protocol 1 will be used in studies defined in Protocol 2. Following identification of genetic status, animals may be:

a) maintained for conventional breeding (this protocol)

b) used in other procedures in this Project which require the genetic modification or supplied to other Projects with authority to use genetically modified animals of this type

The majority of these mice will then be used in Protocol 2. Non-pregnant mice or time-mated pregnant mice will be used, and they will be housed together for companionship. Animals will be treated with therapeutic agents (or control) aimed to modulate labour/preterm labour. Administration will occur prior to preterm birth induction or at the time of preterm birth induction. Preterm birth induction will be induced from embryonic day 14 to embryonic day 17. The majority of our animals will have preterm birth induction either via ultrasound-guided intrauterine injection or intravaginal administration and will

therefore not undergo any surgery. A range of preterm birth inducing agents will be used including LPS toxin and live microbes. The doses of LPS and bacteria which we administer have already been determined to have subclinical effects and, therefore, we do not expect to see any adverse effects. Mice exhibiting clinical symptoms may show immobility, piloerection and fever. If the duration of this exceeds 24 hours, they will be killed by Schedule 1 method. All cases of preterm birth induction will occur under general anaesthetic using isoflurane anaesthetic. A small number of mice that may undergo

laparotomy will only undergo this single surgery and any other treatment will involve injection of agents to modulate parturition. We anticipate that 50% of our animals will undergo imaging, and less than 20% of these will undergo repeated imaging. At the end of protocol 2, all adult female non-pregnant and pregnant mice will be killed by schedule 1 methods or terminal exsanguination. Some of their pups may be kept alive and used in Protocol 3.

The pups will undergo behavioural tests described in protocol 3 to assess the effects of preterm birth on the brain and if the phenotype has been rescued by the preventative therapies.

Pre-weaned animals will undergo no more than 1 testing session of each step, no more than once per day, and lasting no more than 30 minutes per session. Adult mice will only be tested once and not for more than 1 hour per day. All animals will be killed at the end of this protocol by schedule 1 methods or terminal exsanguination.

What are the expected impacts and/or adverse effects for the animals during your project?

Protocol 1:

Breeding will occur in this protocol so we expect to produce pregnant dams (protocol 2), non-pregnant females (protocol 2) and more animals to continue breeding in this protocol.

Breeding pairs will be kept for a maximum of 12 months after birth after which they will be killed by a Schedule 1 method.

Protocol 2:

In order to achieve our aims, we will stimulate preterm labour in some mice. Hence the adverse effects for the mothers and the pups include prematurity, which can be fatal. Some procedures used will result in transient pain (e.g. at injection site), followed with close monitoring. The majority of our experiments are of mild severity. The adverse effects of infectious/pro-inflammatory agents are sometimes of moderate severity; however these effects will be minimised at all times (see below). We will also assess preventative therapies in this protocol and will anticipate rescuing the phenotype and reducing any adverse effects related to preterm birth.

The preterm labour-inducing biological agent dose used will be the minimum necessary to achieve this phenotype as calculated by pilot dose studies.

For studies where preterm labour itself is under investigation, animals normally undergo preterm labour within 48 hrs and are normally culled no later than 72 hours after labour. Signs of inflammation include fever >38 degrees Celsius, piloerection, refusing to eat and a reluctance to move unless prompted. Any animal with these signs will be monitored closely (4x/day). We will monitor temperature with a rectal thermometer. If these signs do

not improve within 24 hours (ie. temperature <38 degrees Celsius, animal freely moving in the cage) the animal will be killed by schedule 1 methods.

For general anaesthesia, appropriate depth of anaesthesia often depends on strain. Therefore, under- or over-anaesthesia will be minimised/avoided by monitoring breathing rate (50-70 breaths/minute is expected). Adult mice will only receive inhalation anaesthesia, isoflurane. Hypothermia is a common adverse effect of general anaesthesia for surgery in rodents. Therefore, we will perform all surgical procedures on a thermally-regulated pad or in a thermally-regulated chamber (not exceeding 30 degrees Celsius). After anaesthesia mice will be observed until they are awake, in a heated recovery box before being returned to their cage.

For surgery, the animal will be monitored continually until it has fully recovered from the general anaesthetic. Possible pain during/after the surgery will be minimized using appropriate analgesia. Where ongoing signs of distress are observed (lack of mobility, hunching, piloerection, discomfort on handling) animals will be administered analgesia until they recover. If the signs of distress continue, despite analgesia, on the day of the procedure, the animals will be culled at the end of that day or within 6 hours of the procedure (whichever is sooner).

Complications including infection and wound dehiscence may rarely occur as a result of surgical manipulations. This will be minimized by the appropriate use of aseptic technique. Frequent observation (3x/day) will be undertaken following the procedure to ensure that wound healing and recovery is free from bleeding or infection. The animals will also be weighed on the day of the procedure and daily for the next 7 days. In the unlikely event of wound breakdown, a single attempt at closure of a healthy wound will be attempted up to 24 hours after surgery. Any evidence of bleeding during surgery will necessitate general compression until bleeding is stopped. In the rare event of bleeding from the wound or signs of infection (redness, swelling, pus exudate and discomfort over wound area) animals will be culled under Schedule 1.

We expect no adverse effects from preventative therapies tested as these compounds will be administered at sufficiently-low published doses as to have no clinical symptoms. However, any newly developed therapeutic compound may cause potential adverse effects including contact dermatitis or weight loss, which will be monitored for on a daily basis.

Protocol 3:

In this protocol, the majority of behavioural tests are not expected to cause any adverse effects. None of these observations or manipulations will cause pain and analgesia will not be necessary. During the Morris Water maze test the water temperature will be kept to an average temperature of 22 degrees Celsius (water will be testing continuously with a thermometer placed in the water). Mice will be placed in a thermally-regulated chamber (not exceeding 30 degrees Celsius) following each trial. If the animal does not swim when

placed in the maze or appears distressed, they will be removed from the trial and placed in the chamber to recover. They will not undergo any further testing.

If an If an animal falls during the cliff aversion test it is unlikely to cause any physical harm but the shock of falling may invalidate the behavioural test. We will monitor all animals closely and ensure there is padded tissue below the platform. If the pup does fall, we will perform no further trials in this animal.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

We aim to use 2500 animals over 5 years;

- 1500 at mild severity
- 1000 at moderate severity

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The whole process of designing and testing a therapy is as follows: i) It is tested in vitro, usually in more than one mouse line and, where possible, in cells differentiated from human induced pluripotent stem cells. ii) The therapies are finally tested for efficacy and, where appropriate safety, in the relevant model. The disease, preterm birth, we aim to cure is a multisystem disease, which cannot be modelled in vitro, neither in single cell cultures nor in mixed culture or organoid systems. Animals are ONLY used when human work is not possible, and when in vitro cell work is unsuitable, both because of the nature of the question being asked. To translate these technologies to the clinic, preclinical studies in mouse models are a minimum requirement. Mice in particular have proved to be a useful model for our studies of parturition due to similarities in the inflammatory and immune response to infectious agents. Usually, well-performed mouse studies, combined with toxicity studies in rabbits, outsourced to a CRO, are sufficient and higher animal studies are now no-longer a requirement for progression to the clinic for preventative therapies.

Which non-animal alternatives did you consider for use in this project?

We considered single cell culture, mixed cell culture or organoid systems.

Why were they not suitable?

The disease, preterm birth, we aim to cure is a multisystem disease, which cannot be modelled in vitro, neither in single cell cultures nor in mixed culture or organoid systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated numbers based on previous experiments and pilot data (see below).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments are designed using the NC3R's experimental design assistant and will be reported in line with ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For the primary aim of this project – preclinical experiments in a translational pathway, it is crucial to ensure experiments are sufficiently powered otherwise they may require repeating in their entirety. Our approach is to perform an initial sample size analysis based on data previously obtained in our laboratory. Where experiments are completely new, we will perform pilot studies with 4-8 animals per treatment group and use this data for statistical analysis in power calculations to determine appropriate sample sizes. For the majority of experiments, we will aim to have a significance level of 5% and a power of 80-95%. Many of our therapy interventions are emphatically therapeutic therefore this experiment tells us if we are on the right track. Most importantly, we can analyse numerous disease parameters. Therefore, we are able to select one of the least corrected parameters on which to base our power calculations for an additional fully powered study, if necessary. Where possible, we share material with our collaborators, thus pooling resources and minimising experimental repeats.

In vitro work is used where possible, either to avoid animal work all together, or to determine suitable doses, time periods etc. before embarking on in vivo animal work.

Using biosensors and bioluminescent bacteria we can specifically reduce the number of animals used in biomedical research, by enabling the monitoring of signalling pathways non-invasively, continually, rather than sacrificing cohorts of animals at repeated time points or, for example, performing repeated blood collections.

For previous multi-treatment comparisons, we have used one or two-way analysis of variance with an appropriate post-hoc test. For time series we used analysis of variance with repeated measures. All preclinical studies are performed fully randomised and fully blinded. Where possible, all end-point analyses are performed at the same time point. For our biosensor work, each animal provides its own baseline, and therefore serves as its own control. We can, therefore, normalise each animal against this baseline, minimising experimental variation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is our chosen animal model, for which there are usually appropriate genetic models. Lower organisms do not recapitulate the pathology of these diseases. Larger animal models are rarely required by the regulators for clinical translation, as mentioned above. Often, we work with models with an acute phenotype (e.g. infection-related preterm birth), with only a short period of time before onset of symptoms and requirement for euthanasia. Therefore, animals are not in discomfort for prolonged periods of time. Our team monitors our mice on a daily basis and, in some cases, more than once a day. They have accumulated many years' experience in recognising clinical symptoms of distress and pain.

Why can't you use animals that are less sentient?

Our main animal model is the mouse for which there are usually appropriate genetic models. Lower organisms do not recapitulate the pathology of these diseases. Terminally anaesthetised animals will not provide the disease phenotype acquired to study disease mechanisms and test preventative therapies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any variation from the norm is followed up with careful weight monitoring and more prolonged observation. Almost invariably, when distress and pain are recognised, the animal is euthanised, since, in our experience, sick mice tend not to get better – they are prey species and so will hide their symptoms until they are very unwell. Also, we recognise that the longer a sick mouse is maintained, the poorer will be the quality of the data, so it is better to euthanise early and justify the early time point, than euthanise late, causing the animal suffering, just for the sake of hitting a time point for which the data will likely be skewed. In our most recent bioimaging work, we demonstrated that it was possible to image young mice noninvasively, freely moving, within the confines of a dark chamber. The animal can even be provided with wet chow for the duration of the imaging. This dispenses with the need for anaesthesia and there is no disturbance of the animal by the operator. The imaging environment, other than being novel, is, therefore, similar to that of their home cage during the dark cycle. Pups are marked, at birth, with a subcutaneous foot tattoo if necessary. This allows us to randomise and blind treatments in each litter and still be able to identify each animal for its lifetime with no need for ear clipping.

We do not anticipate that any experiments will be of “severe” severity.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE guidelines 2.0

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

On the NC3R website and by attending regular webinars provided there.

33. Gamma delta t cells and body surface immunity

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, immunosurveillance, inflammation, T cells, epithelium

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to describe the biology of intraepithelial lymphocytes (IEL) which comprise a large compartment of immune cells sitting at body surfaces, such as the skin, gut or reproductive tract. IEL are particularly enriched in evolutionarily conserved T cells known as gamma delta cells, which can play important roles in key physiologic processes such as dietary adaptation, and in protecting against infections, inflammation and cancer. However they are very poorly understood. To redress this, we aim to establish how specific sets of gamma delta T cells become associated with particular tissues during their development; how they are retained; which forms of local disorder they can respond to; and the biological outcomes of their actions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Body surfaces are the most susceptible anatomical sites to infection, cancer, and inflammation that collectively make up some of the most common and demanding clinical burdens. They can also be sites for resection and transplantation. By understanding how local gamma delta T cells protect their local environments from various types of disorder or disruption, we can add to our fundamental immunological knowledge while potentially improving clinical diagnostics and therapeutic strategies. Indeed, our previous work provided the foundation for two biotech companies committed to applying gamma delta T cell biology to cancer and inflammatory disease with first-in-human trials commencing in autumn 2021.

What outputs do you think you will see at the end of this project?

The following outputs can be anticipated:

• Peer-reviewed primary research publications. To place this in context, our research led to the publication of 25 peer-reviewed primary research papers in the 4.5 years covered by our current license.

• Patents. Our work has led to novel discoveries which have been protected as intellectual property by our host institutions, so that they may be commercialised for practical clinical application(s).

• Abstracts. Our work is primarily undertaken by post-doctoral researchers and PhD students who are encouraged to attend international meetings to which they submit abstracts for presentation and discussion.

• PhD theses. Our laboratory is currently training 4 PhD students whose written, published theses can be anticipated to contain work undertaken as part of this project.

• Public engagement via research updates on open-access websites, etc.

Who or what will benefit from these outputs, and how?

We consider the following impacts:

• Short-term: publications describing our results may have immediate impacts on: [i] other research teams, influencing their own experimental plans, studies, and interpretations; [ii] post-doctoral trainees whose career progressions can be largely shaped by the outcomes of the research; [iii] in rare cases, the impact may be to influence current public health policy, as was recently achieved in the context of COVID-19.

• Short-to-medium term: awarding of PhD degrees to those undertaking studies described in this licence application.

• Short-to-medium term: the establishment of UK and international collaborations to expand upon our findings, as manifest in our successful application to the MRC and its Indian counterpart (DBT) for Anglo-Asian COVID-19 studies.

• Medium-to-longer-term: impacts on textbook immunological knowledge.

• Medium-to-longer-term: the results, including patents filed, may accelerate the development of novel diagnostic and therapeutic modalities for infection, cancer and inflammation.

• Longer-term: changes in clinical practise.

How will you look to maximise the outputs of this work?

We shall disseminate our findings via the outputs described above: papers, abstracts, theses. We shall disseminate our findings via conference presentations.

Where appropriate, we shall disseminate the implications of our findings by public engagement. We shall upload our data and provide lay narratives on open-access web-portals, etc.

We receive advice from experts in science translation about which of our findings are appropriate for filing patents, thereby maximising opportunities for clinical development of our findings.

Species and numbers of animals expected to be used

- Mice: 77,275 split over 20 protocols over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the ideal organism for our research for five reasons

First, it is a long-standing choice of immunologists via which they have successfully identified many of the key operating principles of the immune system, such as the connectedness of innate and adaptive immunity, and made advances upon which major clinical interventions are based, e.g. the successful introduction of cytokine blockade for treating rheumatoid arthritis.

Second, there is an immense spectrum of reagents available permitting the thorough, incisive, and comprehensive obtainment of reliable information from the experiments undertaken.

Third, there is an extensive and evolving bibliography of protocols that inform the design of experiments, promoting reproducibility, reducing excessive need for pilot studies, and enhancing the reduction and refinement of animal use.

Fourth, reflecting extensive breeding programmes and the ease with which it may be genetically engineered, the mouse has emerged as an extraordinarily powerful mechanistic system, permitting the unequivocal assignment of function to particular genes and molecules. It is important to recognise here that there will be occasions when our parallel studies in humans implicate a specific gene or pathway in, for example, regulating cancer immunosurveillance. The power of mouse genetics permits this implication to be tested irrefutably by assessing cancer progression in mice rendered mutant for that gene/pathway. This means that the mice may experience higher severity of discomfort when compared to wild-type mice challenged with tumour cells or carcinogens, and hence will be appropriately monitored (see below).

Fifth, many protocols have been developed and are being refined for highly effective, reproducible longitudinal monitoring.

We examine all developmental stages of this organism, because our research seeks to understand the developmental association of T cells with tissues which often occurs in the fetal and neonatal periods; the cells' responses and functions in adults; and the long-term consequences, e.g. the durability of immunological memory in older individuals.

Typically, what will be done to an animal used in your project?

The main foci of our research are cancer, infection, inflammation and transplantation.

Many animals used will not be treated in any way, but will at different ages be culled solely as sources of different cells and tissues for study in the laboratory; hence they will experience no ill effects.

For experimental models, mice will be injected with and/or otherwise exposed to cells; and/or to agents such as chemical irritants, toxins, ultraviolet light or other mutagens of the kind that humans are commonly exposed; and/or to microbes or viruses, so as to induce cancer or infection and/or inflammation. They may also be injected with and/or otherwise exposed to cells and/or agents, such a chemical inhibitors or biological substances such as immune cell stimulants known as cytokines, that are known or hypothesised to ameliorate or to enhance susceptibility to cancer or infection or inflammation or transplant rejection. In both cases, cells/agents will be administered by the most suitable route leading to very minor effects on the animals.

In some cases, fragments of organs, specifically skin, will be explanted into a recipient mouse, so that the immune response to that may be assessed.

The number of procedures we use will be kept to the minimum needed to answer our research questions with the highest levels of certainty. At any signs of undue distress in

the experimental mice, the experiment will be terminated, and the course-of-events recorded to inform future practice.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the mice will experience no ill effects. Most animals in our breeding and monitoring programme will experience little and/or only transient adverse effects. It is possible that the inter- breeding of novel genetically altered strains will be accompanied by unanticipated adverse effects, such as we observed over a brief period for a very small percentage of mice deficient in butyrophilin- like 1 (Btnl1) which developed hydrocephaly. Our intensive monitoring of our animals means that any adverse events are detected quickly; animals culled; and alternative breeding strategies and/or experimental methods (e.g. bone marrow transplantation of cells from one genotype to another) are adopted.

Different challenge models can be anticipated to provoke different outcomes depending on the age and the immune status of the host. Following some challenges, particularly in young mice and in potentially immunodeficient strains, a standard quantitative measure of the host response is weight loss (more correctly termed weight retardation although this retardation is only temporary, after which the mice develop at the same rate as normal). Some other potential signs of distress may include hunched posture, lack of appetite and ruffled fur. Nevertheless, challenged animals will be monitored closely during periods of potential distress to ensure that appropriate action is promptly taken should any develop severe clinical symptoms.

Mice exposed to cancer cells and/or carcinogenic agents, and those carrying genetic mutations predisposing to cancer may develop cancers for which we have approved protocols for tracking and measurement. The time to develop cancer can vary considerably depending on the nature of the challenge/mutations and the genetic background of the mouse, particularly in relation to its immunocompetence.

When human cells are used for adoptive transfer, the animals may develop human cancers, phenotypically similar to the human disease. The time to develop cancer will again vary depending on the primary tumour cells engrafted and whether or not other cells, e.g. human immune cells, are co- administered. In our experience, the mice are not overtly affected by the cancer growth. It is expected that the mice will have a mild systemic effect.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most mice on our breeding and monitoring protocols that experience any discomfort at all will experience mild severity. As mentioned above, inter-breeding of novel mutant strains

can be accompanied by unanticipated adverse effects. In such cases, breeding and monitoring will be classified as moderate severity.

All the mice on our experimental protocols will fall under the categories of mild/moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of our studies, as considered above, is to understand how body surface gamma delta T cells in vivo offer local protection from infection, cancer, and inflammation, and how they regulate the response to organ transplantation. Clearly, some substantial component of our work needs to be undertaken in vivo, although we quickly move to studies in vitro to investigate the underlying biochemical and cell biological processes that underpin events in vivo (see below). We examine immune responses in vivo in humans, but those studies are limited by three key factors: [i] tissue-resident T cells are our main focus of interest and yet it is challenging to monitor immune phenotypes in tissues as opposed to blood;

[ii] it is extremely unusual to find humans whose genotypes allow unequivocal causative association of a gene and/or biochemical pathway with a biomedical outcome / phenotype; [iii] it is appropriately impossible to challenge humans with a spectrum of infectious agents, potential carcinogens, and inflammatory substances. To overcome some of these issues, we are using human (and mouse) organoids much more than before, and trying to overcome a substantial limitation on their current use, namely the appropriate anatomical intercalation of tissue-intrinsic immune cells, particularly gamma delta T cells, with their host tissue organoids. Importantly, our track record shows that as soon as we make key findings in animal model systems, we set up experiments using human material to test their implications for human health and disease.

Which non-animal alternatives did you consider for use in this project?

As is evident from our publication record, we have where appropriate undertaken human studies (e.g. immune-profiling) and mathematical models and shall continue to do so. Likewise, we have established experimental protocols that employ human and mouse cell lines and organoids that reduce the need for investigations in vivo.

Why were they not suitable?

As considered above, the irrefutable power and value of non-animal alternatives falls far short of recapturing the spatial and temporal dynamics of the interactions between tissue-intrinsic immune cells and their host tissues both at steady-state and after those tissues have been challenged by clinically relevant agents, including microbes, carcinogens, inflammatory substances, and tissue grafts.

Nonetheless, knowledge gained from non-animal alternative systems has helped us refine the design of our animal experiments, enhancing reproducibility and thereby reducing the numbers of animals included in our studies, and limiting the scale of severity.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals we will use based on two parameters:

1) The number of mice we have used in these protocols over the last five years; note that this number has evolved as our knowledge has grown and the incisiveness of experimental protocols has improved (see Appendix C).

2) The projected number of mice that we estimate we shall use on different protocols in the next five years based on our current research focus and the progression of the field in the global scientific community.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have undertaken many steps in this regard.

1. We have and shall continue to investigate the ready availability of genetically-altered strains from the community, prior to generating any de novo. If new lines need to be generated, we shall employ the most efficient techniques such as Crispr-Cas, which reduce animal numbers by virtue of the fact that targeted animals can be generated within fewer generations, particularly when we wish to examine the impact of a genetic change on different mouse background strains.

2. We have been extremely scrupulous in our choice of experimental systems that have wide dynamic ranges that permit us in single experiments to measure immunological improvements and deficiencies, respectively, and that have low likelihood of batch effect variation, that we monitor with programmes such as Tableau. As part of good laboratory

practice, protocols for each experiment defining the objectives, experimental procedures, intended effects, and endpoints will be circulated to all those involved in the care of the mice.

3. We select challenge agents based on: [i] ready availability in defined forms that permit high experimental reproducibility in standard control strains; [ii] our own experience of the challenges and/or ready availability of robust protocols within the community; [iii] our relevant scientific knowledge, e.g. that roles for the agent in gamma delta T cell biology have not already been discounted based on rigorous experimentation; [v] pharmacogenetics, e.g. the probability that an agent may yield important biological data based on clinical observations made in the realms of human genetics and treatment responses, respectively.

4. In our choice of challenge agents and experimental protocols, we consider that all the competences and reagents required for optimal downstream outcomes analysis exist, thereby maximising the amount of information to be obtained from single experiments. As an example of our choice of a tumour challenge model, we ask if so-called antigen-MHC tetramer reagents are available to detect tumour-specific alpha beta T cell responses that may be regulated by gamma delta T cells.

5. In every instance that the experimental design permits, we shall use a non-animal alternative (human immunophenotyping; organoids; immune cell - tumour cell co-cultures in vitro, etc).

6. All models used will be assessed such that we shall employ the minimum severity of disease (e.g. tumour burden; inflammation; infection) required to show an effect.

7. We are not wedded to a single approach. For example, in asking what information skin gamma delta IEL receive at steady state from Skint proteins, one could use mice in which Skint1 can be inducibly deleted. But, we chose instead to plan experiments in which we block the Skint1- gamma delta IEL interaction by intradermally administering anti-Skint1 antibody to ears of WT mice. This reduces animal use because it does not require a complex breeding programme for the mutant strain, and because (for example) a contralateral ear injected with control immunoglobulin can be used as a control for anti-Skint in a single animal, rather than requiring a second, control mouse in which gene deletion was not induced.

8. Where pathophysiologic responses to challenges are to be described, e.g. immune surveillance of cancer; capacity to mount immunity to infection; acceptance of graft, power calculations will be undertaken to determine the minimum numbers of mice required to demonstrate a phenotypic effect. Ideally, we use power of >95% and P=0.01 as thresholds, since our experience shows that conventionally-used thresholds are often too lax for many experiments, and may result in the longer run in more mice being used in attempts to resolve the consequent experimental uncertainties. Reaching stringent standards is promoted by well-established experimental systems with high signal-to-noise

across broad dynamic ranges (above); nonetheless, to limit animal group sizes it will on many occasions be satisfactory to apply thresholds of >80%. Typically, t-tests or chi-squared tests (or non-parametric equivalents) will be suitable for respectively comparing time to phenotype onset, disease burden, or quantitative immunophenotype between groups, but given the multiplicity of measurements and group comparisons we shall also frequently employ ANOVA. According to the number of groups compared, corrections may be required, e.g. Benjamini Hochberg, to reduce false discovery rates.

An informative power calculation for a typical experiment is as follows: suppose WT mice have 25% less tumours than genetically engineered mice deficient specifically in interferon gamma production by gamma delta T cells, n=40 vs n=30, sd=8, then to reveal a significant difference between the groups requires 23 mice in each group.

9. In many cases, the numbers of animals required will be reduced by longitudinal measurement of responses, by serial blood analysis and/or by optimised and ever-evolving intravital imaging protocols. Hence, the immune response to a challenge may be measured weekly in a set of six mice over a period of six weeks, rather than requiring six mice to be sacrificed weekly across that period. Such longitudinal usage provides essential information on the development or not of immunological memory, but does require approval for successive sequential administration of agents and blood sampling.

10. Unnecessary variation in animal cohorts will be excluded by use of gender and age-matched controls housed under identical conditions, as we have published, and likewise transgenic, knockout, and “knock-in” mice will routinely be generated or obtained on the same genetic background, and, where relevant, not subject to experimentation until the appropriate number of backcrosses has been completed.

11. Guidance in experimental design can be consulted at:
https://eda.nc3rs.org.uk/experimental-design

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Apart from good experimental design, we shall use the following measures to optimise the number of animals used in our project:

Pilot studies using limited number of mice to determine feasibility of new experiments
Detailed consultation with others who have used the relevant protocols

Where possible, tissue will be shared between other members of our laboratory so that we optimise information gained from the single unit of analysis – the individual mouse.

Mice will be bred efficiently; i.e.: only enough breeding pairs will be set up to meet the requirement of ongoing experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Models and Methods:

We shall mainly use mouse models of:

[i] tumours (subcutaneous, intradermal and metastatic tumour models).

[ii] inflammation (administration of agents by gavage, intranasally, intravaginally, or epicutaneously) to induce inflammation of the relevant body surfaces.

[iii] infection, via gavage, intranasal, intravaginal, or epicutaneous exposure with systemic exposures as means to test, for example, the impact of local protection on systemic immunity.

[iv] vaccines and adjuvants via gavage, intranasal, intravaginal, or epicutaneous exposure with systemic exposures as means to test, for example, the impact of local protection on systemic immunity.

[v] wound healing.

[vi] skin-graft transplantation.

Suffering and discomfort:

Using past experience, the literature, consultation with colleagues locally and globally, all mouse models that we plan to use will be assessed such that we shall employ the minimum discomfort severity burdens required to show effects. For example, in B16 melanoma tumour challenges, we primarily employ the B16 F0 subline for skin tumours because it is demonstrably less aggressive than the F10 subline that is widely used by others. Moreover we undertake pilot dose response studies before adopting final SOPs.

Because the value of our data will be enhanced by comparison with similar studies by the community, mice will be killed at stages of disease-progression consistent with those widely used throughout the UK and international scientific laboratories.

Most animals produced under the breeding protocols are not expected to exhibit any adverse phenotypes and most immunodeficient mice are also unlikely to show adverse symptoms because of the high health status of the animal facilities. However, it is not

possible to fully predict the nature or severity of any potential mutation: mutations in gamma delta T cell functions critical for gastrointestinal cancer immuno-surveillance may impact upon steady-state barrier functions, for example, water retention. With these risks anticipated, newly developed or obtained strains will be closely monitored and animals exhibiting any unexpected harmful phenotypes will be killed by schedule 1, or in the case of particular scientific interest, advice will be sought, first from the NVS, and if appropriate, then from the local Home Office Inspector.

Invasive mouse procedures required are minimal. Analgesics will be used as required.

Why can’t you use animals that are less sentient?

Gamma delta T cells emerged in and have been conserved in vertebrates, so there is no capacity to employ nematode or fly genetics in their study. While some immune studies make use of fish, they are inappropriate for our studies because of the paucity of reagents, methods, and supporting literature, and because the contexts that we study would be at an even greater physiologic distance from clinical settings.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We shall refine the procedures we are using by increased monitoring according to clearly articulated guidelines, e.g. FELASA “Working Group on Pain and distress”; EC “Endorsed Severity Assessment”; and NCRI. Thus guided, we shall determine the earliest endpoint possible on an experiment-by-experiment basis to allow a valid scientific outcome to be achieved. Our approaches to this, e.g. consultation with colleagues; reference to the literature; our own experience, are described above.

Assessment will be made of pain and distress, as measured by normal and provoked behaviour; movement; physical signs such as altered respiration rate; animal posture (huddling or hunching) skin and coat changes such as piloerection or overgrooming; inactivity; body weight; inflammation of injection sites; and comments on the animal’s general appearance.

Where procedures seem likely to be distressing to animals (e.g. the highly accurate measurement of subcutaneous tumour burdens using calipers), mice may be anaesthetized although this will be avoided if accurate measurements can be obtained without anaesthesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

As mentioned above, we will follow best practice guidance published by:

FELASA “Working Group on Pain and distress”

EC “Endorsed Severity Assessment”

NCRI guidelines

National Centre for the Replacement, Refinement and Reduction of Animals in Research guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will stay informed about the advances in the 3Rs by regularly staying updated with the guidelines specified in the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs): (https://www.nc3rs.org.uk).

I shall regularly appraise my staff of any changes to the guidelines and ensure we try, at every juncture to implement these advances effectively.

34. Developing anti-malarial transmission blocking interventions

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph

Key words

Malaria, Plasmodium, Transmission, Mosquito, Vaccine

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to discover and develop new ways to treat or prevent malaria transmission and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The project aims to contribute to the control and elimination of malaria. With 3.3 billion people at risk of infection and 229 million people infected with malaria every year, resulting in over 409,000 annual deaths (WHO World Malaria report 2020). The development of novel anti-malaria blocking strategies is a major technological drive, specifically requested by funders and policy makers, to complement the status of currently utilised anti-malarial interventions.

By focussing on the manner in which the Plasmodium parasite (the causative agent of malaria) passes between mosquitoes and humans, this project aims to find new vaccine candidates or drug targets within the sexual stages of the parasitic lifecycle. Targeting the parasite in this way will arrest the completion of the Plasmodium lifecycle by preventing transmission, thus preventing disease. In addition, the project includes the study of the fundamental biology of the malaria parasite, performed to advance our general understanding of this globally important disease.

What outputs do you think you will see at the end of this project?

Based on our key collaborations with pharmaceutical companies, understanding of the parasitic biology as well as previous experience, working under multiple projects we are confident we will be able to achieve success within these broad aims of the proposal. Specifically, aim to:

• Identified ~15 several specific parasite targets for further drug or vaccine development;

• Explore the ability of these targets to block the transmission of a rodent malaria parasite.

• Validate modes of action by modifying targets in transgenic parasites to specifically test these ideas.

• Identified multiple (approximately 5) of the most efficacious candidates to translate to human studies in subsequent work.

Further outputs will include; multiple peer-reviewed publications and pre-prints, presentation at national and international conferences, and public engagement activities.

Who or what will benefit from these outputs, and how?

The work proposed to be performed under this project licence aims to contribute to the control and possible elimination of malaria. With billions of people at risk of infection, causing substantial disease and death annually, the disease also presents a significant barrier to socioeconomic development in Sub-Saharan Africa. As such, the development of new anti-malaria blocking strategies is a major objective. Our group has crucial ongoing links with non-governmental organisations, clinicians and field sites, and our research is used to inform the use of current and future anti-malarial interventions.

Specifically, the benefits of our research within the next five years will be to identify new targets which could be used to generate anti-malarial therapeutics. The results of this work

will be disseminated via presentation at conferences and in scientific journals to aid others in the field of malaria research.

In the short term, the benefits of this work will be limited to the identification of key molecules that control how malaria parasites transmission to the mosquito host, and the identification of anti-malarial interventions. In the medium to longer term, the development of novel anti-malarials in a clinical settings is the desired goal.

How will you look to maximise the outputs of this work?

1) Dissemination of results by publication (of both positive and negative data).

2) Presentation at national and international scientific meetings.

3) Collaboration with a range of malaria/vaccine/drug related scientific groups.

4) Links with specialist field-based labs, funders, clinical sites, and non-governmental organisations, to aid the translation of basic scientific research to a therapeutic product.

5) Multiple outreach/public engagement activities.

Species and numbers of animals expected to be used

- Mice: 11500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The rodent malaria parasite Plasmodium berghei (P. berghei) is one of few available safe (non-human infectious), versatile, biologically relevant and reliable species to study transmission of malaria from vertebrate to insect host and back again. The adult laboratory mouse is the most convenient and widely accepted host for rearing P. berghei.

Typically, what will be done to an animal used in your project?

Typically, the majority of animals within this project will receive an injection of phenylhydrazine into the abdomen, with subsequent infection with Plasmodium berghei 3 days later. At the dosages used, phenylhydrazine induces the production of cells called reticulocytes, which Plasmodium berghei preferentially invades. Infection will occur by injection into the abdomen or blood vessel.

In a number of experiments within this project, animals will be humanely killed following a mosquito feed to infect mosquitoes. In these cases, the mice maybe previously immunised (by injection into the abdomen, blood vessel, muscle, or under the skin), or drug treated

(by administration of experimental anti-malarial compounds by oral treatment, or by injection into the abdomen, blood vessel, or muscle) prior to parasitic infection to determine the transmission blocking efficacy of novel anti-malarial agents. Throughout the work within this project, an animal will only undergo one procedure.

Rather than allowing the mouse to wake up following a mosquito feed, some mice will be killed whilst under deep anaesthesia from which they are not allowed to recover. An unconscious/anaesthetised mouse will feel nothing while we remove a large blood sample.

A number of mice described within this project will not be infected with Plasmodium berghei but will be instead immunised to produce antibodies against proteins derived from the malaria parasite. Typically, these mice will undergo immunisation by injection into the abdomen, blood vessel, muscle, or under the skin. This may be repeated up to a maximum of 3 times per mouse. The resulting immune response will be monitored by examining the amount of antibody present in small volumes of blood taken from mice. When the antibody level is sufficient, these mice will be given anaesthetic and killed by removal of a large blood sample before the animal wakes up. Antibodies will then be purified from the blood and used in the lab.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts/adverse effects throughout the project can be split into four different classifications:

1). Impact of infection with Plasmodium berghei:

Infection of mice with P. berghei can result in development of cerebral malaria or anaemia in under 1% of cases. This results in clear signs of distress, which include pallor, bristling of hair, reduced mobility, hunched posture, lethargy/weakness, weight loss and respiratory disease.

2) Impact following blood sampling:

Adverse effects of blood sampling are very rare and can be short lived (under 1 hour). Localised bruising may occur in this time period.

3) Impact of immunisation:

When immunising mice, transient pain at injection site may occur. Animals will be monitored following immunisation and any animals showing signs of prolonged distress will be killed, though no adverse effects are envisaged from straight DNA or protein/peptide vaccinations. Observations include regular weight monitoring and daily observations looking for signs of ill health. Expected adverse effects at the site of immunisation include granulomatous reactions, swelling and redness with or without loss of hair over the injection site, and rarely ulceration. These will occur in <10% of animals.

4) Impact of treatment with anti-malarials:

Adverse effects resulting from treatment with antimalarials are not expected. Animals will however, be monitored for general signs of deviation from normal health.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice:
- Mild severity: 17%
- Moderate severity: 83%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Human malaria can be caused by several species of Plasmodium. However, due to practical, ethical and safety restrictions, transmission stages of malaria are almost impossible to use when working with lethal human parasites, such as Plasmodium falciparum. Therefore, the use of animals, such as mice, are currently the only way to study the full malaria transmission cycle of malaria.

The rodent malaria parasite Plasmodium berghei is one of few available safe, relevant and reliable species to study the transmission of malaria and generate genetically altered parasites. Plasmodium berghei cannot be grown in culture, offering only limited insights into the biology of the parasite. As such, the full replacement of the mouse model is not currently possible. Additionally, there is currently no alternative to animal species that can be used to test with regards to vaccine or drug sensitivity studies in a biologically relevant environment.

Which non-animal alternatives did you consider for use in this project?

Use of cultured human malaria parasites (i.e. – P. falciparum or P. vivax) was considered, as was the potential use of enhanced 3D cell culture systems.

The use of non-antibody systems (e.g. lab produced agents that bind to molecules) to target proteins essential for malarial transmission was also considered.

Why were they not suitable?

Unfortunately, despite these options, the need to continue experiments with P. berghei in mice remains necessary. Transmission stages of malaria are unsafe and challenging when working with lethal human parasites, therefore the use of animals remains the only way to replicate a full malaria transmission cycle. The ability to perform this is essential for the examination of transmission blocking interventions (both vaccines and drugs). In addition, the generation of transgenic parasites in other malarial species is at an efficiency far less that that observed in the P. berghei model.

There is no organid or culture system that facilitates the development or maintenance of the transmissible stages of P. berghei.

The use of non-antibody systems to target transmission-related molecules does not offer characteristics that are suitable for target identification (e.g. clearance rate, binding affinity). Their use would also not result in information regarding the immunogenicity of vaccine candidates.

We additionally continue to explore viable alternatives to replace the experimental procedures requested, by the use of new experimental culture systems on human malaria parasites.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals proposed to be used under this project licence will be reduced by using well- established, robust systems for parasite propagation, transgenesis and mosquito infection. The robustness of these systems greatly reduces the number animals used, as nearly 100% of animals become successfully infected upon inoculation. Our long experience (over 15 years) of working with these systems enables us to reduce the number of animals used by careful planning of experiments, using appropriate controls and replicas to avoid unnecessary experimental repetition. Tissue sharing will be performed where appropriate.

Typically, blood feeding on live animals is required for mosquito colony maintenance. This has been requested in previous project licences, however, we have successfully adapted our mosquito colonies to feeding via an artificial membrane, greatly reducing the number of rodents requested within this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For statistical/experimental design, in the majority of occasions, direct experimental measurements are not made on animals during the course of the procedure; instead, animals are used to generate parasite material for subsequent analysis. In these cases, the minimum number of animals needed to produce this material is used based on the acceptable minimum standards for publication of the results.

If statistical analysis is needed, the numbers of samples/experiments/observations is determined by previous experience, hundreds of available literature and using the most appropriate statistics. In all cases, all experiments are designed to minimize the number of animals used, e.g. data from initial experiments is examined, and only if justifiable the full experiment is carried out (e.g. duplicate and triplicate). For assessment of transmission in the mosquito, specialist statistical analysis is typically required due to non-normal distribution of Plasmodium transmission. All analysis will be 'performed taking into consideration variation between individual animals and the distribution of the parasite in the mosquito. We will additionally utilise in-house enhanced statistical methods to assess parasite distribution/transmission in mosquitoes, ensuring appropriate design of experiments.

In addition to more specialist analysis, the NC3Rs' Experimental Design Assistant has been utilised, along with PREPARE guidelines, and the field accepted-mimima for statistical significance

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In all cases, all experiments are designed to minimize the number of animals used, e.g. data from initial pilot experiments is examined, and only if justifiable the full experiment is carried out (e.g. duplicate and triplicate). For assessment of transmission, mosquitoes will be examined for intensity of infection and prevalence. Wherever possible, tissue-sharing of animals will be performed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodents infected with Plasmodium berghei to examine malarial transmission to mosquitoes.

In almost all our work, the infecting parasite dose is large (to ensure rapid establishment of infection), animals are monitored daily and are used within a few days of infection. The use of phenylhydrazine enables rapid establishment of the required parasite levels before clinical signs. Under these conditions, infections are well tolerated, causing little discomfort to mice with animals typically displaying a normal behaviour. In procedures outlined here, mice are humanely killed prior to the start of chronic infection, reducing the severity of any procedures. During generation of transgenic parasites, drug treatment follows well-documented regimens and is known not to induce adverse phenomena.

During antibody production, resulting immune responses are monitored by taking very small blood samples by the least invasive method. Different immunization programs are established to raise robust immune responses, ensuring maximum chance of success using the smallest number of animals under minimal duress.

For the study of potential anti-malarial drugs, animals will be given doses based on data derived from lab-based studies, and initial doses used are not anticipated to cause health problems since compounds have been tested for toxicity. Known anti-malarials, which are investigated for their effects on transmission or the parasite in the liver, will be used at doses equivalent to those already routinely used for humans and are unlikely to result in toxicity effects.

Why can’t you use animals that are less sentient?

Less-sentient animals cannot support a malaria infection.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To improve the quality of life of the animals we will:

- Reduce contingent harm by using group housing where possible and not using the single housing of mice. This in turn reduces any stress and stereotypical behaviour.
- Use environmental enrichment (EE), within what is available to us at our animal facility. In general, EE is an animal housing technique composed of increased space, physical activity, and social interactions, which in turn increases sensory, cognitive, motor, and social stimulation. Igloos, running wheels, saucer wheels, tube mazes, and other objects in the housing environment promote exploration and interaction. EE can be maintained through restraining (e.g. tube maze whilst handling), thus minimizing stress when for example an injection is needed.
- Keep animal transportation to a minimum.

- Use scoring sheets to monitor the health of animals undergoing procedures. v). Utilise non-tail handling methods.
- For any methods using anaesthesia, mice will be monitored closely for the duration of their recovery.
- If required, following veterinary advice, palatable pain medication will be used to reduce discomfort following the formation of local inflammation post vaccination.
- If more than 50 bites are given, mice are treated with saline solutions (under the skin) to compensate for blood loss.
- Eye drops administered to prevent dry eyes while the animal has no blink reflex while under anaesthesia.
- Heating pads to ensure maintenance of body temperature.
- A specialised Malaria Rodent Endpoint score sheet to help with the monitoring of our animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use guidelines from the Laboratory Animal Science Association (LASA) to make sure all experiments are conducted appropriately. In particular we will follow the information described in 'Avoiding Mortality in Animal Research and Testing'.

To ensure refined experimental design we will follow the PREPARE guidelines for planning experiments, and for thorough, responsible reporting of results we will follow the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We constantly review methods for replacement, reduction and refinement provided by the scientific literature and our support team within the facility, attending workshops to stay up to date.

During this project we will continue to be informed about the 3Rs by regularly checking our institute's 3Rs search page, and being registered fo regular NC3Rs emails and newsletter updates. Regular reference to guidance documentation provided by the Laboratory Animal Science Association (LASA) and the RSPCA will be made.

We will also ensure continued contact with the organisational teams in the facilities where our animal work will be conducted. Any new recommendations will be incorporated into our experimental plans wherever possible.

35. The chicken chorioallantoic membrane (cam) assay for biomaterial testing in tissue engineering

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Skeletal tissue engineering, Stem cells, Bone, Angiogenesis, Biomaterials

Animal types	Life stages
Chicken (Gallus gallus domesticus)	Embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to evaluate biomaterial structures and growth factors developed for the repair of the skeleton using a live, pre-clinical chick egg chorioallantoic (blood vessel) membrane model. Our rationale is centered on the urgent need to develop tissue regenerating biomaterials capable of activating and growing both blood vessels and bone to help patients repair their damaged and diseased skeletal tissue.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With the advent of an ageing population, skeletal tissue loss due to injury or disease is steadily growing. This significantly impacts the quality of life for the patient over time and

has socio-economic costs for healthcare providers. For example, each year in the UK there are over 50,000 primary hip replacement operations at a cost in excess of £350million. Hence, for reconstructive bone surgery and fracture repair, the need to develop better techniques and alternative bone therapies is vitally important.

The combined development of blood vessels and skeletal tissue are critical in the growth and maintenance of our skeleton and more importantly in the repair of our damaged bones. Without the cell communication from these two sets of tissues we find that our skeleton fails to function properly and is therefore less capable of successfully repairing itself.

Currently, our knowledge of the processes involved in cross-talk between these two tissues is incomplete. If we can understand the scientific unknowns of the developmental interaction of these cells and factors from these two sets of tissues, then we can develop and design smart biomaterials to mimic these interactions to successfully regenerate skeletal tissue lost due to trauma or disease.

The embryonic chick egg membrane model, which has a rapid growth of blood vessels (21 days), is ideal for understanding the role of the blood vessels in skeletal tissue formation. This rapid blood vessel growth can help provide information in how it is involved in tissue and organ development.

Conversely, this model can also be used to study diseases by simple exposure to stimulatory factors, hormones or drugs, or by transplantation of tissues, isolated cells or materials. This model has been used for many years in the cancer field studying the role of blood vessels in the development of tumours. Recently, we have used this model to try and understand the cellular interactions of the blood vessels in growing skeletal tissue. We have discovered that chick-derived blood vessels grow into and provide vital stimulatory factors and nutrients to the cells attached to or inserted into bioengineered products to help fix bones. As a result, this living model has become an important tool for testing experimental bioengineered materials to optimise the best combined design which can simultaneously promote the development of blood vessels and skeletal tissue.

A better understanding of how bones repair themselves could help develop treatments for patients and animals suffering from diseases and fractures affecting the skeleton. These include non-healing bone fractures and weakened bones due to diseases like osteoporosis and bone cancers.

What outputs do you think you will see at the end of this project?

The chick egg membrane model is being used in these studies to gain new insights that will help us in the development of tissue regenerating biomaterials to rebuild broken bones.

Specifically;

1. we aim to develop suitable new formulations of materials that can stimulate bone and blood vessel formation individually and simultaneously, to generate products that can be used in the clinic.

2. we will present our findings at scientific and medical conferences and we will publish these outcomes in peer-reviewed scientific journals.

3. we aim to use the latest technological applications to find out how the biomaterials stimulate the bone and blood vessel cells/tissue to grow and repair, and to use these imaging devices to track tissue development to reduce the numbers of embryos required to study these new biomaterials.

Who or what will benefit from these outputs, and how?

As with all our research goals the aim is to develop improved therapeutic strategies and products for patients who suffer from skeletal diseases and bone trauma injuries. We envisage that these project protocols and novel biomaterials have the potential to provide new treatments to help rebuild bones and skeletal tissues. In addition, the findings from musculoskeletal research can be applied to the veterinary field due to similarities in orthopaedic conditions between people and animals, leading to novel applications in a 'one health' approach.

Beneficiaries will include:

1. Patients and animals suffering from broken bones and skeletal diseases. Healthcare providers.

2. UK, EU and worldwide tissue engineering/biotechnology companies involved in tissue regeneration, stem cell biology or developing innovative tissue scaffold technologies,

3. the academic community in the generation of new protocols and avenues for skeletal tissue regenerative research.

Many materials we use in our studies are biocompatible and currently used in clinical practice for other applications. Modifying them to enhance their properties can result in new therapies in a relatively short time frame, benefitting patients due to the known track record of efficacy and safety. However, with the complex materials proposed the final outcomes for patients may require months to years of investigation due to thorough testing to ensure safety and efficacy prior to use in the clinic.

When these new treatments become available, we envisage growing the tissue constructs in the laboratory and transferring the regenerated samples to the patient in theatre. Ultimately, we believe this work will be translated to the clinic and benefit patients within the National Health Service and the wider medical community in the area of musculoskeletal repair. Alternatively, the development of materials that exploit the

regenerative potential of the patient's own repairing cells would minimise costs and hasten the material's therapeutic implementation.

In addition, the information from this project, including the study protocols and techniques will be made freely available via publication in peer-reviewed journals, in order to benefit patients, other researchers, doctors, vets, and pharmaceutical companies who are involved in the development and assessment of novel therapeutics which target the repair and regeneration of skeletal tissues due to disease and injury.

How will you look to maximise the outputs of this work?

Training & Collaborations

The team undertaking the research will acquire skills and expertise in the chick egg membrane model, blood vessel and skeletal stem cell biology, biomaterial development, imaging techniques in real-time such as 3D x-ray scanning and 3D optical imaging. Training will be achieved through an extensive local network of multidisciplinary collaborations within the University and established national and international collaborations in regenerative medicine.

In addition, the model and research work will be communicated to our Student & Postdoctoral researchers to provide new students and established researchers information regarding the models available for research projects in the University and to foster collaborative projects. We are part of a UK wide collaborative group network where we share our methods and results from acellular materials that will be available to be tested in skeletal and other tissue/organ regenerative models.

Education & Public engagement

The information and findings generated from this project will be presented through the scientific community by presentations at national and international meetings. We will also communicate findings to the public through outreach activities such as the University and laboratory open days for GCSE and A-level students in tissue regenerative medicine.

Progress of the study and results will be regularly presented at ongoing teaching events and public lectures. The press office of our university will also publicise the results.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The development of bone into a large anatomical tissue requires a fully functioning blood supply. Unfortunately, this cannot currently be created in the laboratory; therefore, an animal model is needed to provide the missing functional blood supply to test our bone development and regenerative biomaterials.

From fertilisation of the egg to hatching is 21 days, as a result, the blood vessel membrane surrounding the chick embryo develops rapidly. The advantage of the model is that any tissue placed upon the membrane will become surrounded and nourished by blood vessels and continue to grow. This model is unlike other models that use mice or rats where anaesthesia and a surgical procedure on the animal has to be performed to implant the test biomaterial to investigate its tissue regenerative properties. With the chick membrane model, no invasive surgery is required, we are just "piggy-backing" the chicks external blood supply to grow our skeletal bioengineered scaffolds. In addition, as the chick embryo has a subfunctional immune system, biomaterials incorporating cells from any species can be placed onto the membrane, the limit being the overall size of the explants (probably not in excess of 2-3cm3).

Typically, what will be done to an animal used in your project?

A typical experiment will comprise of the egg (day 3) having a light shone upon it (candled) to determine fertilization and that the embryo is growing. Under sterile conditions a window (approx. 1-3cm2) is created in the eggshell and our test skeletal bioengineered materials are placed on the highly rich blood vessel membrane surrounding the chick embryo. The window is sealed over with clear film and the chick is placed in a 37-39oC humidified (45-60%) incubator to continue its growth and development. Only one procedure per egg is done, which is the opening of the eggshell window and the placement of the sample(s) on the membrane. The duration of the experiment is no more than 16 days. Gestation of the egg is 21 days.

In addition, another method is applied whereby the contents of the egg at Day 3 is carefully separated from the eggshell and placed in a sterile dish. Thereafter, a bioengineered material is placed onto the membrane covered and returned to the incubator to grow and develop up till day 19. At varying time points in both models imaging of the developing embryo, blood vessel membrane and biomaterial will be done either by microscopy or x-ray scanning.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects associated with this model are expected to be very minimal as we are not undertaking any harmful techniques on the developing embryo. There is a small risk of infection, however, this is minimised as all work is carried out in a sterile clean cabinet with sterile instruments and biomaterials.

When opening the egg shell window, there is a small risk that egg shell fragments will spill into the membrane, triggering a minor reaction. This actually helps the embryo as it normally uses the eggshell as a source of calcium to help grow.

There is also the potential to damage the blood vessels when creating the window as the membrane is close to the surface which can result in the embryo not developing.

With the shelless external membrane model, there is the potential to damage the embryo, blood vessel membrane and the yolk sac when transferring to a dish. This can reduce the development of the embryo.

X-ray scanning. There is the risk that radiation doses during a micro-CT X-ray examination may produce adverse effects such as delayed growth. However, doses of x-rays and duration of scans are way below any threshold that will cause problems to the animal.

Biomaterials. The adverse effects of the implantation of biomaterials are expected to be extremely rare. We will have tested the safety of these materials in the laboratory using cells, toxic and biochemical testing prior to consideration of implantation on the chick blood vessel membrane assay.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities will be gauged to be sub threshold to mild.

We will have tested the biomaterials prior to implantation in cell culture work to ensure there is no release of any toxic factors or toxicity to cells directly in contact with the material. As with all batches of eggs we receive, there is a very small percentage 2-3% that are not fertilised or do not develop normally to hatching during the incubation period. We anticipate that 95% of animals will have severity scores of subthreshold, and up to 5% will have a severity score of mild.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development of bone requires a fully functional blood supply. Unfortunately, to date, this cannot be created in the laboratory with current tissue and cell culturing experiments, therefore an animal model is needed to provide a functional blood vessel network in order test the capabilities of new bone regenerative materials.

Which non-animal alternatives did you consider for use in this project?

Using laboratory cell culture experiments we are gaining as much information as possible to understand the functions and toxicities of new biomaterials being developed. In addition, we are studying the interaction of cells that make up the blood vessel and bone and how they combine to create 3-dimensional vascularised bone tissue known as organoids.

Artificial Intelligence (AI) modelling is now being developed to test biomaterials implanted into the chick membrane, so that this technique can be used to predict and determine how a new material will act in producing blood vessels and new skeletal tissue. However, there are limitations at the moment as this AI modelling is based on data provided from real studies. Once enough data has been accumulated for AI, this can, in principle, remove the need for the chick membrane model when researching new biomaterials in the future.

Why were they not suitable?

We have been unable to identify a cell model or a lab-based tissue/organ model that can copy a functioning blood vessel network essential for skeletal growth and repair. The generation of new bone requires multiple steps and the interplay of many different bone cells and blood cells in a co-ordinated manner in a 3-dimensional environment.

This interaction cannot be consistently or correctly reproduced under tissue culture conditions to meet the criteria expected to inform a clinical translation. In addition, in vitro model systems make it difficult to detect unexpected toxicities and observe the integration and degradation of materials over time.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any.

These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used our current and past experimental data to inform us of an estimation of the number of animals required per group and the number of control and test groups to give statistically valid experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the design phase we have used chick eggs to reduce intra-group variability of biomaterials and by using this model and the results obtained has allowed us to reduce progressive experiments in mice models. We have designed experiments using the fewest animals consistent with obtaining statistically valid results as determined from our power calculations. Using the NC3R's Experimental Design

Assistant we have calculated the minimum number of eggs required for a determined amount of new bone and blood vessel formation in comparison to control implanted samples.

In certain cases, mathematical modelling may be used to predict the release of growth factors from biomaterials, allowing us to determine how many chick eggs we can exclude while still achieving a meaningful outcome in the experiments. In addition, multiple scanning and imaging of the chick membrane at different time points reduces the number of chick eggs required in these type of studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Rigorous laboratory testing will be performed on the newly constructed biomaterials before any candidates will be put forward for the chick membrane experiments.

Multiple analysis will be undertaken on biomaterial samples implanted on the chick membrane, this will include X-ray and microscope imaging, blood vessel scoring, biochemical and molecular analysis, and histology. The multiple data that can be derived from one sample will optimise and minimise the number of eggs to be used in a single study. In addition, real time optical/microscope imaging will significantly reduce the number of time points required to assess blood vessel development within the implanted biomaterial. This will further reduce the number of eggs required for one study involving multiple time point assessments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Refinement is any measure to reduce suffering, or improve welfare, throughout an animal's life; however, this is not always achievable depending on the research question.

The chick membrane model is especially valuable, given that it has the ability to reduce the number of conscious, sentient animals (mice & rats for example) in subsequent experiments and therefore limiting pain and suffering of other animals used in subsequent confirmatory experimental models. As already alluded to, the chick membrane provides a vascular supply distant from the embryo, which does not involve a surgical procedure or anaesthesia compared to other models investigating bone and blood vessel formation, such as the mouse subcutaneous implant model. Through laboratory testing and biocompatibility cell studies we expect the biomaterials implanted onto the chick membrane is not harmful to the chick embryo. However, we cannot be 100% certain when a biomaterial is implanted on the chick membrane that the embryo will not experience any harm from the implant integrating with the surrounding tissue. From previous studies we ascertain there may be a 5% chance that the embryo will experience a very mild level of harm.

The advantages of the use of chicken egg embryos for research are the reduced conscious characteristics whereby it is reported that their nervous system is underdeveloped until day 17. It is important to note that while procedures on the chick membrane are often perceived as harmless there are still mitigating risks such as damage to the membrane or factors released from the biomaterial which may be incompatible with the development of the embryo. To date, research that identifies the timing of pain perception in the chick embryos remains limited. This research understanding is essential for safeguarding the necessary welfare standards when using this experimental model.

Why can’t you use animals that are less sentient?

The chick embryo is the least sentient species that has a functioning blood vessel system that enables us to investigate the skeletal regenerative properties of biomaterials designed in the laboratory. This model allows the screening of many biomaterials to inform us of the most effective materials that can be applied to a more complex animal model. In the mainstay, this has the potential to reduce experimental testing in more sentient animals. Zebrafish models for testing biomaterials involve injecting or implanting materials into the zebrafish to test the inflammatory response, but it is known that fish have the capacity for nociception which may be greater than that of the chick membrane and it is also difficult to quantify vascularisation in zebrafish.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Standard operating procedures for the chick membrane models will be constantly updated in line with advances in new methods developed. Annual risk assessments are carried out on the model and close record keeping of the experiments and eggs helps us to determine problems that have arisen. This will allow us to develop new practises to further minimise

any potential harm to the embryo. On a technical note the incubators will be cleaned and regularly tested to be in correct working order prior to each study and throughout the duration of the studies. The temperature and humidity at egg level are monitored digitally and the incubator functions monitored by a thermometer. These digital readings are recorded daily and the egg rotation is ensured to be occurring daily as well.

The eggs are candled to ensure the chicks are developing correctly and this is repeated on the day prior to creating the eggshell opening. Any undeveloped or cracked eggs will be discarded.

Users of the model will hold a personal license, attained accredited training in the avian egg modules and will be trained and confirmed to be competent in all necessary procedures by experienced users of this model.

Careful implantation of materials with no/minimal disruption of the chick membrane will be performed so that the embryo is not directly contacted during the procedure.

Chick embryos will be humanely killed using a schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are a number of detailed publications on the chick membrane model that provide excellent guidance in the methodologies, study design and best practise that we will follow and adapt to our scientific research.

We will follow the ARRIVE guidelines which provide a 20-part checklist of the minimum information required to be reported by groups using animals in research. ARRIVE guidelines are essential to help overcome issues in science such as reproducibility, reducing bias and the correct use of statistical methods of analysis.

In addition we will follow and consult the Norecopa (Norway's National Consensus Platform for the advancement of "the 3 Rs" (Replacement, Reduction, Refinement) in connection with animal experiments) database platform and PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for better science experiments using animals to ensure that we are using the best defined models for our work in investigation of biomaterials for skeletal biology.

Importantly, the chick membrane model offers additional details that can be used to direct progression to preclinical animal models. In vivo trials, without a doubt, serve as a vital link between laboratory bench discoveries and clinical use of medicinal instruments, pharmaceuticals, and products. As a prior ‘screening' model, the chick membrane assay may theoretically minimise the weak association observed between laboratory experimental results and those from animal models. The chick membrane model, according to current evidence and our viewpoint, offers a rapid, cost-effective, flexible,

stable, and repeatable method for assessing materials prior to evaluation in animal models comprising of complex bone repair.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs website to identify any changes that will be relevant to the workings of this model. In addition, we will follow the latest findings from the Laboratory Animal Science Association (LASA) and the PREPARE guidelines from Norecopa in better planning for research involving animals to prepare for better science and advance the 3Rs. Any changes will be implemented directly through the experimental design, and if necessary, through a project licence amendment. In addition, we follow the latest publications on using the chick membrane model and identify any new methods that reduce, replace or refine the chick membrane model workings. If applicable to this model in improving the 3R's we will request amendments from the Home Office to adjust the techniques/methods required and training or notification of relevant staff in updated techniques.

36. Development of novel therapy strategies for skin diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

genetic skin disease, gene therapy, skin sheet graft, topical delivery, inflammatory skin disease

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop specific and effective treatments for rare genetic skin diseases and common inflammatory skin diseases such as eczema.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In human beings, skin as the first barrier plays a protective role against infection and water loss and maintaining our normal bodily function. In patients who have inherited faulty

genes, the protective function of the skin is impaired or defective. These patients are vulnerable to infection, dehydration, and other conditions secondary to impaired skin. For example, in patients with a faulty gene called COL7A1, their skin is very fragile and often forms blisters following even minor mechanical stress and this symptom starts from birth. Moreover, in severe forms, chronic erosions with secondary infections can progress to widespread, mutilating scars and joint contractures, and aggressive skin cancers. All this can cause significant disability and affect the quality of patients' lives and sometimes is life threatening. There are no curative treatments for these genetic skin conditions and the development of novel therapy is, therefore, urgent.

Apart from rare genetic skin diseases, we are also concerned about the treatment for eczema, which is a chronic and relapsing inflammatory skin disease affecting 15-20% of children in the UK. Patients with eczema have redness, itching, flaking and blistering skin. In a considerable proportion of patients, eczema affects not only on the quality of life of the affected individual but also places a social, emotional, and financial burden on families. In these patients powerful oral immunosuppressive therapy is often required for many years with the attendant side effects and risks of long-term immunosuppression. Development of effective treatments for dermatitis (AD) are therefore highly desirable.

What outputs do you think you will see at the end of this project?

The skin diseases we have been investigating are debilitating skin conditions, causing significant illness, disability and severely affecting the quality of the patients' life. Currently, there are no curative treatments for these rare genetic skin conditions (less than 1 in 50,000 to 200,000 affected individuals) and no effective therapy for the common skin disease eczema.

This project is designed to develop new therapies for these diseases. If successful, our results will lead to treatment of these diseases to reduce patients' suffering and their families' burden. In addition, the outcomes of the research are likely to provide new insight into how these skin diseases contribute to skin disease, for examples, morphological changes, protein expressions, enzyme activities and lipid composition in the skin. We will present and publish these information and findings in national and international conferences and peer reviewed journals.

Who or what will benefit from these outputs, and how?

If successful, these therapies will provide clinical benefit to patients with rare genetic skin diseases or Eczema.

If the outcomes of our research are promising, we will transfer the research from 'laboratory bench' to 'clinical bedside', known as translational development. For example, in the past years we developed a gene therapy strategy for a rare genetic skin disease Netherton syndrome. We started with a series of studies including making vectors suitable for clinical use, correcting patients' skin cells, and then grew these gene-corrected cells in a 3D skin equivalent culture model to evaluate the efficiency of gene correction. Since the

results from these studies were encouraging, we further tested the durability of gene-corrected skin grafts and feasibility of the therapy strategy in the human:mouse skin graft model. The results confirmed that the skin grafts generated from gene-corrected cells could restore defective protein productions and reverse abnormal skin architecture to the normal. We presented these data to the Medicines and Healthcare Products Regulatory Agency (MHRA), an executive agency of the Department of Health and Social Care in the UK which is responsible for ensuring that medicines and medical devices work and are safe. This has directly led to initiation of translational developments and approvals for a first-in-man gene therapy clinical trial for Netherton syndrome.

We will launch new therapies for patients with these conditions using similar platform and pathway developed for Netherton syndrome in the project.

How will you look to maximise the outputs of this work?

The research outcomes will be disseminated via open-access publications in widely read, peer reviewed journals, oral and poster presentations at national and international meetings, and at public engagement events such as fundraising events. A close working relationship with our institute press office and the relevant patient support groups ensures that key messages from our work will be broadly disseminated.

Species and numbers of animals expected to be used

- Mice: 480

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use severe combined immunodeficiency (SCID) mice in our study. The reason for using immunodeficient mice is that being immuno-deficient, the mice do not reject human tissues. Since we will graft human skin sheet generated using human skin cells onto mice in the study to test therapeutic efficiency, the SCID mice will be the animal that meet the requirements.

We will use 2 to 3 months old mice in our studies, as they are adult mice and have large back (dorsum) surface for skin graft. In addition, if we graft human skin on 2 to 3 months old mice, allowing the graft growing for further 2 to 4 months, it means that mature adult mice (range in age from 3 - 6 months) will be used in the study. As mature adult mice are past the 'development' but not yet reach the 'aged' stage, their physical condition is stable with less incidence of age-related disease. All this will provide us a stable period with minimum unpredictable factors which may affect our study results.

Typically, what will be done to an animal used in your project?

Genetically altered mice known as SCID mice that can tolerate transplantation of human tissue will be used in our study. A piece of skin will be removed from the back of the mouse to make a wound and a human skin sheet generated from patients' or normal donor cells will be grafted onto the wound and secured with sutures. The typical surgery time will last 30 mins per mouse. The grafted skin sheet will grow on the mice for further 2 to 4 months, allowing them to blend with the surrounding mouse skin and form normal or disease-like human skin architecture. We will then test therapeutic strategies on the grafted mice by intravenous or intradermal injection or topical application of various drugs and therapeutic reagents. Following the treatment, the grafted human skin will be collected post-mortem and analysed to reveal whether the treatments are effective.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects include

i) The post-operation complications including dehydration, acute pain and infection. However, based on our previous studies, the symptoms of post-operation complications were short-lived (lasting less than 24 hours) and mild, and the incidence was less than 1%.

ii) Abnormal skin growth on grafted area. If grafts are generated using patients' cells with genetic conditions, abnormal skin growth is expected to be observed, such as mild blisters or exfoliated skin surface or thickening or scab skin. All this phenotype will last during the study. However, as the abnormal growth skin generated from patients' cells are relatively small (1-2 x 1-2 cm), localised and well blended with the surrounding mouse skin after wound healing, the abnormal engraftment does not affect normal behaviour of the animals. It has also been reported in a previous study that the engraftment generated from skin cells lacked nerve endings in the graft area for as long as 5 years post- grafting. Therefore, blisters or scab skin on the graft area would not cause pain and discomfort on grafted mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity for skin graft procedure is moderate and all mice subject to the procedure will have this severity. However, experimental mice will be anaesthetised. Prior to and post-operatively, analgesia will also be used to reduce the stress and pain caused by the surgery. According to our previous experimental record, 99% mice recovered (and have normal behaviours) 4-12 hours post-operatively.

Less than 1% mice had post-operative complications such as pain and delayed recovery. The majority reason for this was due to individual differences of mice.

The severity for injection is mild. This is because pain or suffering experienced by the animals following injection is only slight or transitory and minor. The animals following injection will return to a normal state, almost immediately. All mice subject to this procedure will have this severity

The severity for topical administration is mild as it is a non-invasive procedure. The topical drug will be made in non-irritant solution such as oil/cream or PBS/saline. The administration process may cause stress in the animals, but it is transitory and minor, and the treated animal can return to its normal state within a short time. All mice subject to this procedure will have this severity.

The severity of the project is therefore, graded as being of moderate (75%) and mild (25%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To achieve a clinically-relevant method for skin disease therapy, it is essential to evaluate strategies used for these therapies in an appropriate preclinical model. There are in vitro 3D skin equivalent culture models which can be used to assess the efficacy of transgene expression and function.

However, this model cannot be used for observing the long-term effects of the transgene as cells can only survive for three to four weeks in the culture system. In addition, the in vitro system lacks a blood circulating system as seen in the human body and it cannot be used to assess trans-effect of transgenes.

Which non-animal alternatives did you consider for use in this project?

A skin equivalent 3D culture model, also known as organotypical culture, was considered for use in this project. In this model, human skin cells isolated from skin biopsies are firstly expanded and cultured as a skin sheet on a support matrix. After 2 to 3 days, the cell/matrix complex is lifted and further cultured at the air-liquid interface for 14 days to allow skin cells to grow and form a skin architecture in conditions that resemble the skin development in the human body.

Why were they not suitable?

The reason that the skin equivalent 3D culture model is not suitable for use as a pre-clinical study model is that i) it cannot be used for observing the long-term effects of the transgene as cells can only survive for 3 to 4 weeks in the culture system, and ii) it lacks a blood circulating system as seen in the human body, so it cannot be used to assess trans effect of transgenes.

Compared to the skin equivalent 3D culture model, the skin graft mouse model provides a unique opportunity to grow and keep cell survival for more than year. This long-term engraftment will allow us to analyse the durability of gene expression, the maintenance of skin barrier function and other safety issues including screening for transformational changes. This animal model also allows us to assess trans (generalised) effect of transgenes via blood circulating system and examine morphological changes on grafts. In addition, our previous studies have shown that the epidermal architecture of the grafts generated from normal or patients' keratinocytes and grown on this model resembled the original normal or patient's skin structure respectively.

We therefore chose the skin graft model mouse model for our study. It must be emphasised that before carrying out any study, we will test all materials and reagents in vitro first to confirm their efficacy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice to be used in the study has been estimated based on our previous studies. A typical experiment will be two groups, positive and negative group. Due to nearly 80% successful rate of skin graft from our previous studies, the study using protocol 1 needs 4 mice for each group, and the study using protocol 1+2 and 1+3 need 6 mice for each group respectively. In this way, we can ensure that we have enough successful grafted mice for performing further treatment and data analysis. In addition, the same experiments will be carried out at least two to three times with different patients' cells for evaluation of the efficacy of therapy.

Considering all these factors, the numbers of animals in five years have been estimated as following.

Protocol 1: 8 (mice) x 3 (times) x 5 (years) = 120 (mice)

Protocol 1+2: 12 (mice) x 3 (times) x 5 (years) = 180 (mice)

Protocol 1+3: 12 (mice) x 3 (times) x 5 (years) =180 (mice)

Total mice that will be used in the project in five-year time are 480.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will only carry out studies in live animals when the outcomes of in vitro or other laboratory bench- based studies are promising. In this way, we will make sure that each animal study is necessary. In addition, we will consider sharing controls between groups, between two repeat experiments. For topically-treated, an internal control will be used, i.e a skin biopsy will be taken from the mice before treatment. In this way, we will reduce the mice numbers used in this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will reconfigure/modify and test vectors, small molecule drugs, siRNA, and other therapeutic reagents in the laboratory first, and will only test materials and reagents on the animals when we have promising outcomes from laboratory studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The human:mouse chimeric skin graft model will be chosen for our study. A piece of full skin with 30mm diameter is removed from the back of anaesthetised mice to make a graft bed. A bio-engineered skin prepared in advance in the laboratory is immediately grafted onto the wound bed to minimize further trauma. The graft area is then covered with denatured mouse skin and fixed with sutures to protect and hold the skin graft in place. Based on our previous experience, grafted mice recover and return to their normal status within 24 hours. Since this model does not involve massive invasive surgery and the suffering period in animals is transient and short, this animal model causes the least pain, suffering and distress on animals.

Why can’t you use animals that are less sentient?

Mice have been chosen as the experimental animal as they have a body environment with comparable complexity to the human. In addition, the use of gene therapy on mice is highly representative of the procedure in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The skin graft procedure (protocol 1) can cause moderate welfare costs to the animal, we will therefore, refine the following steps.

1. Before operation, analgesia will be used in mice to reduce the stress and pain caused by the surgery.

2. During operation, the graft bed will be covered with wet gauze between the interval of preparing graft bed and grafting to prevent dehydration. The grafting will be carried out immediately once the graft bed is ready to reduce the water loss.

3. After surgery, animals will be given post-operative analgesia to further reduce the stress and pain caused by the surgery.

4. The grafted mice will be closely monitored by the dedicated PIL every day in the first week post graft. Any abnormal finding will be recorded and discussed with NACWO/NVS and appropriate decisions will be made to reduce the suffering of the animals including humane killing by a Schedule 1 method.

5. Only PILs who have been trained and assessed as competent for operation techniques will be allowed to carry out the surgery

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The best practice guidance that we will follow including

i) Guidance on the Operation of the Animals (Scientific Procedures) Act 1986 published by Home Office, UK.

ii) ARRIVE guidelines (2.0) published by NC3Rs.

iii) PREPARE: guidelines for planning animal research and testing published in the journal Lab Anim. 2018 Apr;52(2):135-141.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use the following ways to keep up to date with latest 3Rs.

1. Attending monthly Western Laboratory Advisory Group meeting to get latest news about 3Rs

2. Reading NC3Rs Newsletter about latest 3Rs news. This will be sent by NC3Rs Regional Programme officer and/or our university Biological Service Department

3. Regular discussions with the NACWO/NVS at our institution to review current approaches and whether there are any new 3Rs opportunities.

4. Attending events, symposiums and workshops hosted by NC3Rs/Society of Biology to keep abreast of 3Rs advances and approaches.

5. We will keep the contact information of our local NC3Rs Regional Programme Manager to having a direct route to get 3Rs advice, developments, and best practice.

37. The role of transposable elements in cichlid fish development and evolution

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Transposable elements, Gene silencing, Epigenetics, Adaptive Evolution, East African cichlids

Animal types	Life stages
Haplochromine cichlid fish of the East African Great Lakes.	adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the role of certain genes, termed transposable elements, in the evolution of East African cichlids.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to identify the genes underlying the evolution of animals. The knowledge of the genetic basis of evolution is relevant, for example, to predict how animals react and adapt to a fast changing environment. This understanding is most important nowadays given global climate change trends, which are increasingly having a deep negative effect

on biodiversity. This is particularly relevant for animals that live in a "closed" environment, from which they cannot migrate out of. Such is the case of fishes specialised to life in lakes.

Transposable elements are genes that exist in most animals. The special feature of these genes is that they can multiply and change their location within cells. As this change in location may damage other genes, yet another set of animal genes is dedicated to the control of the mobility of transposable elements. However, the mobility of transposable elements does not have only negative effects. In fact, some transposable elements may lose their ability to change location and become fixed in one location (termed "domesticated"), by evolving a useful function.

In the proposed research we will use a fascinating group of animal species, the cichlid fish of the East African Great Lakes, to investigate two aspects related to transposable elements:

1) the contribution of "domesticated" transposable elements to the evolution of these fishes; and

2) the genes that prevent the mobility of transposable elements.

What outputs do you think you will see at the end of this project?

Due to the presence of transposable elements in most animals and their ability to multiply, these genes are responsible for providing new genetic diversity that may, in some cases, be important for evolution. Genetic alterations of transposable elements and the genes that control them is required to understand what their function is in animals.

The results of the proposed work, using genetically altered animals, have the potential to result in several publications reviewed by other scientists. These publications will report findings related to the following main topics:

1) Identification of the genes controlling the mobility of transposable elements in cichlid fish, across several relevant parts of the body (including the reproductive organs and the brain), as well as in eggs and sperm.

2) Determination of whether the activity of transposable elements is affected in animals created by mating individuals of different species.

3) Identification and characterisation of "domesticated" transposable elements important for the evolution of these fishes.

Furthermore, it is likely that the data generated in our work will be useful to other researchers and lead to collaborative work. Importantly, our data will be deposited in publicly available, free repositories, so that other researchers can download it and use it to answer their own biological questions. This is also a reduction measure, as it should avoid repetition of the same work by other researchers.

These publications and collaborations are direct benefits resulting of this work, which will be likely produced within the timeframe of the license and shortly after. It is also likely that our publications will provide a substantial contribution on the medium-/long-term to biological research.

Who or what will benefit from these outputs, and how?

Our research is of a fundamental nature and will build important knowledge on the "domestication" of transposable elements and on the genes that control transposable elements. This will increase our understanding of nature and of the genes implicated in animal evolution. As transposable elements exist in most animals, our discoveries may be relevant to understand the evolution of other groups of animals, including mammals. As our project touches upon so many fundamental biological aspects, we expect to impact on several fields of the biological sciences, e.g. evolution, molecular biology, and genetics.

Given the fundamental nature of the proposed work, the research output is not likely to produce directly any product or method with commercial potential.

How will you look to maximise the outputs of this work?

I intend to present my results in international and local scientific conferences, or other scientific meetings. I will attend, at least, one major scientific conference per year on topics relevant to my proposed research. These conferences will provide opportunities to communicate my results broadly. Other persons involved in this work will also participate in dissemination efforts.

Our investigations and the data generated are expected to lead to new collaborations with other researchers. Our work will be published in free, public repositories online and in international scientific journals.

The genetically altered animals, or their eggs/sperm, will be openly available and shared with the scientific community, if requested and assuming all legal permissions are in place. Sharing animals worldwide will replace the creation of novel genetically altered animals, and reduce the total number of animals used in animal research.

Species and numbers of animals expected to be used

- Other fish:

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using East African cichlids of the African Great Lakes due to their unique and fascinating diversity of body sizes, shapes, diets, and behaviours. Although they vary in these ways, they do not vary much genetically, in fact being genetically very similar. The combination of these features make them, as a whole, a great system to pinpoint the genes underlying cichlid evolution.

It is beneficial for transposable elements to be active and multiply in the reproductive organs, eggs or sperm, or during early development, as this increases their chances of transmission to the next generation. Thus, the activity of transposable elements and of the genes that control them should be studied in the reproductive organs and during early development. In addition, we discovered genes that inhibit transposable element activity in the brain. This raises the interesting possibility that transposable elements are important for brain development and function. These exciting preliminary data justify the use of these parts of the body.

Typically, what will be done to an animal used in your project?

Creation of genetic alterations - fish eggs will be gently held and injected so as not to damage the egg. Immediately after, the eggs will be returned to aquaria. Injection of a batch of 25 eggs takes less than 20 minutes. Injections will be performed to create genetic alterations, meaning the addition or deletion of genetic material. Genetic alterations will be generated in transposable element genes, or genes involved in the control of transposable elements. These alterations will, in principle, not cause lethality.

Confirmation of the genetic alterations - After the creation of genetic alterations by injection of fish eggs, fish will be grown until they reach their juvenile stage. At this point, we will confirm the genetic alterations that we introduced. This will be done either by cutting a little portion of a fin, or by taking a swab from the fish. Swabs will be preferred to fin cutting, as recent data indicates that swabs provide the more refined method. Swabs gently collect skin cells and mucus, in a way that does not damage the scales and skin of the fish. When confirming genetic alterations using a portion of the fin, the amount of fin removed will not compromise swimming or any other aspects of normal fish physiology or behaviour, and taking the sample takes less than a minute. The cichlid fish we are using are large and robust.

Therefore, these procedures will be preferentially performed without anaesthesia, as this brings a higher risk of adverse effects.

Isolation of eggs and sperm - Adult fish will be anaesthetised and eggs and sperm will be obtained by applying gentle pressure on the sides of the fish.

What are the expected impacts and/or adverse effects for the animals during your project?

Our proposed procedures will impact the animals' health and welfare minimally and will not lead to long-lasting pain, suffering, or distress. The genetic alterations we propose to

introduce are highly unlikely to lead to any malformations or adverse effects. Some eggs may be damaged during the injection procedure, but these, whenever detected, will not be allowed to live past the stage where they are still very small and immature fish, before they start to feed independently. East African cichlids are large and will withstand well our proposed procedures. These procedures will be performed in the least amount of time possible and are not expected to lead to any long-term consequences or distress. After any procedure, animals will be monitored for an adequate amount of time to ensure recovery.

Animals are expected to remain healthy and normal and, should this not be the case, they will be humanely killed immediately to prevent any pain, suffering, or distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Fish: Mild severity: 100%.

What will happen to animals at the end of this project?

Killed
Used in other projects
Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Transposable elements are important genes for animal evolution. However, their roles in the evolution of East African cichlids remain unknown. We aim to understand if and how transposable elements influenced the evolution of diverse colours, shapes, behaviours, and dietary adaptations in these fishes. To conduct this investigation we need to generate cichlid fishes with genetic alterations.

Which non-animal alternatives did you consider for use in this project?

We have considered computer simulations and cultures of cells.

Why were they not suitable?

At the moment there are no alternative resources capable of recreating the natural development of fish. Likewise, eggs and sperm are created and maintained in a unique

and complex natural environment impossible to replicate in the laboratory. In order to fully understand animal evolution, we need to understand the role of transposable elements. To do so, we need to see how live animals with specific genetic alterations look and behave in a natural context. Other alternative systems, such as cell culture, or computer simulations, are not able to recreate the complex interactions that occur during development, between neighbouring cells and tissues. These interactions are most important for proper animal development. Thus, our aim cannot be accomplished without using animals.

We will use methods to collect mature sperm and eggs of cichlids, effectively bypassing the need to kill adult animals for the dissection of their reproductive organs. Eggs and sperm will be used as described, or frozen after their isolation. As these frozen eggs and sperm can be thawed and combined together in the laboratory to create new animals, their isolation will allow for the long-term conservation of our animals. Generation of animals in the laboratory will replace the continuous breeding of specific cichlids, when not in use.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We plan to produce animals with 3 distinct types of genetic alterations (maximum of 3000 animals):

1) We plan to produce up to 5 lines of animals with added genetic material. For their breeding, we expect to use a maximum of 1000 animals (5x200).

2) In addition, we will alter or delete genetic material of up to 5 genes required for preventing the activity of transposable elements. For their breeding we will need a maximum of 1000 animals (5x200).

3) We plan to alter or delete genetic material of up to 5 transposable elements in cichlids. We expect to need a maximum of 1000 animals (5x200) to breed these animals for the duration of the project.

Lastly, we aim to collect eggs and sperm from a maximum of 200 individuals (200 protocol 2).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Genetic alterations will be performed on a carefully chosen set of genes. At the beginning of this research programme, we used computational methods and available data to confirm that the candidate genes are active in the tissues of interest. In this programme of work, validation of our candidates will be performed using procedures not regulated by law. This careful consideration and preliminary analysis ensures our set of candidate genes are most relevant to the biological questions we aim to answer.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout the duration of the project, we will use the minimum number of animals required to acquire satisfactory data. Experiments will be designed, conducted, and reported according to published guidelines (namely the PREPARE and ARRIVE guidelines).

Whenever an animal is culled, a variety of tissues will be extracted and frozen. As other colleagues may have an interest in tissues not necessarily relevant for the purpose of this project (e.g. scales, muscle, liver), tissue sharing will avoid culling of additional animals. Similarly, sharing data obtained from dissected tissues with colleagues will avoid culling of additional animals for repetition of these experiments.

Frozen eggs and sperm will ensure the long-term maintenance of fish lines. This practice will reduce the number of individuals bred, when they are not required, and will prevent duplication of experiments (i.e. re-generating animals with particular genetic alterations).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

I will use East African cichlid fish for the proposed work plan. As these fish species are large and robust, they can be effectively bred and grown in an aquaria environment. Moreover, these animals can tolerate the mild regulated procedures we propose to perform with the minimum amount of stress and pain.

The egg and sperm collection, the creation of genetic alterations and their confirmation will be conducted using current best practices and technology. These procedures are expected to cause little pain, suffering, and distress to the animals. Genetic alterations will

be created by injection of eggs, an immature life stage before the animals feed independently. None of our experiments will require animals to live in isolation.

Why can't you use animals that are less sentient?

The work proposed here takes advantage of the extreme diversity of shapes, sizes, colours, diets, and behaviours of East African cichlids, in spite of very close genetic similarity. The diversity of these cichlid fishes is unique amongst vertebrates and even amongst the entire animal kingdom. Therefore, other less sentient, or invertebrate, animals will not allow us to answer the same biological questions.

I will use whenever possible tissues obtained from immature life stages, i.e. from early development, before the animals reach the independent feeding stage. Tissue dissection and extraction, besides the methods to confirm the genetic alterations, will be exclusively performed in dead animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will incorporate new recommendations on animal welfare, as soon as possible after their publication.

Cichlid housing will be continuously improved to faithfully mimic the sandy areas rich in vegetation and hiding places characteristic of their natural environment. This will be achieved by introducing sand, artificial plants, clay pots, and plastic tunnels in the aquaria. Fish will be housed in groups, in order to decrease stress and aggression levels. Manifestations of aggression, including chasing, fighting, and injuries will be monitored daily by the scientific and animal care staff. These aggressive behaviours are normal to these species and not a product of captivity. If required, fish will be temporarily separated and groups redesigned to avoid further injury and aggression. Continuous monitoring of water parameters, food regimen, and breeding will ensure the wellbeing of the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the best practice guidelines available at www.nc3rs.org.uk. Experiments will be planned, documented, and reported according to published guidelines (namely the PREPARE and ARRIVE guidelines).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will follow the website of the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs, available at www.nc3rs.org.uk), and stay up-to-date with new information and new resources that become available. To achieve this, I have signed-up to the NC3Rs e-newsletter. In addition, named persons at my

establishment (i.e. the Named Animal Care and Welfare Officer, Named Veterinary Surgeon, and Named Information Officer) will inform us of relevant new information and resources, and will advise, together with the animal care staff, on the best ways of implementation.

38. Understanding the mechanisms and mediators involved in adverse pregnancy outcomes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

pregnancy morbidity, immune system, coagulation, placenta, imaging

Animal types	Life stages
Mice	adult, pregnant, embryo
Rats	adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to use a model of pregnancy to evaluate:

1. The role of inflammatory mediators and the clotting cascade in the development of pregnancy related disorders

2. Which cells are recruited and activated in pregnancy morbidity

3. The role of these different cell types (e.g. monocytes, macrophages, neutrophils, platelets, B cells, T cells, trophoblasts) in abnormal pregnancy outcomes

4. The use of non invasive imaging methods for early diagnosis and prevention of pregnancy complications

5. Novel cellular and molecular targets for therapy

6. A variety of agents and compounds as potential treatment for pregnancy complications

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

According to the WHO, 1500 women die from pregnancy or childbirth-related complications each day. In 12% of the cases, maternal death is caused by preeclampsia. In addition, among the 133 million babies who are born each year, almost 3 million die in the first week of life and a million in the following three weeks. Frequent pregnancy complications include unexplained recurrent early pregnancy loss, fetal death, or premature birth due to severe preeclampsia (high blood pressure), eclampsia (onset of seizures due to high blood pressure), intrauterine growth restriction (babies too small for their gestational age) or other consequences of placental insufficiency, a serious complication of pregnancy when the baby is unable to get nutrients and oxygen from the mother.

A developing baby goes through important growth throughout pregnancy— including in the final months and weeks. The brain, lungs, and liver need the final weeks of pregnancy to fully develop. Babies born too early (especially before 32 weeks) have higher rates of death and disability. Preterm birth is the leading cause of perinatal morbidity and mortality worldwide with figures from 2017 showing that preterm birth and low birth weight accounted for about 17% of infant deaths.Effective prevention or treatment of these pregnancy complications could significantly lower maternal and neonatal mortality and morbidity as well as health care costs. Unfortunately, there is no procedure or test that an obstetrician can employ to predict if the mother and the fetus are at risk for any of these pregnancy disorders. There is growing evidence of the association between coagulation, inflammation and activation of innate immunity with pregnancy complications. However, the mediators, receptors and cellular mechanisms responsible for adverse pregnancy outcomes remain unclear.

By using a model of pregnancy, we will be able to evaluate the role of inflammation, coagulation and other mediators in the development of pregnancy complications. In addition, we will be able to characterise effector cells and the potential mechanisms by which these cells influence the outcomes. We anticipate that our work will give important information on the mechanisms responsible for adverse pregnancy outcomes and will identify possible targets for therapy.

What outputs do you think you will see at the end of this project?

The project outlined will allow us, with the help of this model, to develop knowledge on the pathogenesis of pregnancy-related disorders in particular the role of mediators, receptors and effector cells. Novel imaging techniques may help us to better recognise mechanisms, diagnose and quantify the risk of pregnancy complications and to improve current interventions. Data from this project may allow us to more efficiently diagnose and treat patients at higher risk. We anticipate that our work will give important information on the mechanisms responsible for adverse pregnancy outcomes and will help us identify possible targets for therapy. This knowledge will help us develop the appropriate treatment to patients based on more quantitative and objective measures.

Who or what will benefit from these outputs, and how?

The animal models will allow us the identification of the mediators responsible for adverse pregnancy outcomes and targets for prevention and therapy. The expected immediate benefits of this research are the ability to make an informed decision whether to test the new agent in humans, or to abandon the agent, or return to the in vitro or chemical laboratory for further modification. If any of the targets identified in the different mouse models of pregnancy complications are present in humans, they could be effectively used to detect pregnancy complications before they manifest and develop new therapies to improve the health of mother and unborn child.

How will you look to maximise the outputs of this work?

We will closely collaborate with industrial and university partners. We will disseminate the results of this work at conferences and workshops and publish in peer reviewed national and internal scientific journals. In addition, we will organise workshops at KCL where we will share our results to KCL and external academics interested in this work.

Tissues will be harvested for use in histology. These tissues will be kept for re-probing or further quantification. Imaging data will be compiled in an imaging library and shared with other investigators.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Considerable number of features of pregnancy are similar in humans and mice, therefore, mice constitute a good animal model. Mice are quick to reach sexual maturity (7-8 weeks) and they have a short reproductive recovery (less than a week) with a short intergenerational interval. Mice have short gestational period (≈ 20 days) and the reproductive tract is relatively small, thus it is possible to analyze the course of pregnancy in exquisite detail with minimum or no harm.

Typically, what will be done to an animal used in your project?

The typical experience for an animal includes:

1) Animals will be mated by conventional breeding methods to induce pregnancy

2) An agent which is likely to perturb pregnancy (i.e. antibody) will be administered

3) Blood collection (optional)

4) Administration of a drug or agent to potentially revert pregnancy morbidity (optional)

5) Imaging in vivo (by MRI, PET, SPECT, etc) under anaesthesia with or without administration of contrast agents (optional)

6) Food withdrawal for up to 18h (optional)

7) Schedule 1 culling

What are the expected impacts and/or adverse effects for the animals during your project?

In the mouse model of pregnancy morbidity, around 40% of the embryos die in utero. The dead embryos quickly undergo resorption and the remaining 60% make it to term. No signs of maternal health compromise are observed in this model.

All agents will be administered at doses known to be non-toxic, based on experience and dosages reported in the literature, and at volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm.

Besides the momentarily discomfort of the injections no distress or harm is inflicted by the procedures.

Moderate severity may be reached by 20% of animals to which a microosmotic pump is inserted. This procedure carries the risk of wound breakdown and infection.

Regular monitoring of the wound and the animal behavior will be performed.

Deaths resulting from anaesthesia or surgical complications are uncommon (<1%) and will be minimised by correct dosing of anaesthetics, by accurate weighing and by maintenance of body temperature during and post procedure e.g. use of heat pads.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 80% mild severity

20% moderate severity

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To date, there are no alternate systems such as computer models, cell culture or in vitro assays to adequately replace animal models for pregnancy.

We require the use of animals because:

1. Our project needs mammals of the order eutherians (placental mammals like humans) to allow us a correlation of our results to humans. The study of the physiological dynamics between mother and offspring requires an intact animal and are essential to the understanding of pregnancy complications

2. Data generated from this body of work may be used to inform whether to go forward to human clinical applications. Regulatory agencies require animal data to demonstrate safety and efficacy before therapeutics (that can be validated through imaging) or molecular imaging agents can enter human trials.

3. To validate the mode of action new/improved agents or molecular imaging compounds, experiments are required that cannot be conducted in humans for ethical and scientific reasons (e.g. contrast agent distribution requires intact physiological barriers and excretion mechanisms).

4. Bio-distribution in whole organisms (i.e. tracking the injected agents route/ accumulation and excretion through the body), with intact biological barriers and excretion mechanisms, is key to clinical use.

Which non-animal alternatives did you consider for use in this project?

Pregnancy is a phenomenon that only occurs in animals. Our project needs mammals of the order eutherians (placental mammals like humans) to allow us a correlation of our results to humans.

The study of the physiological dynamics between mother and offspring requires an intact animal and are essential to the understanding of pregnancy complications and to date, there are no alternate systems such as computer models, cell culture or in vitro assays to adequately replace animal models for pregnancy complications.

Whenever, and if, possible (i.e. toxicity, binding or stability studies) in vitro experiments will be performed using cells and ex vivo tissues to minimise unnecessary harms.

Why were they not suitable?

If we are to further investigate the causes of pregnancy complications, the study of the physiological dynamics between dam and offspring requires an intact animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals required based on published information on the proposed model. Whenever possible, we have looked at our previous data for reproducibility and compared to what is available in the literature.

A typical study might be planned as follows:

- For testing a new agent in mice, we estimate animal numbers using a power calculation (two-tailed t- test, α=0.05, power=0.9), yielding N=6 animals/group. To account for complications with anaesthesia, interventions or treatments, we would plan to investigate 10 animals/group. If difference between experimental and control groups, is expected to be large (>1 order of magnitude change, e.g.in the case of using effective blocking substances/treatment), or found to be so by pilot experiments, statistical significance may be achieved with fewer animals/group. However, we will not use less than 3 animals per group to comply with generally accepted scientific reproducibility criteria in the field.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. We will limit the group size to the minimum needed to obtain statistically significant data. Sample sizes will be set using power analysis. For the majority of the experiments we will aim to have a significance of 5% and a power of 90%

2. Wherever possible, we will perform multiple experiments simultaneously so that the same control group can be used for all experiments

3. Wherever possible, we will try to collect as many different tissues from each animal so that additional animals are not needed

4. Wherever possible, we will try to use new instrumentation/methodology that improves precision and reduces the number of animals. For example, following the observations of Seaborn et al. (Promoting the "3Rs" Principle in Developmental Biology with Early and Convenient Diagnosis of Pregnancy in Mice J Reprod Dev 2011), we will address Reduction and Refinement in the use of mice by using maternal percentage of weight increase at gestational day 8 to diagnose pregnancy in mice. Body weight increase is a better indicator than vaginal plug, which is associated with false negative and positive rates. Ultrasonography may be accurately used as an alternative non-invasive technique for pregnancy diagnosis in the mouse from very early stages of gestation (day 5.5). These methods allow pregnancy detection before midgestation and propose an ethically sound approach to experimental animal use by optimizing the number of mice used and refining animal manipulation.

5. Non invasive sequential imaging of individual mice at differing time points (longitudinal study) will enable each animal to act as its own control. Previously animals were sequentially sacrificed at pre- determined time points to enable sequential data to be collected. In vivo imaging will diminish the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible, we will perform multiple experiments simultaneously so that the same control group can be used for all experiments and will try to collect as many different tissues from each animal so that additional animals are not needed.

When a new agent is used for the first time in mice the concentration of the agent in the blood will be used an indicator to calibrate the dosage. The minimum number of mice will be used in a pilot study (n=6). Animals will be treated with the new compound and small amounts of blood will be drawn from a superficial vein, with or without local anaesthesia, to measure the concentration of the agent in the plasma.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project, we will use a model of normal pregnancy obtained by conventional breeding methods.

Species: Mice and rats are the species of least neurophysiological sensitivity that provide the capability to support the development of a normal pregnancy and the minimum size compatible with the scale of resolution/movement associated with the imaging technique. Resolution of whole-body imaging techniques is of the order of 0.1-1mm. The considerable larger size of rats compared to mice make them more suitable for diagnostic imaging.

Only moderate severity may be reached by those animals to which a micro-osmotic pump is inserted. In these cases, close monitoring, anesthesia and pain relief will be provided.

Why can’t you use animals that are less sentient?

A considerable number of features of pregnancy are similar in humans and rodents and, therefore, mice for example constitute a good animal model. Mice are quick to reach sexual maturity (7- 8 weeks) and they have a short reproductive recovery (less than a week) with a short intergenerational interval. Mice have short gestational period (≈ 20 days) and the reproductive tract is relatively small, thus it is possible to analyze the course of pregnancy in exquisite detail. There is not a less sentient animal that can be used to replicate elements of human pregnancy.

The considerable larger size of rats compared to mice make them more suitable for diagnostic imaging and therefore, rats may be used for some of the experiments whenever necessary.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We do not anticipate animal distress or suffering as the protocols we will use are mild. Animals will be monitored daily at early stages and at least three times weekly once early clinical signs have developed.

Only moderate severity may be reached by those animals to which a microosmotic pump is inserted. In these cases, pain management will be administered under the close consultation with the NVS.

All agents will be administered at doses known to be non-toxic, based on experience and dosages reported in the literature, and at volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm.

Inhalation anaesthesia will be used wherever possible to minimise transient pain and distress, e.g. mini-pump insertion, during imaging. In addition, full recovery between periods of anaesthesia, rehydration during long imaging sessions, respiration/cardiac function monitoring, body temperature monitoring/maintenance will be conducive to animal wellbeing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow established published guidelines to ensure experiments are conducted in the most refined way. These includes:

1) The Responsibility in the use of animals in bioscience research produced by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

2) The Home Office Guidance on the Operation of the Animals (Scientific Procedures) Act 1986.

3) Accepted limits of volumes and frequencies when administrating compounds and anaesthesia (Appendix 1a in Action Plan section).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) website and seminars on the 3Rs organised within and outside of our institution.

Additionally, we have direct support and contact with an NC3R's regional Programme Manager who supports the application of the 3Rs at King's College London and the Francis Crick Institute and is a member of the Policy and Outreach Group. This includes providing expert advice and coordinating the sharing of best practice.

39. Understanding trait variation in migratory birds

Project duration

5 years 0 months

Project purpose

- Basic research
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Animal Migration, Ecology, Breeding biology, Ornithology, Stable isotopes

Animal types	Life stages
Brent goose Branta bernicla	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Studied for 1000s of years, migration remains one of nature's most puzzling phenomena. This project seeks to understand the causes and consequences of variation in foraging and movement behaviours in migratory birds and how these in turn link to fitness and drive changes in demography.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Migrants are amongst the most threatened of all bird groups, climate change, habitat change and increasing urbanisation are all thought to play a role but our understanding of

their importance and how they might interact is limited. This is in part because, it is exceptionally difficult to identify where and when in the annual cycle different migratory populations are regulated. To progress we need to be able to map individual responses to changing environments onto population processes and to do this we need to be able to track individuals throughout their migratory journeys. My group are working on a series of study systems that are allowing us to start to piece together the links between the drivers of change in migratory species and this licence will enable us to use forensic approaches to infer habitat choices and migratory routes.

What outputs do you think you will see at the end of this project?

In general terms, the tracking and stable isotope data will contribute to the basic research on obligate and partial migration route of multiple species, many of which have long remained unclear. More specifically, the recent technological advancements in the application of stable isotope techniques this project will provide empirical migration data to the ornithological and scientific community. By integrating stable isotope data, environmental data, behavioural data and morphology, this project will enhance our understanding of partial migration and the processes that drive it. The novel insights the project is likely to generate will be of interest to a range of scientists working on migration, ornithologists (both academics and enthusiasts) and conservationists.

In short term, the major outputs of this project will be the production of a PhD thesis and peer-reviewed scientific papers. The former will be fundamental to the career development of young scientists and both will enhance our knowledge of the phenomenon. These outputs will be largely targeted at the academic community, but also hobby ornithologists, bird ringers and managers (particularly if we can develop morphometric assays for identifying the migratory and non-migratory components of populations).

In medium and long term, output from this project is expected in influence and guide further research in the largely under-studied field of (1) avian partial migration and (2) ecological conditions that may shape migration strategies. Moreover, understanding the links between migratory behaviour, body size measurements and other individuals of the same species has the potential to inform conservation strategy for threatened migratory species (e.g. which components of the population are at most risk and where in the annual cycle this risk is greatest).

Who or what will benefit from these outputs, and how?

The major beneficiaries are likely to be other scientists with an interest in intra-population variation, the ecological niche and migration. However as outlined above, information on habitat use of geese and shorebirds may help conservation managers in the areas where we catch them. Elements of basic research on migratory origins and distinguishing resident/migrating individuals is also expected to contribute to future studies into the origins of migratory species, population structure within migratory species and in turn conservation planning. Tracking the migration origin/destinations of individuals will enable

much more precise and targeted conservation plans that can cover protection/management of the habitats required by both the migratory and resident subsets of the population. This will be particularly important for shorebirds in Northern Ireland that are currently undergoing population decline such as the Oystercatcher which is listed as Near Threatened on the IUCN Red List.

How will you look to maximise the outputs of this work?

My research team have an excellent record of data analysis and publication. As such I see this as the primary route for dissemination. Work will be presented at conferences and workshops (including unsuccessful investigations) and publications will be shared in accessible form (e.g. tweetable abstracts) on multiple social media channels (Twitter, Instagram, Facebook etc). The university also has an excellent media team for reaching the more conventional media outlets and some of our proposed work is likely to be of interest here.

Species and numbers of animals expected to be used

- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The research will investigate what drives variation in migration behaviour and its consequences. We have chosen 9 different species of wild bird. The species have been chosen according to their migratory behaviour in order to allow us to test the questions of interest. As such, we have long distance migrants, short distance migrants, species where migration distance varies among individuals and species where there are both resident and migrant individuals. We use adult individuals as they are the ones that make the decisions of when and how to migrate, as breeders is it also possible (in some instances) to measure the reproductive benefits or costs associated with different behaviours.

Typically, what will be done to an animal used in your project?

All birds will have feathers and a small amount of blood collected, and some will have a small piece of toenail clipped. We will measure chemical fingerprints in these samples in order to infer the diets and migratory origins of individuals. The entire procedure will typically take less than 5 minutes and birds will be released back into the wild after it is complete. We would plan to collect these materials from around 1600 individuals across all species over the course of the project (species breakdowns detailed below). Any individuals retrapped during the course of the project will not be resampled. These animals will be identified via individual rings fitted at the time of original capture.

What are the expected impacts and/or adverse effects for the animals during your project?

There may be a small amount of pain during blood collection or the collection of feathers, but these are likely to be transient. Birds may show panting, gaping, closing eyes, fluffing up feathers or immobility butt usually return to normal behaviour within a few minutes of release.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities are very mild for all animals.

What will happen to animals at the end of this project?

- Set free
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This is a study of a wild behaviour, there are no appropriate models available

Which non-animal alternatives did you consider for use in this project?

There are no non-animal alternatives to consider that can address our questions.

Why were they not suitable?

NA

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For all species, sample sizes in excess of 100 individuals are needed to account for variation among life histories (e.g. sex and age class) and migration behaviour, but vary as such life history variables are not consistent across species.

For Brent geese the number is higher than other species because we need to have data from sufficient individuals returning with offspring. Breeding is highly variable on an annual basis (in some years less than 1% of individuals breed successfully). In order to account for the exceptionally high yearly variation, larger sample sizes across five years is required to answer the research questions detailed below in later parts of the report.

For oystercatchers and redshanks, numbers are based on the frequency of alternate migration strategies and size of flocks in catchable areas.

For the other species (Blackcap, Robin, Blackbird, Chiffchaff, Goldfinch and Greenfinch) the numbers are estimated numbers to secure sufficient sample sizes of both resident and migratory individuals (while accounting for additional variables such as sex and age) based on their proportions within the population in the local area of capture.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The numbers of individuals are estimated based on the uncertainties outlined above, along with the necessary sample sizes needed to provide enough power to handle multiple explanatory variables (e.g. sex, body size, habitat, body condition, date etc) in addition to those of interest (diet and migratory behaviour).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Sample sizes will be large in the early stages of the project. However, once the first data sets start to come online, it will be possible to run pilot analyses in order to estimate whether subsequent sample sizes can be reduced.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Each species represents a route to testing a different aspect of the hypothesis. There are no model alternatives and the sample collection (blood, feathers and claws) is the least invasive way of accessing the forensic information on diet and migratory origins. Alternative methods (such as the collection of muscle tissue) would be more painful, stressful and more likely now to cause lasting harm to the animals.

Why can't you use animals that are less sentient?

The questions are focussed on the behaviour of adult animals in the wild. Thus, immature life stages would be inappropriate. Likewise less sentient models or terminally anaesthetised animals would not enable us to address the questions of interest.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The effect of the procedure is likely to be transient and the approaches are well-established. But all animals will be marked offering the opportunity to assess the behaviour of a subset of individuals post release.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to consult the species/taxon focussed literature and the relevant Home Office wildlife research pages for new approaches and guidance. Likewise there will be ongoing discussions about approaches with colleagues, veterinary teams, technicians and the HO inspector for ongoing advice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep abreast of advances via reading the recent scientific literature, discussions with colleagues and discussions with the HO inspector and university support teams. Any new guidance that emerges will be incorporated into the procedures and the licence will be amended accordingly.

40. Developing flare-responsive intra-articular steroid injection

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Glucocorticoid, hydrogel, rheumatoid arthritis, inflammation, metabolism

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Intra-articular injections of therapeutic glucocorticoids (GCs) are widely used in the treatment of chronic inflammatory arthritis to suppress inflammation and joint destruction.

This proposal has two core aims. The first is to test whether specially designed gels known as 'hydrogels' are able to extend the release and therapeutic duration of intra-articular GC injections relative to standard formulations used for this purpose.

The second is to test whether we can utilise the natural 'metabolism' and inflammatory targeted activation of inactive GCs within the joint to reduce their off target side effects, to prevent local bone loss and cartilage damage.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Intra-articular glucocorticoids (GCs) injections are routinely administered to patients with joint pain and inflammation, including rheumatoid arthritis, with a predicted global market value of 5.7 billion by 2026. However, the intra-articular delivery of therapeutic GCs such as methylprednisolone suffers from limitations that restrict efficacy. These include short therapeutic duration (up to 4 weeks) and recent high profile reports of localised bone loss and cartilage damage that exacerbate joint destruction. Therefore, there is an unmet need to develop better tolerated, longer lasting injectable GCs. This project aims to address this problem using novel GC loaded hydrogels

What outputs do you think you will see at the end of this project?

This project will provide new knowledge on the delivery of therapeutic glucocorticoids within novel gel formulations that we predict will extend their duration of action, therapeutic efficacy and safety profile in rheumatoid arthritis. This knowledge will be shared with the wider research community in the form of publications in scientific journals and presentations at conferences. Furthermore, the project will inform further funding applications to support and inform the development of new drugs and clinical trials with the goal to help patients with rheumatoid arthritis.

Who or what will benefit from these outputs, and how?

In the short-term, the improved understanding of whether slow release metabolism activated steroids are effective in the treatment of rheumatoid arthritis will benefit many research groups exploring steroid application in human inflammatory disease. This will include fundamental insights about the importance of steroid metabolism on the actions of therapeutic glucocorticoids and the efficacy of gel delivery to extend their therapeutic application and safety. These findings will be shared with the research community over the next 1-3 years of the project.

In the medium-term, these data will guide the design of future clinical trials examining glucocorticoid delivery in these gel formulations. These benefits of our research are expected to manifest in 5-8 years.

In the long-term, the development of novel treatment approaches to safely prevent side effects, and increase the anti-inflammatory efficacy of therapeutic intra-articular glucocorticoid injections would mean that patients with rheumatoid arthritis are the major future beneficiary of this research. The clinical benefits may be transferrable to other patient groups with inflammatory arthritis where there is common underlying pathophysiology and are expected to be realised over 8-10 years.

How will you look to maximise the outputs of this work?

This research fits within the interest of major research centres of excellence studying inflammation and aging and rheumatoid arthritis treatment and pathophysiology. Through our current links and involvement with these centres, we would ensure wider dissemination of findings to research organisations working in this field, as well as interested patient engagement groups. All findings will be routinely published to inform methodological approaches in appropriate journals and academic conferences regardless of experimental outcome.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Murine models of polyarthritis arthritis have been extensively studied and validated to model human disease where they share relevant immune mechanisms of human disease. Crucially we have selected models that present with the articular and extra-articular manifestations of inflammatory joint disease that we aim to prevent. Whilst alternative models of monoarthritis were considered in this setting, their application is not suitable in this instance based on the requirement for additional intra-articular injection to induce disease activity that would complicate interpretation of intra-articular therapeutics interventions, and increase experimental variability between animals and require significantly greater experimental animal numbers to detect therapeutic efficacy. This is coupled with a limited understanding of how intra-articulate glucocorticoids mediate their anti-inflammatory effects in this model, requiring additional validation and supporting studies. In contrast, the proposed models of polyarthritis more accurately model the rheumatoid arthritis disease setting where the therapeutic steroids proposed in this study are aiming to be employed. Further key points that make the proposed murine models of inflammatory arthritis the ideal in vivo organism to examine this include that the methods proposed have been validated and optimised by my research team. Here, murine models are recognised as showing the least degree of neurophysiological sensitivity, pain, suffering, distress and lasting harm for this nature of research. Consequently, exploring novel treatments in these well- established murine models before humans reduces risks of harm to humans.

The study will utilise the TNF-transgenic murine models of polyarthritis, which develops spontaneous and reproducible disease. Producing and maintaining these animals will employ breeding techniques that involve all stages of the life cycle. Research on the therapeutic actions of GCs administered by intra-articular injection and their role in

suppressing disease activity and preventing joint destruction requires animals that have completed development and we will therefore use adult mice only.

Typically, what will be done to an animal used in your project?

Breeding genetically altered animals involves mating and reproduction of mice by natural means. Small tissue samples may be taken infrequently to track the genetic alterations present in each animal.

TNF-tg mice will receive up to two intra-articular injections (given at least 10 days apart) of either saline or injectable therapeutic glucocorticoids that aim to suppress inflammation and prevent localised joint damage. Animals will be monitored for joint inflammation at regular intervals three times a week using score sheets to measure number of joints affects and severity of inflammation. Blood sampling may be taken on no more than three occasions to assess systemic exposure to GCs. Further samples and data will be collected during non-recovery general anaesthesia or after death.

What are the expected impacts and/or adverse effects for the animals during your project?

The TNF-transgenic model of poly arthritis develops progressive joint inflammation. From 8 and 12 weeks of age TNF-transgenic animals show reduced weight gain, reduced mobility and evidence of pain behaviour (including reduced weight bearing). These are monitored and scored three time weekly and where evident are indications to initiate pain relief. For the TNF-tg model of inflammation, arthritis will be maintained for no longer than 28 days to assess anti-inflammatory properties and steroid release over this duration. Any animals developing persistent discomfort (despite pain relief) beyond moderate changes, which exceed predetermined scoring criteria, will be humanely killed. If an animal loses weight rapidly, stops eating or displays persistent abnormal behaviour they will be humanely killed.

Intra-articular injections of steroids under anesthesia are predicted to cause mild discomfort and pain for up to 72 hours post injection. Evidence of pain and reduced weight bearing will be managed with daily buprenorphine pain relief. Evidence of persistent pain and loss of weight bearing beyond 72 hours will be humanely killed.

Injections, and blood sampling, may cause mild discomfort that is short-lasting. In exceptional circumstances when more significant discomfort is observed in an animal with these procedures, it will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 95% of animals will develop arthritis and so are expected to be of a moderate severity, with the remainder of animals under this PPL being of a mild severity. All experimental animals developing polyarthritis are expected to experience discomfort that will not exceed moderate severity. The majority of animals undergoing breeding procedures, injections and blood sampling may experience short-lasting and mild discomfort.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

My research group routinely use human ex vivo tissue biopsies and primary cell cultures to model the rheumatoid arthritis joint environment and examine and test our research questions. Using these resources we have performed the initial testing and validation of the novel intra-articular gel formulations being examined in this proposal. These methods have been instrumental in demonstrating the anti-inflammatory efficacy and bio-compatibility of our intra-articular glucocorticoid formulations for use in diseases such as rheumatoid arthritis. However, based on these findings there is now a strong impetus to ascertain whether these glucocorticoid interventions would represent an effective way of to protect suppress inflammation and joint destruction in a human disease setting. Unfortunately, we cannot proceed down this pathway until these concepts have been validated in an in vivo model prior to entering clinical trials and being tested in patient cohorts.

Which non-animal alternatives did you consider for use in this project?

We have explored conducting studies in human ex vivo biopsies of rheumatoid synovium and using cell culture models from key target immune and stromal cell populations.

Why were they not suitable?

Human cell culture models of the key cell populations found within the joint and ex vivo tissue models will be utilised within this project where possible to study cellular and molecular processes and reduce the number of animals required for research. However, these in vitro and ex vivo models cannot adequately replicate the complex interactions between multiple organ systems that occurs in the rheumatoid joint in a living organism. Moreover, tissue culture models cannot adequately replicate the specific environment that act on these cell populations during movement. Animal models are therefore needed to replicate human disease faithfully and address our research question with relevance to

clinical medicine. They are also an essential component required for preclinical testing of therapeutics designed to treat rheumatoid arthritis and are necessary for examining the interventions outlined within this proposal in future clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experimental group sizes have been calculated using existing in house preliminary data in TNF-Tg mice receiving traditional therapeutic glucocorticoids to inform statistical calculations on the lowest required number of animals to detect meaningful scientific results. During these projects we developed first-hand experience in delivery and dosing of therapeutic glucocorticoids required to suppress disease activity and joint destruction in these models. The planned pilot study adheres to a design that is embedded in the experimental protocol. This means that data from animals used in the pilot study can contribute to final result analysis, rather than duplicating use of animals. Colony sizes for breeding animals have been determined based on existing breeding protocols for the TNF-transgenic mouse model that are ongoing within our institution and informed by published research reporting welfare guidance on their maintenance. These are under continual review with expert advice from both the NACWO and NVS to ensure that numbers required for maintenance and breeding new transgenic lines are kept to a minimum.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experiment is devised in a 2x3 factorial design, allowing efficient use of data generated from control groups and thereby minimising the number of animals required. Care has been taken throughout the experimental design and with selection of outcome measures to reduce unwarranted variability as much as possible. Steps to this effect include randomisation, blinding, or selecting muscle mass as a highly sensitive outcome measure. This will reduce the number of animals required to identify meaningful results. In conjunction with pilot studies, we have optimised methods of tissue and data collection from individual animals ensuring that these numbers are sufficient to address all of our research goals whilst providing biologically significant results that would not require further experimental repeats. Throughout these protocols full factorial designs will be used where applicable, with routine use of blocking where appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In house resources and expertise will reduce the number of animals needed to deliver this project. C57Bl6 mice with appropriate genetic alterations for this protocol are already available in house, reducing the need to establish new genetic lines or backcrossing animals. Breeding practices will adhere to local standard operating procedures and national NC3Rs guidance to maximise efficiency.Our research group has previously optimised the data and tissue collection methods required to deliver this project. This avoids need for further optimisation, reduces variability and ensures that high quality data is obtained from every animal. Where operator-dependent measurement variation is possible, we will take precautions to perform measurements according to standard protocols and by the same operator wherever feasible. The application of the anti-TNF biological therapy 'infliximab' has been utilised for all TNF-transgenic breeding animals to fully suppress disease activity, increase welfare, breeding lifespan and litter sizes. These allow smaller breeding colony sizes for these TNF-tg animals. Finally, we will conduct a pilot study to confirm that our estimates for the minimum required animal number is indeed correct, prior to embarking on the full-scale project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The TNF-tg murine model of polyarthritis will be examined in this project. Importantly, this model displays the articular and extra-articular manifestations such as bone damage, cartilage erosion and joint inflammation that our interventions are aiming to prevent. A model of polyarthritis rather than a model of monoarthritis has been chosen for this study for several important reasons. Firstly, the intra- articular injections required to initiate monoarthritis are themselves a potential cause of local joint damage at the injection site that would act as an additional confounder in delineating the impact of subsequent therapeutic glucocorticoid intra-articular injection. Secondly, the therapeutic efficacy and off target effects of glucocorticoids in bone and cartilage that we are investigating in this study have yet to be fully characterised in models of monoarthritis. Consequently, additional experimental animals would be required to establish effective therapeutic dosing ranges and characterise effects on bone and cartilage relative to the polyarthritis models where these experiments have already been performed.

Thirdly, this study aims to model and examine the efficacy of intra-articular glucocorticoids in human rheumatoid arthritis where features of disease and their response to glucocorticoids differ from mono- arthritic diseases such as osteoarthritis. In particular, leukocyte recruitment is known to differ, and therefore their response to metabolism activated steroids remains an unknown, meaning further validation and optimisation would be required for these models. Finally, whilst experimental model choice is limited due to scientific requirements, the polyarthritis models have been refined to ensure they cause the minimum possible pain and distress.

This species and procedures have been chosen as they represent the lowest animal models with a musculoskeletal system in which it is possible to study the complex arthritic joint and interventions designed to prevent joint destruction that reflect human disease. All methods and protocols applied within this proposal have undergone rigorous prior optimisation, ensuring we are able to use pre- optimised doses of glucocorticoids within the lowest acceptable therapeutic ranges that are well tolerated, and mean that all inflammatory models will run for the shortest possible duration to minimise suffering. Throughout, behavioural nociceptive (pain) testing in conscious unrestrained animals

provides an important and strong indicator of changes in pain thresholds and provide clear indications for the application of pain relief that minimise suffering in experimental animals.

Why can’t you use animals that are less sentient?

Less sentient animals and embryos pre E14.5 do not possess the same sort of skeletal structure that composes the joints, and often their vascular tree and immune system do not fully represent that of humans. Small rodents are the lowest mammals that can be used to recapitulate the human immune systems response to joint inflammation. The development of polyarthritis, modelling human disease, is a gradual process occurring over several weeks. As such these models are not suited to terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The application of the anti-TNF biological therapy 'infliximab' has been utilised for all TNF-transgenic breeding animals to fully suppress disease activity, increase welfare, breeding lifespan and litter sizes. These allow smaller breeding colony sizes and improved animal welfare. For the breeding of TNF-tg animals, we use heterozygous TNF-tg males paired with wild type females. Consequently, pregnant females do not have the burden of pregnancy plus arthritis. Each experimental model will be monitored daily following intervention and mice will be assessed for any signs of distress such as pain and inability to feed. Therapeutic substances identified within this proposal will be tested in a small pilot study and the mice monitored daily for signs of distress. Humane endpoints will be strictly adhered to at all times. To support this we have extensively refined the scoring system for each individual polyarthritis model to capture the specific aspects of each arthritis

phenotype, ensuring clear and consistent analgesia and humane endpoints. In particular, we have shown that opiate pain relief using buprenorphine does not interfere with disease progression and therapeutic glucocorticoid responses in this model.

We have also made refinements to the housing of the animals to cater for any disability arising from arthritis - including soft flooring, non-tangling nesting material, long spouts on water bottles, food on the cage floor.

These aspects will be systemically reviewed following each experiment to see what lessons can be learned from the study in terms of endpoints (scientific and humane) and any animal welfare issues that may have arisen during the experiment that could then guide the subsequent experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will abide by local best practice procedures for breeding, maintenance and surveillance of animals. National guidance by the Laboratory Animal Science Association, National Centre for the Replacement, Reduction and Refinement of Animal Research, and the Royal Society for the Prevention of Cruelty to Animals was used in the development of this protocol, including:

Avoiding mortality in animal research and testing (https://view.pagetiger.com/RSPCAAvoidingMortalityResearchReport/RSPCA)

Blood sampling techniques, frequencies and volumes (https://nc3rs.org.uk/3rs-resources/blood- sampling, https://www.nc3rs.org.uk/blood-sample-volumes)

Genetically altered mice (https://nc3rs.org.uk/gamice)

Animal handling and husbandry (https://nc3rs.org.uk/3rs-resources)

The PREPARE guidelines (https://norecopa.no/prepare) informed the project planning phase, including engagement of relevant stakeholders and implementation of quality controls. Furthermore, the ARRIVE guidelines have been considered to ensure that results can be communicated with the highest scientific rigour. Specific guidelines in regards to the welfare and maintenance of rodent models of polyarthritis by Hawkins et al, have been utilised in the design and implementation of this proposal:

Hawkins, P., Armstrong, R., Boden, T. et al. Applying refinement to the use of mice and rats in rheumatoid arthritis research. Inflammopharmacol 23, 131–150 (2015). https://doi.org/10.1007/s10787-

015-0241-4

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to engage with Institutional efforts to promote the 3Rs and workshops; and receive the NC3Rs newsletter.

41. Investigating mechanisms and novel therapeutics for critical limb ischaemia

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Blood, Vessels, Development, Mechanisms, Therapy

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

1.Investigate how blood vessel develop following a blockage in arteries supplying blood to the legs leading to a poor blood supply (limb ischaemia) and low levels of oxygen reaching the tissues in the legs.

2.Investigate treatment strategies, using cells and molecules, to promote the development of new blood vessels or help to enlarge existing blood vessels in order to overcome the lack of blood flow in an ischaemic limb

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fatty deposits (atherosclerosis) in the arteries of the legs (peripheral arterial disease) affects 20% of individuals over 75 and can cause narrowing of the blood vessel, creating a poor blood supply to the legs which reduces the supply of oxygen to tissues in the affected leg. When severe enough, this can result in a condition called critical limb ischaemia (CLI) that manifests in pain, ulceration and gangrene. The quality of life in patients with CLI is similar to those with terminal cancer, with ~33% of patients with CLI that cannot be helped by conventional treatments requiring amputation of the affected limb. A limb is amputated every 2hrs in the UK as a result of CLI.

What outputs do you think you will see at the end of this project?

1. A better understand of the mechanisms that regulate blood vessel development in legs with poor blood supply (ischaemia) and in particular the relationship between tissue resident and circulating cells in promoting blood vessel development in the ischaemic limb.

2. Novel therapeutic targets will come from biochemical and cell analysis, with comparisons of blood and tissues obtained from patients with a critically ischaemic limb and from our temporal studies in our mouse model of hind limb ischaemia (HLI).

3. An optimal delivery strategy (good retention and activity/viability over defined delivery frequencies) for the administration of factors and/or cells at the sites of delivery in the ischaemic limb.

4. A molecular and/or cellular therapy ready for clinical trials.

5. A series of high impact publications that will disseminate our findings to the greater scientific and medical community and stimulate further work in this area.

Who or what will benefit from these outputs, and how?

Patients with limb ischaemia would not be expected to benefit from these outputs in the short term, as properly designed clinical trials would need to be instigated for any potential therapy to enter the clinic.

How will you look to maximise the outputs of this work?

We will closely collaborate with clinical colleagues to ensure that any therapeutic strategy derived from our work can be tested in clinical trials for safety and efficacy and ultimately be commercialised to ensure widespread clinical use.

We will also disseminate the results of this work at conferences and workshops and publish in peer reviewed national and internal scientific journals. Workshops will be

organised within our institution where we will share our results and provide hands on training for internal and external academics interested in this work. Other means of dissemination will include talks at the Pint of Science initiative or active participation in the summer festival of the Royal Society.

Species and numbers of animals expected to be used

- Mice: 7100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mouse models of compromised blood flow to the limb (ischaemia) will be used in this project licence because their molecular and cellular responses to ischaemia is similar to that seen in patients with this condition.

Typically, what will be done to an animal used in your project?

A. Mice used for the hind limb ischaemia model may undergo the following.

1) (i) Bred to express certain gene defects that will allow us to interrogate the importance of those genes in blood vessel development in legs with poor blood supply, or be given a diet that promotes a similar condition (fatty arteries) to that seen in patients with this condition.

AND/OR

(ii) Be given a diet that promotes a similar condition to that seen in patients with arteries that are narrowed because of fat deposits in their wall (atherosclerosis), and/or treated with a chemical to induce diabetes. This combined condition closely mimics Type 2 diabetes in man.

2) Undergo an operation to tie off or remove a section of a major blood vessels in order to cause a significant reduction in the blood supply to a rear limb (hind limb ischaemia, HLI).

3) Treatment with cells or agents that might help blood vessels to develop. These will be administered via direct injection into the mouse's ischaemic hind limb, injection via a blood vessel or infused by a mini-pump placed inside the mouse.

4) Imaged over time to see how well those blood vessels have developed and whether any cells that have been given are part of the developed blood vessels.

5) Have small blood samples taken at the time of imaging.

6) Humanely killed and blood and limb muscle tissue removed for analysis in the laboratory.

The duration of this experiment will typically be no longer than 21-28days

B. Mice used as a cell donors may undergo the following.

1) Bred to express specific gene defects so that cells obtained from these mice also express the same gene defect.

2) Administration of an agent to induce the production of inflammatory cells, via injection of the agent into their abdomen that will induce the production of inflammatory cells we believe may be important in blood vessel development.

OR

Administration of an agent via a mini-pump placed surgically into the abdomen that delivers the agent over a period of time to promote the release of cells from the bone marrow that we believe may be important in blood vessel development.

3) Humanely killed and cells removed from the abdomen or bone marrow for use in our mouse model of hindlimb ischaemia or analysis in the laboratory.

The duration of this experiment will typically be no longer than 5-14days.

C. Mice used for screening of agents or cells that have the potential to stimulate blood vessel growth may undergo the following.

1) Bred to express certain gene defects

2) Administration of a protein matrix plug containing cells or agents of interest via injection or small surgical incisions in the back of the mouse (maximum 4 places).

3) Imaging of the growth of vessels in the administered matrix plugs at defined intervals.

4) Humane killing and removal of the plugs for analysis of blood vessel growth in the laboratory.

The duration of this experiment will be no longer than 42days

All protocols have been refined so that the minimum experimental duration and animal numbers are used to achieve the scientific objectives.

What are the expected impacts and/or adverse effects for the animals during your project?

The mouse hindlimb (HLI) model is commonly used for the study of limb ischaemia as this condition is reasonably well tolerated by the animal, because there is an inherent recovery

of blood vessel function over a relatively short period of time. Animals may experience temporary lameness in the affected limb (up to 1wk), while the new blood supply is established. The protocol for this procedure has been classified as 'moderate' as a surgical procedure is involved and in a smaller number of animals (<10% of the number of animals) tissues of the toes in the affected limb may die (develop dry gangrene) and these toes break off naturally. Neither the lameness nor loss of digits appears to affect their well-being as the animals are seen moving around the cage, grooming and feeding and drinking normally. This is similar to patients with limb ischaemia, who may also experience loss of multiple digits and yet are able to mobilise independently without discomfort. Pain following surgery will be minimised by treatment with an appropriate analgesic.

The use of mice in which specific genes have been removed or manipulated to be switched on or off, and agents that induce conditions that are associated with increased artery narrowing leading to poor blood supply to the leg (e.g. atherosclerosis or diabetes) are also commonly used in investigations of the regulation of blood vessel development. The genetic manipulations and agents used to promote the build-up of fatty deposits in arteries may result in a small number of mice suffering adverse effects such as skin irritation that can lead to skin ulcers. Agents used to promote diabetes could result in higher blood sugar levels than is warranted and these can lead to infection and loss of life. Both of these conditions can be treated early with creams for the skin and insulin injections used to control levels of blood sugar (in much the same way we treat diabetics). Those animals that do not respond within a few days of treatment will be humanely killed.

Bone marrow transplantation between mice with different genes enhances our understanding of the importance of those genes on reparative processes in the ischaemic limb. While mice tolerate ablation of their bone marrow by irradiation reasonably well, it exposes them to the possibility of infection (immunocompromised). For this reason, irradiated mice are housed in independent ventilated cages during the time they are immunocompromised (up to 21days). Prophylactic measures (e.g. treatment with antibiotics) will also be undertaken to prevent the risk of infection. The mice also tend to lose some weight after irradiation, but most will recover the lost weight within a few days.

Mice used as cell donors may suffer adverse effects such as the build-up of fluid in the abdomen leading to abdominal tenderness on handling. Mice displaying this condition will be immediately humanely killed, and the cells that have accumulated in the abdomen removed for our investigations. Surgical wounds may rarely become infected or the stiches breakdown (<1% of cell donors) following surgery to implant a device (e.g. mini-pump) that can deliver an agent that promotes cell release from the bone marrow. These can be treated with antibiotics or resewing of the wound. If these treatments are not effective, the animals will be humanely killed.

Mice used in the screening of potential treatments that promote blood vessel development and undergo surgery for implantation of protein plugs may rarely (<1% of mice) experience, adverse events such as infection at the site of the implantation (by a surgical procedure), but this can readily be treated with an antibiotic.

All animals will be humanely killed at the end of an experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities and proportion of animals from all experimental protocols experiencing each severity includes:

1. Mild – ~ 74%

2. Moderate - ~ 26% (surgery carried out and in ~ 4% of these there may be tissue death leading to loss of toes)

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The processes of how blood vessels block and prevent oxygen reaching end target tissue such as muscle (ischaemia) and how the body may grow existing or new blood vessels to try and compensate for this, involve dynamic interactions between a myriad of molecules and cells that are impossible to replicate on the laboratory bench (in vitro). It is not ethical to study the effect of injecting substances and cells into patients with disease of their blood vessels without preliminary evidence that this form of intervention may be of benefit. We therefore have to carry out our initial experiments in an animal model of hind limb ischaemia (HLI), which allows the study of the dynamic cellular and molecular responses and interactions that take place during blood vessel growth in low oxygen environments, and assessment of the effects that treatments, derived from our studies in patients, might have on this process.

I am satisfied that the potential gain, in terms of treatment of human disease, is sufficient to justify the use of animal models.

Which non-animal alternatives did you consider for use in this project?

We use methods that employ cells cultured in the laboratory to assess mechanisms of how blood vessels grow and cellular or molecular interventions that might stimulate this process. We also use these as an initial screening tool when assessing which cells or molecules have the potential to promote robust blood vessel development in before they are used in our mouse models of hindlimb ischaemia. We continue to develop more complex cell culture systems that more closely mimic tissue compartments (organoids) to help us to interrogate pathways that may be involved in blood vessel development in ischaemic environments and for use as extra screening tools prior to the use of our mouse models.

Why were they not suitable?

Studies in the laboratory cannot truly replicate the complex, dynamic interactions that take place between the many factors and cells that are involved in the development of an existing blood vessel or the formation of a new blood vessel.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals required for our experimental studies based on our previous experience with the HLI animal models and of breeding for use in these models. Of the total number of animals we expect to use over the 5yrs of this project

- ~70% of animals will be used in breeding and maintenance (Protocol 1)
- ~21% will be used in for the hind limb ischaemia experiments (Protocol 2)
- ~4.5% as cell donors (Protocols 3&4)
- ~4.5% for the in vivo neovascularisation assays (Protocol 5)

We have estimated the number of animals required for our experimental studies based on our previous experience of the variability in the end-point measures (e.g. degree of improvement in blood perfusion, number of vessels and size of vessels) in these models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the HLI model we use the unaffected leg as an in-built internal control against which we can assess the recovery in blood perfusion (perfusion index) in the ischaemic limb in the

same animal over time. Our extensive experience with these models in a variety of wild-type and genetically modified strains of mice has provided us with a good analysis of the variability in the endpoint measures that we have developed with these models, and we have used this experience to carry out appropriate statistical power calculations for the numbers of animals required in our experiments.

Where we find ourselves using a strain of animal or treatment that we are unfamiliar with, or there is little data in the literature on, then we will carry out pilot experiments using longitudinal or dose escalation analysis in small cohorts of animals in order to provide statistical data that allows animal number estimations for definitive larger experiments.

Other measures we have taken to reduce animal numbers includes the development of 'test tube'- based analytical methods systems for the laboratory screening of cells or agents highlighted by our human studies as potential modulators of revascularisation. We will also use a simplified in-animal screening model that allows assessment of multiple cells or agents, or doses of these, in the same animal, prior to their assessment in our more complex models in which we induce limb ischaemia. We will also use imaging techniques (such as laser Doppler blood perfusion imaging (LDPI) that allow measurement of limb blood perfusion in the same animal over time (longitudinal imaging), thereby reducing the numbers of animals required for experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always carry out pilot studies using small cohorts of animals prior to embarking upon a new experimental plan. If we are planning to interrogate ischaemic tissue, we will first check repositories of tissue banks that may be available to use, prior to obtaining our own specimens. We also work with other scientists who are international experts in their field and use the hindlimb ischaemia model. We will discuss our experimental strategy with them to optimise the number of animals we use and determine whether tissues and data can be shared between our groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Species: Mice are the lowest mammalian group in which models of hind limb ischaemia have been successfully characterised and are therefore the species most often used in the

study of limb ischaemia. In our experience mice tolerate the ischaemia reasonably well, as new blood vessels develop spontaneously in the affected limb through processes similar to those seen in man. The mouse models have the advantage that they also allow the use of animals in which we can test the activity of specific cells of human origin without rejection; as well as facilitating investigation of the importance of specific genes on blood vessel growth through genetic modification in these species.

Animal models: Mice tolerate surgery well, with good recovery rate and low post-operative infection, but as a result of the reduced blood flow, animals may have temporary lameness for a few days and a small proportion may have toe loss in the affected limb (in much the same way as we see in patients with critically ischaemic limbs). Existing blood vessels (collaterals) increase in their size and, together with new blood vessel growth, establish blood flow. The lameness (or loss of toes in some) does not appear to affect their well-being as they are seen moving around the cage and feeding, drinking and grooming normally within 24hrs of the operation and for the remainder of the experiment's time course (up to 42 days).

The techniques to evaluate blood vessel growth in this model such as angiography (X-ray based imaging of blood vessels), laser Doppler perfusion imaging (LDPI) and analysis of muscle by specific staining of blood vessels in sections of muscle (histology), are well characterised and internationally accepted in these models.

Why can't you use animals that are less sentient?

Less sentient animals cannot be used as they do not have a vasculature that replicates that of man or allow interrogation of the complex processes giving rise to blood vessel development in the context of ischaemia. Mouse models also have the advantage that they allow testing of the activity of specific cells of human origin without rejection.

Blood vessel development needs to be assessed over a period of time that precludes assessment under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pain relief is given during and after the operation, to minimise suffering, in much the same way that we treat patients. Animals will be monitored daily at early stages post-surgical interventions and at least 3 times weekly once early clinical signs have developed.

Inhalation anaesthesia will be used wherever possible to minimise transient pain and distress, e.g. during surgery and imaging. In addition, full recovery between periods of anaesthesia, rehydration during long imaging sessions, respiration/cardiac function monitoring, body temperature monitoring/maintenance will be conducive to animal wellbeing.

In animals in which diabetes is induced, we will monitor glucose levels and treat mice who develop very high blood glucose levels (severe hyperglycaemia) with slow release insulin to bring this down to an acceptable hyperglycaemia.

Animals to be exercised will receive up to 5min of training on 2 consecutive days prior to their inclusion in full experiment on effect of treatments on distances covered following HLI. Those that do not respond to the exercise regimen will be removed from the exercise component of the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow established published guidelines to ensure experiments are conducted in the most refined way. These includes:

1) The Responsibility in the Use of Animals in Bioscience Research guidlines produced by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

2) The Home Office Guidance on the Operation of the Animals (Scientific Procedures) Act 1986.

3) Accepted limits of volumes and frequencies when administrating compounds and anaesthesia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) website and seminars on the 3Rs organised within and outside of our institution.

We will also have direct support and contact with an NC3R’s regional Programme Manager who supports the application of the 3Rs in our and other major institutions and is a member of the Policy and Outreach Group. This includes providing expert advice and coordinating the sharing of best practice.

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We want to better understand how neural circuits in the retina and brain process visual information, and how these circuits evolve.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We are pursuing this project because relatively little is known about the diversity of mechanisms by which neurons transmit different kinds of sensory information. These mechanisms play a key role in determining what we can and cannot see, and we need to understand these processes as they operate in the intact retinal circuit.

This project will advance science in several ways. First, we will improve our understanding of the processes which transfer signals between nerve cells. Defects in these processes

have been associated with important diseases, such as Alzheimer's and Parkinson's. Second, we will improve our understanding of the variety of ways in which visual signals are processed in the brain.

What outputs do you think you will see at the end of this project?

We expect to obtain information about signal processing in the visual system, that we will communicate through scientific publications.

Who or what will benefit from these outputs, and how?

The most immediate beneficiary of our research will be the scientific community devoted to vision research. In the mid- and long-term, our findings could have the potential to be incorporated into the frameworks of ophthalmological and neurological research for clinical applications, and/or in those of ecological and evolutionary research for conservation efforts of species that live under different illumination conditions.

How will you look to maximise the outputs of this work?

We will collaborate with other research groups across the world that work on related topics, and exchange findings, new tools and methods develped, etc. in events such as conferences and seminars, to ensure that progress is made as steadily as possible for everyone involved. Furthermore, details on any new tool or method developed during the project will be made widely available in open source repositories.

Species and numbers of animals expected to be used

- Xenopus laevis: 50 adults + 10000 tadpoles
- Xenopus tropicalis: 50 adults + 10000 tadpoles

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Frogs are a key step in the evolutionary transition of vertebrates from water to land. Moreover, frogs lack "key higher brain regions", such as a mammalian-like cortex, and thus represent a good trade-off for studying fundamental principles of vertebrate vision with fewer ethical implications than e.g., mammals.

We will use both adults and tadpoles for behavioural experiments. Adults are needed as the tests have been developed and standardised for that life stage, and we need those data to confirm previous results on other types of frogs. However, for physiological work we will use tadpoles, because they are transparent and allow us to run our experiments

using non-invasive recording techniques. To then link these two sets of experiments, we will also perform behavioural work on tadpoles.

Typically, what will be done to an animal used in your project?

Adult frogs and tadpoles will be used for non-invasive behavioural experiments in which they will be allowed to follow their innate preferences for visual stimuli. Some frogs will also undergo a harmless injection with hormones to obtain eggs (breeding).

Tadpoles will be obtained from wild type or genetically manipulated eggs and sperm, and they will typically be anesthetized and/or paralysed with appropriate doses of tried and tested drugs to keep them immobile. While in this condition, we will show them different visual stimuli while we observe them under a two-photon microscope to record the activity of neurons in response to those stimuli. Each of these experiments will last for a maximum of 3 hours, and the vital signs of the animals will be monitored throughout. Tadpoles will be humanely killed immediately after each recording session.

What are the expected impacts and/or adverse effects for the animals during your project?

None of the procedures that we will apply is expected to generate adverse affects, as they are non- invasive, done under anesthesia, or both. Some of the transgenic tadpoles that we will use might turn out visually defective or blind, and in such case they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity for procedures involving adult animals is mild or subthreshold in all cases. For tadpoles, up to 50% of the animals might undergo procedures classified as moderate.

What will happen to animals at the end of this project?

Used in other projects
Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Behavioural experiments can only be performed in live animals, and they are necessary for confirmation of the sensory abilities enabled by the visual system of Xenopus.

For our in vivo physiological work, we have no alternative but to use the intact retinal circuit or the whole tadpole brain. Using the actual, unperturbed, neural circuit is the essence of our approach, as there is no substitute for the retina or brain to understand how each of them work.

Which non-animal alternatives did you consider for use in this project?

Retinal organoids are the most sophisticated tool available at the moment, and they can provide valuable information about some aspects of retinal cell biology.

Why were they not suitable?

Organoids remain at best incompletely explored for the purpose of understanding visual function in the intact circuit. Retinal organoid technology in general is not yet at a stage where it can realistically replace in-vivo or ex-vivo preparations. Moreover, organoids are mostly being explored in the context of mammalian vision - to our knowledge retinal organoids of anuran origin are non-existent.

Moreover, retinal organoids cannot "see" and are not connected to the brain in the way the visual system is in the intact animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For breeding and stock replacement, we estimate that we will need no more than 50 animals over the five year project duration. Of these, ~20 will also be used for adult behavioural experiments

For the tadpoles, we estimate that we will need a total of approximately 10,000 individuals to collect enough physiology and behavioural data from a variety of stimuli from an appropriate number of replicates, and taking into account that expression differences between animals will inevitably lead to the need of a surplus in breeding.

However, the vast majority of embryos (~90%) will not reach the developmental stages that we will use for the actual imaging/behavioural experiments, but instead only be grown until expression of desired transgenes (e.g. GCaMP variants) can be non-invasively acertained (e.g. fluorescence screening). An expected large fraction of non-expressing

animals, as well as any potential surplus in well-expressing animals for immediate experimental requirements, will be humanely killed. Moreover, we also take into account the fact spawns contain many eggs, and that sometimes not all of them will reach the developmental stage that we need.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All visual stimuli that we will use in behavioural and physiological experiments are designed to be harmless, meaning that each individual animal can be repeatedly tested for many stimuli, so we will use substantially fewer animals than we would need if each animal would be exposed to just one single stimulus. These repeated measures will also allow to reduce variability and enhance statistical robustness while keeping the number of animals to a minimum.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As both the behavioural experiment and the hormonal induction of ovulation are mild (or subthreshold), non-invasive procedures, the same females from which we will obtain eggs will be also used for the behavioural tests.

Furthermore, whenever an adult animal needs to be humanely killed, their retinas can be used for ex- vivo experiments and/or preserved and processed for other studies, avoiding the need to use more animals specifically for these two purposes. These additional use-scenarios are all ongoing in the lab.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use frogs, which are thought to be amongst the "least sentient" representatives among tetrapods. We will use adults only for behavioural tests that do not involve administration of any substance, and for obtaining eggs through mild, standardised and safe procedures.

All physiological work will be done on more immature life stages (tadpoles), using established harmless stimulation and recording procedures. Immobilisation of the animals

will be accomplished using anaesthesia and embedding in low-melting point agarose, and the general wellbeing and clinical status of the animals will be monitored at all times.

Why can’t you use animals that are less sentient?

Frogs are amongst the least sentient tetrapods, and our physiological work will be done on their most immature (tadpole) stage.

Terminal anaesthesia for physiological imaging experiments will only be avoided in those cases in which we need to confirm that the data obtained under anaesthesia really represents what happens in the unperturbed visual system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedures are designed in such a way that they minimise the welfare cost to animals by relying on non-invasive techniques that also allow to control for markers of stress levels and overall clinical status in real time during the procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will rely on the Animal Scientific Procedures Act for general guidance, and on Xenopus-specific guidelines such as the Animal Care Protocols form the Marine Biological Laboratory at University of Chicago (https://www.mbl.edu/xenopus/protocols) and Guidance on the housing and care of the African clawed frog Xenopus laevis from the Royal Society for the Prevention of Cruelty to Animals (https://www.rspca.org.uk/webContent/staticImages/Downloads/GuidanceXenopusLaevisReport.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our main source of general information about advances in the 3Rs will be the newsletter from the National Centre for the Replacement Refinement & Reduction of Animals in Research (NC3Rs), which will keep us updated about novel approaches and developments and training opportunities. For advances specifically related to our experimental animals we will be in close contact with the European Xenopus Research Centre to learn about any potential advances in Xenopus-related protocols that could be directly applicable to our project.

43. Production of normal blood

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Assay, Red Blood Cell, Antigenicity, Diagnosis, Surveillance

Animal types	Life stages
Ferrets	adult
Guinea pigs	adult
Turkeys	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will be used to provide normal blood that will be used in in-vitro diagnostic or research assays relating to microbial diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

- It is important to carry out this work because the microorganisms that cause disease in humans and animals can be demonstrated in the laboratory using specific animal blood and tissues, for example, the way viruses have the ability to attach themselves to the host can be illustrated by mixing virus particles with mammalian/avian red blood

cells which have specific pathogen receptors on their surface. We also carry out tests to ascertain the likelihood of an immune response of influenza/viral pathogens, mammalian and avian red blood cells are vital for these tests.

What outputs do you think you will see at the end of this project?

- The outputs will be data and knowledge used for the diagnosis, control, or prevention of communicable diseases that primarily affect humans but could have originated in animals.

Who or what will benefit from these outputs, and how?

- The benefit from this project is great as far as diagnosing new and re-emerging strains of influenza, the work also contributes to the UK vaccine development which leads to positive outcomes in terms of the benefits to public health. There are a network of surgeries that send samples of patients with suspected influenza to be tested, they rely on the diagnostic services which acts as a surveillance tool that helps forecast what strains of the disease is circulating. With this information interventions can be made i.e. vaccine development , pandemic curtailment. This is a direct public health benefit.

How will you look to maximise the outputs of this work?

Global network participation, presentations and publications are routine mechanisms. These publications inform both national and international agencies insiders and the public of the progress and benefits of our work such as surveillance of influenza and other respiratory viruses in the UK which will be shared via digital platforms.

Species and numbers of animals expected to be used

- Other birds:
- No answer provided
- Guinea pigs: 400
- Ferrets: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals that are used in this project are the most appropriate species for the purpose. For example, we use turkey (avian) and guinea pig (mammalian) red blood cells as they are highly compatible with influenza. This allows us to differentiate between different strains of influenza and therefore they are a vital part of the identification and control of the disease.

It is more advantageous to use young adults rather than infants or older animals as young adults are at the peak of their physiology and less likely to suffer from age-related illnesses or organ immaturity and this is a possibility if immature or aged animals are used. The blood and tissues are therefore optimal for the in-vitro assays

Typically, what will be done to an animal used in your project?

- Invariably general anaesthesia is used briefly to obtain samples of blood from the animals as this reduces handling stress, makes for easier handling and therefore eliminates contingent (albeit minimal) distress/suffering. Where general anaesthesia cannot be used where possible we will opt for a local anaesthetic instead to minimise the harms.
- The red blood cells will be collected and used for diagnosis, surveillance, control and prevention of communicable diseases.

What are the expected impacts and/or adverse effects for the animals during your project?

- The impact on the animals during this project is mild, any pain, suffering, and distress will be transient. We do not expect any animals to exceed the prospective severity of the protocols.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- The severities of this project are non-recovery and mild, any pain, suffering, and distress experienced will be transient. The turkey and ferret protocols are mild, and all guinea pig procedures are non-recovery.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

- We currently use animal red blood cells in a laboratory setting for testing that supports the diagnosis and surveillance of communicable diseases.

- Synthetic blood products are not available commercially or within the scientific community; the work we carry out would not be possible without the use of red blood cells. We cannot use a lower species such as fish or mice for example, as their red blood cells are not compatible with influenza viruses (new, emerging and re-emerging) that affect humans, also they are too small to produce the volumes of blood needed.

Which non-animal alternatives did you consider for use in this project?

- There are no suitable non-animal alternatives for the tests that we carry out.

Why were they not suitable?

- Some specific mammalian and avian red blood cells have a protein coating that binds to specific differentiating influenza antigens. At present, there are no suitable methods that achieve the same results as the tests that are agreed as the 'gold standard' and standardised across the world.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- These numbers are based upon the experience of 40 years of using the techniques to determine animals to be used in a ‘normal’ non-pandemic or routine use scenario plus additional that would be used to consider a spike in infections across the UK.

- These numbers provide a surge capacity in the case of an epidemic/pandemic that enables us to provide a critical service in the prevention and control of transmissible diseases.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- There is no experimental design phase to the process.

- The red blood cells are used routinely ex-vivo and in-vitro, i.e. the testing is carried out on the blood samples collected from live animals and used in the laboratory.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Animals are procured at the point of need in order to keep the numbers to a minimum and animals can be re-used on this and other projects once they have passed a health assessment carried out by the NVS.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- Ferrets, turkeys, and guinea pigs will be used in this project. Ferret, guinea pigs, and turkey red blood cells are used for specific tests, all the red blood cells mentioned react differently to different strains of influenza e.g. avian RBCs respond well to H1N1 and guinea pig responds well to H3 subtypes. To minimise pain, suffering, distress or lasting harm blood samples are invariably taken under general anaesthesia.

- Non-recovery procedures are always conducted under general anaesthetic. All the procedures are brief.

- Where blood is withdrawn other than no-recovery, samples amount are limited e.g. birds will have no more than 10% taken at one time or 15% in a 4 week period.

- Ferrets will have no more than 10 % taken at one time. We always take less blood than the volume percentage mentioned as this supports good welfare.

Why can’t you use animals that are less sentient?

- We must consider the maturity of the cardiovascular system to be able to produce viable red blood cells. Immature animals are not able to produce the volumes needed.

- Guinea pigs are terminally anaesthetised in order to collect large volumes of blood from the heart, this is the most humane method to collect large volumes of blood from this species in a single event.

- Anaesthetic is used to significantly minimise any pain and suffering when collecting blood from the superficial veins of turkeys and ferrets.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- The procedures are already well refined from experience over many years of their use. We always aim to minimise pain, suffering, distress, or lasting harm.

- We use the most appropriate methods for collecting blood samples and use anaesthesia where the use of anaesthesia will cause less harm than the procedure itself.

- Post-procedure observations are carried out and the animals are monitored throughout the project e.g. via strict weight monitoring and health assessments.

- Turkeys and ferrets enjoy human interaction which they receive daily. All animals are housed in floor pens and have plenty of environmental enrichment which keeps them mentally stimulated.

- All animals are fasted or have food withdrawn 20-30 minutes prior to undergoing a procedure involving general anaesthetic. Guinea pigs are physically incapable of vomiting but they can regurgitate, hold food in their oesophagus and buccal cavity that can be aspirated into the lungs when under general anaesthesia. This is eliminated by withholding food prior to the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- We follow best practice regarding experimental techniques such as blood-letting from literature such as The Manual of Animal Technology by Stephen W. Barnett, other reliable online resources such as Understanding Animal Research 'Procedures with Care': a training resource on the administration of substances and the Handbook of Laboratory Animal Management and Welfare by Sarah Wolfensohn.

- The above literature gives detailed guidance on animal management, welfare, and the correct/most refined methods of experimental techniques.

- The experimental techniques used under this project only consist of blood withdrawal that is always of mild or non-recovery severity.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

- I am connected to the NC3Rs i.e. we are signed up and receive newsletters informing us about advances in animal science. I am looking to advance the refinement through environmental enrichment programmes and all the animals used in this project are floor housed.

- I am an associate member of the Institute of Animal Technology and receive regular correspondence.

- I stay informed via discussion with the NVS and through networking with colleagues from other organisations.

44. Breeding and maintenance of genetically altered and germ free mice

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Rederivation, Germ Free, Cryopreservation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To provide genetically altered and germ free mice to the researchers in the establishment. This project also attempts to cryopreserve lines with no immediate use, and rederive clean colonies from animals with lower heath status.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The main benefit of this project is that animals required under the authority of various project licences, will be bred centrally under the best possible conditions. This will allow management by trained animal technologists who have expertise in the breeding and colony management, ensuring the husbandry of these animals will be in full control of the breeding programmes. In addition, a centralised facility for breeding ensures that the

technicians, by carrying out the work as a routine, are well skilled in the techniques involved.

Under this licence, the number of animals bred will also be regularly reviewed through discussions with the end users and animals will only be bred if a requirement has been established and the authority for the use of such models have been granted to the end uers. New strains or models may be imported onto this PPL as long as authority exists to use such a model on the end users' project.

Some strains for importation may only be available as embryos, typically cryopreserved, or may be of an unacceptable health status, in which case we will need to import them into our facility via embryo transfer.

In addition, despite the maintenance and management of high barrier animal housing facilities, our mice at some point may become exposed to pathogens, which can adversely affect their welfare or interfere with experimental results. This project licence seeks to use well-established embryo transfer techniques to rederive clean, previously pathogens-exposed, or to produce germ free mice. This will benefit our research community. Furthermore, the use of microbiologically defined animals kept under good husbandry conditions will reduce the number of animals required for each study, while the absence of disease can be considered a refinement in the animal's life.

Since, novel genetically altered strains are continually being produced and new research models being created the need for a service licence to support the basic and transnational research of the scientific groups at the institute is likely to continue.

What outputs do you think you will see at the end of this project?

This licence will be used to import animals ahead of new research groups arriving at the university. This will facilitate the research of these groups by providing cohorts of animals as soon as they have Home Office approval.

In order to support the 3Rs within the scientific community, there has been increased demand for research groups to cryopreserve mouse embryos of strains which are currently not in use, with a view to subsequent re-implantation at a later stage when the requirement for use is established. The cryopreservation procedure will be carried out under this licence.

In addition, on site rederivation will enable us to clean up imported animals with unacceptable health status, before introducing them into our SPF(Specific Pathogen free) facility. This not only benefits the animals' general wellbeing but also addresses any issues concerning animal welfare, reducing the variability in experimental results as animals are free from defined pathogens.

Breeding germ free mice will assist the users to investigate the effect of intestinal microbes in immune cells cross-talk and to determine how specific microbiomes protect from or contribute to disease.

Who or what will benefit from these outputs, and how?

The research community will benefit as we will produce good quality animals for their research with accurate breeding and phenotyping data. By producing animals which have good genetic integrity the reproducibility of experiments is improved. By using colony calculations we can reduce the number of animals being produced and potentially wasted.

How will you look to maximise the outputs of this work?

We will have animals which are good quality in terms of genetics as we will follow best practice. This involves refreshing the background of strains by mating them out to the genetic background on regular basis.

Strains with either mixed or ambiguous background strain information will undergo genetic monitoring to confirm the background substrain. By carringing out gentic monitoring it will give confidence to the reproducibility of the work.

We also use the breeding data which is generated from GAA colonies maintained under the service licence in colony sizing calculations. Using sizing calculations will help to make sure that the colones are sized to produce the number of animals required for experiments whilst also not overproducing animals which will be killed as surplus.

Breeding and maintaining animals under one service licence can reduce the number of mice which are potentially wasted. The use of service licence is disseminated through our animal users and animal wefare meetings, and the benefits of it in reducing the number of animals wasted, genetic integrity and reproducibility will be discussed with the researchers.

Species and numbers of animals expected to be used

- Mice: 23,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to fully understand the effects of human genes and their disease-associated mutants there is no suitable substitute for a mammalian model. The complex interaction between molecules, in the majority of cases, cannot be replicated in culture and in-vitro assays cannot adequately model the complete array of cellular, physiological and

behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes. We will be using animals of all ages and stages of development in the breeding protocols.

For crypreservation, we will use females between the age of 3-4 weeks old as it has been shown that females in this age bracket produce a higher yield of ova and a higher percentage of females which are mated produce fertilized ova.

The germ free mice are used to investigate the effect of intestinal microbes in immune cells cross talk and to determine how specific microbiomes protect from or contribute to disease. The colonisations and investigation on the effect of microbiome will be carried out under end-uers' PPL.

Typically, what will be done to an animal used in your project?

Most animals will be bred and maintained with no welfare issues. They will be maintained up to 15 months of age. Where required animals will be earmarked to obtain a sample for genotyping. Females may be injected twice by hormones 46-48 hours apart to generate transgenic embryos for the cryopreservation of lines or rederivation. A very small number of males may undergo surgery for vasectomy and will experience short-lived post-operative pain and discomfort. Embryos and blastocysts will be implanted surgically under inhalation anaesthesia or non-surgically into the reproductive tract of a mouse rendered pseudo-pregnant by mating with a sterile male.

What are the expected impacts and/or adverse effects for the animals during your project?

There might be adverse effects due to genetic modification of the genome. Information on expected phenotypes will be collected prior to breeding and will be recorded in a colony passport. Any animals on mild breeding protocol exhibiting any unexpected harmful phenotypes or deviation from normal health will be killed, or will be transferred to a moderate protocol of a PPL with the relevant authority on which the harms can be suitably monitored. Intraperitoneal or subcutanous injections should involve only slight and transient pain. Animals undergoing surgery for vasectomy or implantation of embryos will only experience short-lived post operative pain and discomfort. Ear notching should involve only slight and transient pain and no healing problems. If blood sampling is taken, then any bleeding will be controlled by local pressure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols we expect the majority to experience subthreshold severity (approximately 85%), and a small number to experience mild severity

(approximately 5%) and less than 10% to suffer moderate severity.

With the superovulation procedure we expect 100% of mice experience mild severity.

Animals undergoing surgical embryo transfer or vasectomy will experience moderate short-lived post- operative pain and discomfort (100%).

Animals undergoing non-surgical embryo transfer will experience no more than mild transient discomfort and no lasting harm.

What will happen to animals at the end of this project?

Used in other projects
Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice are required to supply the needs of the end users' project licences. In order to fully understand the effects of human genes and their disease-associated mutants there is no suitable substitute for a mammalian model. The complex interaction between molecules, in the majority of cases, cannot be replicated in culture and in-vitro assays cannot adequately model the complete array of cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes. The justification for their use lies with the end users' project licences and cell culture, human tissue assays will be used whenever possible.

Which non-animal alternatives did you consider for use in this project?

The aim of the service licence is to provide end users with mice for their studies and the consideration of non-animal alternatives will depend on the end users' area of research. Any researcher who wishes to use this service licence is requested to provide justification of why they wish to use this licence and the details of any non-animal alternatives they have considered. They will also be requested to provide the detail on whether they have explored and used search engines to find non-animal alternatives.

Why were they not suitable?

This licence aims to provide end users with mice for their studies and will only be done when non animal alternatives have been considered and rejected. The reasons for this will vary between projects but typically the reasons are that a whole organism is required to investigate the interactions between cells or organs in the body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have extensive experience of calculating animal numbers on a previous licence and plan to carry on with this practice. I work with end- users to calculate the minimum number required to reach their scientific goals. This involves estimating the final number of animals required and then calculating the number of breeding animals required using existing best practice guidance. This includes ensuring the appropriate age of animals used for breeding, replacement of breeding animals before productivity declines and the use of production efficiency index calculations to size the colony. All colonies on the service licence undergo a regular review where the productivity of each breeding pair/trio is assessed and any which fall outside of our guidance is removed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animals will be bred if a user requirement has been established. The user will be expected to provide a rationale for the number of animals required to meet their scientific goal. We will calculate the number of breeding animals required using known breeding data. The breeding programme will be subject to regular review to meet anticipated demands while avoiding overproduction.

Strains that are no longer required will be cryopreserved which will preserve the ability to revive the model should it be required but without the need for continued breeding. The use of superovulation significantly increases the numbers of embryos which can be harvested from each mouse and therefore means that fewer animals are required overall.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding animals under a service PPL provides the certainty that animals are bred only to requirement. The strains will be overseen by experienced animal technicians to ensure that the breeding programmes designed for the colonies are followed. This will help to minimise any potential wastage from overbreeding.

This service licence also provides the opportunity to consolidate the breeding of models used by several end users. This would prevent the wasteful maintenance of several smaller separate colonies to provide each of the end-users with these animals.

Breeding will be optimised, wherever possible, to produce only the genotype required e.g. Homozygous breeding pairs, and breeding colonies monitored closely to avoid inefficient and non-productive crosses. Samples for genotyping will be taken in timely manner so that the incorrect genotypes are not kept within the colony.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used because many transgenic and knockout mutant mouse strains have been created as disease models. The models that are bred on this project are typically used for experiments to investigate basic mechanisms that regulate activation of immune cells. Germ free mice are used to investigate the effect of intestinal microbes in immune cross-talk and to determined how specific microbiomes protect from or contribute to disease. By consolidating the breeding of various lines we can ensure that breeding and maintenance is done in the most refined manner. This includes efficient breeding practices and the calculations used to size the colonies. We also routinely refresh inbred lines to ensure the genetic integrity of the lines and prevent potentially harmful genetic drift.

Where a line is no longer being actively used this would be cryopreserved which involves superovulation. This is performed using a very established procedure and is considered to be the most refined. In brief, this involves two timed intraperitoneal injections prior to breeding. This procedure will allow the production of oocytes for in-vitro fertilisation, the production of fertilized embryos or the generation of blastocystes from mated superovulation. Vasectomy will produce males with full mating behaviour but are infertile.These males will be used for mating with females to produce a pseudo- pregnant state. The females are used to provide foster mothers for embryos revived from frozen storage or for rederivation purposes. Inhalation anaesthesia will be used during the aseptic surgery and analgesia will be provided pre-operatively.

Why can’t you use animals that are less sentient?

The justification for a particular line of mice lies with the end users’ Project Licence. Typically, the justification for using is that lower-order organisms do not exhibit the

required features. Mice are required for work involving adaptive immune response or investigations into ageing diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Best practice will be applied when designing breeding strategies to ensure genetic stability. Project licence holders will also be advised and encouraged to routinely cryopreserve their lines for both disaster recovery and genetic stability reasons. Where substances are administered by injection the minimum effective dose and most refined route will be chosen.

Analgesia will be provided pre-operatively. General anaesthesia will be induced and maintained using agents and routes suitable for the species, nature and duration of the procedure. Surgery will be performed under aspetic technique.

We will also evaluate the new non-surgical methods for transferring mouse embryos to recipients. If these methods prove superior to surgical methods i.e. by refining the technique and reducing mouse numbers, they may be adopted as standard. Where possible, genetically sterile T145 mice will be used as non-surgical alternative for vasectomy.

Whilst this service licence includes the option for producing animals for cryopreservation by embryo we will always recommend sperm freezing, as the most refined method of cryopreservation, before we agree to carry out embryo cryopreservation.

All strains are bred in a fashion to avoid infection. Routine health checks are carried out to monitor welfare. The animals are bred by a dedicated team of trained staff with experience in the care of such animals. Environmental enrichment, including nesting material is provided to accommodate natural behaviour of the mice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Home Office efficient breeding guidance will be followed as a routine practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Recommendations and updates regarding aspects of housing, husbandry and welfare of transgenic strains of mice will be consulted throughout the duration of this licence, and published guidelines for best practices will be followed. We will use effective breeding programmes for breeding of colonies in line with the principles of the 3R's. The information is also distributed through the establishment to other licence holders who maintain breeding colonies. These guidelines will be regularly reviewed based on any advancements made in this area. These advancements will be identified through regular

attendance of conferences (LASA, IAT Congress, NC3R's tech symposium, etc.) and comparisons to other large breeding institutions. We receive frequent updates from these institutions as well as information from the NC3R's, Norecopa and our internal 3R's subcommittee. The 3R's subcommittee collects advancements from across the establishment and disseminates this information. This enables the wider implementation of the advancements made by individual groups.

45. Molecular imaging and radionuclide therapy research for cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cancer, imaging, molecular radiotherapy, biomolecules, cellular therapies

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

One of the central aims of this project is to develop new radiopharmaceuticals for nuclear imaging (positron emission tomography (PET) and single photon emission computed tomography (SPECT)) and molecular radiotherapy of cancer. We will develop, evaluate and use non-invasive imaging tools, techniques and protocols in living animals to study the targeting, biodistribution, pharmacokinetics and/or pharmacodynamics of new imaging contrast agents, biological therapies, radionuclide therapies, or targeting vectors for cancer. We will also develop imaging tools that allow quantitative and non- invasive measurement of disease in rodents at different timepoints, thus reducing the numbers of animals needed to evaluate therapies or biological processes in cancer research.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Imaging is a vital tool for clinicians in managing patients with cancer, used in diagnosis, treatment planning, measuring response to therapy, surveillance and evaluation of recurrent disease. There is a great need to develop new, cancer and target specific imaging agents, able to give information not only about tumour location but also biochemical status and patient prognosis. A great many of these imaging agents are themselves biological molecules that bind to particular targets on the surface of cancer cells or are taken up by cancer cells in preference to normal cells thus making it easier to visualise disease. The likelihood of response to targeted therapies is increased if the tumours highly express the receptor of interest. Tumour receptor density can be evaluated via injection of radiolabelled, gamma-emitting versions of the targeting agent suitable for imaging. These targeting agents can also be radiolabelled with alpha- and beta-emitting radionuclides which can directly kill tumour cells in their vicinity and this is known as molecular radiotherapy. Currently there is great interest in evaluating new molecular radiotherapy agents with a range of isotopes, especially in combination with current treatments to which the tumours usually develop resistance. The hope is that tumour cells and chemo-resistant cells can be overcome using molecular radiotherapy, a systemic treatment which has a completely different mechanism of action and is effective against even small clusters of cells (known as micrometastases) which are too small to detect. Imaging is also vital for evaluating new therapies in vivo. Currently there is great interest in the development of cell therapies. For example, CAR T cell therapy- a type of immunotherapy- utilises T cells from patients, which have a critical role in the immune response by killing infected cells. T cells are initially isolated from blood samples of patients and modified in the laboratory to make them express special protein receptors on their surface, called CARs. These CARs recognise specific proteins, known as antigens, on the surface of cancer cells. The modified T cells, now known as CAR T cells, are then multiplied and infused back into the patient where they recognise, target and kill cancer cells expressing the target antigen. We would like to study these cells in living subjects in order to inform dosing, biodistribution, expansion and persistence. These cells can be directly radiolabelled and tracked in vivo for days/weeks or genetically modified to take up imaging probes and tracked in vivo over months. This information will speed up the development of these exciting new therapies and allow evaluation of efficacy and toxicity, vital for reducing the risk to patients. As well as providing benefit to patients, non-invasive imaging allows measurement of disease burden in experimental animals without culling. Computer models to do this more accurately and efficiently can help researchers to evaluate their new therapies in animals that have tumours deep within their body. This reduces the numbers of animals needed for experiments as well as reducing suffering through more accurate measurement of disease burden.

What outputs do you think you will see at the end of this project?

Our outputs will be new data, new radiotracers, new molecular radiotherapy agents and publications. We will generate pharmacokinetic, efficacy and dosimetry data and use them to apply for ethics approval and funding for clinical trials in the area of molecular imaging and therapy agents. This work will allow us to have as much information as possible to optimise the design of the clinical trial and to supply data to MHRA and ethics committees. Animal imaging studies will provide information on the likely effects of timings and combinations of different therapies on cells and what molecular changes are seen in the cells in response to the therapies. In molecular imaging and radiotherapy studies, animal studies are used to determine the radioactivity dose to the target tissues (as well as the normal organs) to determine efficacy and dosimetry for human studies. In some cases, the data obtained from imaging studies will be validated by reference against molecular studies on tissues samples taken for ex-vivo analysis. Targeting studies using radiolabelled antibodies, peptides, cells etc will generate data on target density, accessibility and predict how well the treatments will work. Our results will also be used to eliminate any imaging or therapy candidates that do not meet our requirements in terms of targeting properties, visualisation of disease or therapeutic efficacy with the minimum possible toxicity/off target effect.

This project will provide a set of building blocks, molecular tools and reagents for modifying cells, enabling the cells to take up radioactive molecules for imaging. We will also develop techniques and mathematical models to image and quantify cell therapies in vivo. Furthermore, the project will provide new computational machine learning tools and imaging tools for measuring the tumour microenvironment in living animals, thus allowing us to reduce and refine the numbers of animals used in scientific research.

Who or what will benefit from these outputs, and how?

The short term the beneficiaries will be ourselves and others in the scientific community (both academia and industry), to use the data produced to move the field forward or to use our tools to speed up development. In the medium term, the benefits are to bring new therapies/molecular radiotherapies to the clinic as well as new diagnostic imaging agents. Other scientists will be able to use the computational tools we are developing to obtain more (and better) in vivo data from each animal and reduce the numbers of animals being used in these experiments. The long term beneficiaries will be patients. We hope to have an impact on patient survival or to achieve improvements in patient management, be it from new molecular imaging and therapy agents, more effective combinations or targeted drugs, faster development of cell therapies for solid cancers and new therapies for pancreatic and other cancers that are based on modulation of the tumour microenvironment. These will be used by ourselves and others who are developing cell therapies.

How will you look to maximise the outputs of this work?

Our results will be disseminated internally and within our collaborator network through presentations and at national and international conferences. Both positive and negative data will be published in order to prevent unnecessary duplication of animal work, in accordance with the NC3R's ARRIVE guidelines. We will use our data in future grant applications for further scientific work and to obtain funding for clinical trials. We will share our computational models (we are already doing this nationally within our collaborator network) in order to ensure wider uptake of techniques and to increase the impact of the work. Through our clinical collaborators and a national advocacy program around the UK supply of radionuclides, we will work with cancer charities and patient groups within individual cancer types.

Species and numbers of animals expected to be used

- Mice: 4000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For this project some normal healthy mice will be used (for control pharmacokinetic (PK) studies, for studying target expression in normal tissues, or for inoculation with mouse tumour cells). The majority of mice will be immune suppressed so that they can be implanted with human cells in order to study targets in human cancers. Some animals will be genetically modified to develop pancreatic cancer and this is to study animals that have more clinically relevant disease (i.e. developed over months rather than weeks) and within a normal immune system. Some rats will be used used (e.g. in cases where the normal target expression is more similar to that in humans, where pharmacokinetics differ between rats and mice or where a larger animal is required due to imaging resolution or mass dose constraints of e.g. radiosensitisers). All animals used in this project will be adult to decrease variability due to growth.

Typically, what will be done to an animal used in your project?

Animals will receive tumour cells injected subcutaneously (typically once, but occasionally one on each flank), intravenous tail veil injections (typically one, but sometimes one per week for up to four weeks). Animals will be anaesthetised using inhalation anaesthesia for minimally-invasive imaging (typically 30 min - 1 h duration) and this could typically happen once (sometimes twice) a day, but no more than 7 times in one week. Most animal imaging experiments are finished in 3 to 7 days when the animals are humanely culled and their tissues collected for analysis. One protocol allows for surgical implantation of tumour cells in the pancreas and this will be done under anaesthesia with analgesia given. More commonly this procedure will be carried out using a non-surgical image-guided injection of

cells into the pancreas. Some animals will also receive therapy by mouth or by injection (e.g. one dose or once a week for three weeks) and will be monitored for any side effects and also by in vivo imaging for disease regression/progression. Some imaging protocols require removal of food (typically for four hours) before administration of the contrast agent.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals should experience no more than transient discomfort due to injections or imaging. Tumour growth in efficacy studies may cause some discomfort or weight loss, but animals will undergo daily welfare checks for clinical signs and will be humanely culled to prevent any effects beyond moderate. The discomfort experienced with minimally-invasive imaging is due to repeated inhalation anaesthesia. This will be kept as light as possible to ensure fast recovery and animals will only be re-anaesthetised after complete recovery from the previous anaesthetic period. Animals experiencing tumour implantation via minor surgery (5%) will be given sufficient and suitable sufficient and suitable analgesia to temper any unnecessary pain during wound healing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

35% of mice and rats will be mild/low to moderate severity (e.g. subcutaneous tumour inoculation, one i.v. injection followed by culling).

65 % of mice and rats will be of moderate severity (e.g. in addition to tumour induction, undergoing more than one imaging event (cumulative severity increases from mild to moderate) and sometimes also surgery and/or therapy).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The work we are doing is to develop radiotracers and molecular radiotherapy agents that can be used to locate tumours in the body and treat cancer. These are administered intravenously to humans and are distributed round the body via the bloodstream. Tumour visualisation is highly dependent on how efficiently the tracer is retained in the tumour

while being cleared from the rest of the body. We need to use in vivo methods to determine the whole body biodistribution of new radiotracers, molecular radiotherapies, targeting agents and cell therapies to demonstrate visualisation of tumours or migration of therapeutic constructs through the bloodstream to tumour.

Which non-animal alternatives did you consider for use in this project?

In vitro methods such as cells or spheroids.

Why were they not suitable?

The studies being carried out in animals as part of this project are done only when selection of imaging agents and therapeutics has been performed using non-animal alternatives (for example, in cellular/spheroid models). These include the likely effect of the drugs or imaging agents on the target cells. However, the activity/uptake in cells cannot predict the behaviour of the drugs or imaging agents in a living body where they will interact with their target as well as undergo metabolism and excretion, therefore whole animals must be used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on our current and projected experimental program, we have estimated that around 2000 animals will be used in subcutaneous tumour radionuclide therapy studies over the next 5 years, researching around 10 new biomolecule-based constructs (approximately 2 per year) including control groups and comparison with standard biomolecules or treatments. These studies often involve detailed biodistribution pharmacokinetics in both males and females for dosimetry purposes in addition to imaging. We also expect to work on a minimum of three different T-cell based therapies during that time (500 animals over 5 years). A further 500 animals will be used in imaging-only studies (radiotracer development and response to therapy) in subcutaneous tumour models. In the case of tumours that develop deep within the body (orthotopic pancreatic mouse models, either implanted or transgenic), we will use 1000 over the lifetime of the project. Animal numbers in experimental groups are estimates based on the size of the effect that we expect to see between our various test conditions, standard agents and controls (using our own previous data, pilot data and/or that seen in the literature) and individual variability within groups, and will be different for each experiment. For example, receptor targeting studies in normal animals (where no therapeutic effect is expected) are usually carried out against a non-targeting (i.e. large difference in uptake in target organ between test and control) or

standard targeting molecule (i.e. smaller difference/equivalence or improved pharmacokinetics, reduction in off-target organ uptake).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Minimally-invasive imaging in live animals allows collection of data at multiple timepoints in the study, thus decreasing the numbers used compared to studies where groups of animals must be killed at multiple timepoints in order to collect data. Imaging studies can also allow each animal to act as its own control (similar to patient imaging studies) and allows paired comparisons. This increases the statistical power of experiments and decreases the number of animals needed, compared with terminal studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Better measurement of disease progression using imaging leads to a decrease in variability within groups (and therefore smaller groups). We will use a computational mouse atlas for image analysis which provides extremely accurate and fast estimation of tumours deep within the body.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For most of our imaging approaches, we will be using well-established cancer models. Nevertheless, tumour growth and development remains a key area of research to set up new predictive biomarkers, including imaging. This PPL particularly aims to target the early-mid stage of tumour development, and the combination of imaging and clinical assessment will support the implementation of comprehensive welfare approaches and early decisions on humane endpoints. In the case where tumours are developing deep within the body, screening using minimally-invasive imaging will allow us to detect tumours sooner and thus place animals into studies when their disease is less advanced, leading to a reduction in suffering. Imaging will be carried out under Inhaled anaesthesia wherever possible to minimise metabolic effects and achieve faster recovery times. Analgesia will be used for all surgical models.

Why can't you use animals that are less sentient?

The tracers and therapies we are developing and evaluating need to be evaluated in mammals before going into clinical trials. These animals should be metabolising normally during the study period in order that the pharmacokinetics of the agents are not altered.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In the case where tumours are developing deep within the body, screening using non-invasive imaging will allow us to detect tumours sooner and thus place animals into studies when their disease is less advanced, leading to a reduction in suffering. Imaging will be carried out under Inhaled anaesthesia wherever possible to minimise metabolic effects and achieve faster recovery times. Where possible, we will use implantation of tumours in the pancreas via ultrasound-guidance rather than open surgery, positioning the implantation in such a way so as to reduce constraint on the head of the pancreas . All surgeries/implantations will use appropriate aseptic technique and analgesia. Tumour-bearing and post-operative animals are monitored daily.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Refining procedures for the administration of substances, Report of the BVAAWF/ FRAME/RSPCA/UFAW Joint Working Group on Refinement, D.B.Morton et al; 2001.

Guidelines for the welfare and use of animals in cancer research. Workman P et al, Br J Cancer. 2010 May 25;102(11):1555-77.

A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Diehl et al, J. Appl. Toxicol. (2001) 21, 15–23.

LASA 2010 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. A report by the LASA Education, Training and Ethics section. (M. Jennings and M. Berdoy eds.). www.lasa.co.uk/publications.html

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have an effective 3R's network through the NC3R's (who fund some of our work) and attend our establishment 3R's events as well as those within our network. Staff attending conferences (such as the IAT Annual conference) will bring back best practice in terms of the 3R's and new techniques and we will keep abreast of the literature to ensure that we use the best and most reproducible methods.

46. Minimising tissue damage in electrosurgery

Project duration

2 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

polypectomy, electrosurgery, colorectal cancer, polyp lifting solution, Type II medical device

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to provide in vivo proof-of-concept that using a novel material ‘X’ leads to an improvement in the electrosurgical procedure compared to currently used procedure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Colorectal Cancer (CRC) is the third most commonly diagnosed cancer and the fourth leading cause of cancer-related deaths in the world, and its burden is expected to increase by 60% to more than 2.2 million new cases and 1.1 million cancer deaths by 2030. In the UK it constitutes 11.5 % of the cancers and 10 % of cancer deaths are due to CRC. Most colorectal cancers start as a polyp and slowly grow into carcinoma over a period of few

years. The polyps larger than 2cm have highest risk; they are often sessile or flat requiring removal before development into CRC.

Polypectomy is the electrosurgery-based procedure used to remove polyps. It involves lifting of the polyp by injecting a solution underneath it (submucosal-injection (SMI)) so that it can be removed from the colon wall using an endoscope and electric cutting device without causing perforation of the colon. It is estimated that in the England alone around 600,000 polypectomies are performed every year. Perforation (1 -4 %), bleeding (0.5 -7 %) and partial polyp removal are major risks in polypectomy . The risk of post-polypectomy bleeding varies with polyp size, it is 0.4 %for small polyps and 5.3% for the larger ones. The odds ratio (OR) for the delayed bleeding was found to be 2.49 and 5.6 for the perforation for polypectomies involving large cecal polyps. The perforation risk for the large sessile polyps in the cecal region has OR of 12.19 and bleeding risk OR is 13.5. This high OR represents the cases where bleeding needs blood transfusion. It is estimated that in the UK heavy bleeding may occur in 60,000 cases (10 %) and perforation in around 6,000 cases (1 %) (https://www.hey.nhs.uk/patient-leaflet/advanced-polypectomy-for-large-polyps/), with global levels estimated as at least 20-times higher these rates.

Current practice in NHS, EU and many parts of the world involves inefficient practice using a mixture of Hypermellose eye drops and a dye injection (methylene blue or indigo carmine injection) solution. These SMIs are rapidly absorbed and require multiple injections to maintain polyp lift and offer minimal protection from thermal damage to the surrounding remaining tissue.

A research group at our Institution has developed a novel formulation ‘X’ which is a Type II medical device. 'X' has been shown in an ex vivo porcine stomach model to provide ~5x more polyp-lift than currently used SMIs, with a similar ~5x reduction in heating rate and thermal damage during electrosurgery.

Whilst these results in an ex vivo model are promising, they do not take account of tissue repair and the effects of disruption of the vascular network and at the site of surgery, and the next step is to obtain proof of concept in vivo, where repair can be more accurately modelled. The least invasive way of doing this so as to minimise distress to the animal is to use a skin model and this application seeks to test the formulation in a rat skin model.

What outputs do you think you will see at the end of this project?

The use of ‘X’ which forms the basis of this licence has the potential to overcome the current challenges with polypectomy surgical procedures, and the in vivo proof-of-concept studies carried out under this licence will validate the potential of this approach and allow further progress towards the clinic through late-stage preclinical and clinical trials. The output of the project will strengthen patent claims, and data which is not commercially sensitive will be used to generate research publications.

Who or what will benefit from these outputs, and how?

Ultimately the hope is that the ‘X’ solution being investigated here will translate to the clinic and benefit patients undergoing polypectomy, as the potential risks of undergoing the procedure will be reduced.

This will not be until beyond the timeframe of this project, with perhaps another four years of preclinical and clinical development required to realise this aim. The objective is to launch the product by 2025.

How will you look to maximise the outputs of this work?

The ‘X’ inventors will make the decision on the form of dissemination of any positive or negative information, which would comply with the ARRIVE guidelines.

Where we have any information that we can use that is non-confidential, then we will use this on our website and associated material to promote the work as a potential service going forward via social media, public audience events, and engaging with patient networks.

Species and numbers of animals expected to be used

- Rats: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats are one of the most frequently used mammalian species for skin wounding healing studies and are selected here as opposed to the other common rodent model (mouse) as their larger size allows for more numerous and larger wounds to be studied. Adult rats will be used due to their larger size.

Typically, what will be done to an animal used in your project?

The in vivo model used in these studies is a cutaneous raised wound model. This is the least invasive way of evaluating the surgical technique in vivo and will minimise distress to the animal. Hair will be removed from areas on the back of the animal, & a small volume of solution injected sub-cutaneously (‘X’ at one site and a control solution at another site). The raised skin area (no more than 10 x 10mm) will then be excised using the thermo-electric cutting device & the wound covered with a loose dressing and allowed to heal for 2 months following the procedure, to give time for wound healing and scar remodelling to complete. The animal will be housed singularly until wounds have healed sufficiently to minimise risk of other animals interfering with the healing process, and then group housed The animal will then be euthanised and the wound area excised and examined histologically for extent of repair and any signs of tissue damage.

What are the expected impacts and/or adverse effects for the animals during your project?

Apart from potential discomfort due to inflammation at the site of surgery, which could potentially be moderate severity, and mild discomfort through repeated handling during the follow-up period, the rats will be able to live according to the 5 freedoms within the restrictions of being a laboratory animal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that up to 75% of the animals will experience Moderate severity (the other 25% Mild). This is because 75% of the animals will be subject to surgical procedure where a small disc (10mm in diameter) is excised from the skin and then the healing process will be observed for 2 months, and therefore the animals will experience moderate discomfort as a result of the surgery, although this will be alleviated by the administration of post-surgical analgesia.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are a few key reasons why it is necessary to use animals in order to evaluate the efficacy of the 'X' material under investigation here.

• Whilst results in an ex vivo model are promising, they do not take account of tissue repair and the effects of disruption of the vascular network and at the site of surgery, and the next step is to obtain proof of concept in vivo, where repair can be more accurately modelled.

• In addition, ex vivo assays do not take account of how the material behaves in a complex system,

i.e. are there interactions with surrounding tissue, circulating immune system cells and systemic toxicity away from the surgical site due to dissemination and degradation of the lift material.

•	Ethically it does not warrant proceeding directly from formulating a biomaterial in an ex vivo laboratory situation to evaluation in clinical trials in human patients.

Which non-animal alternatives did you consider for use in this project?

For efficacy, none, for the reasons given above

Why were they not suitable?

See above

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on carrying out a pilot study of 3 animals, followed by one extensive study (4 groups x 5 animals), with potentially a repeat of the study if borderline advantage (a trend of better efficacy but lacking statistical significance) was seen with the ‘X’ solution in the first experiment, and where a slight modification in the methodology, e.g. volume of ‘X’ administered, time of administration before surgery, would most likely improve the efficacy significance.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Reference to the literature and discussion with the biostatistician on the Institution’s AWERB and the inventors of ‘X’.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The use of pilot studies as mentioned elsewhere.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats are one of the most frequently used mammalian species for skin wounding healing studies and are selected here as opposed to the other common rodent model (mouse) as their larger size allows for more numerous and larger wounds to be studied.

We will always use aseptic technique and will commit to the LASA Guidelines as set out in 'Guiding Principles for Preparing for and Undertaking Aseptic Surgery' (2nd edition, April 2017).

Analgesics and anaesthesia will be used where required, and we will take advice relating to care and welfare via the AWERB and other appropriate sources.

Why can’t you use animals that are less sentient?

It is important to use a mammalian model, since this closer models for wound healing seen in the clinical situation, which would not be the case if a different Class is used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Analgesics and anaesthesia will be used where required, and we will take advice relating to care and welfare via the AWERB and other appropriate sources.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will commit to the LASA Guidelines as set out in 'Guiding Principles for Preparing for and Undertaking Aseptic Surgery' (2nd edition, April 2017), as well as referring to PREPARE and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through scanning most recent literature, referring to the NC3Rs and Norecopa websites and through information passed on by the local NIO.

47. Role for xxx in gene regulation

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

XXX, cancer, cell, gene expression

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To investigate the function of a protein called XXX, which is located in the nucleus of mammalian cells. When XXX is not produced correctly cells become abnormal and this can lead to cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

When cells do not function correctly many different changes can occur that lead to a range of different diseases. Without XXX, or with the wrong type of XXX, cells can change and become cancerous. In fact XXX has been linked with many different types of cancer and other diseases, making it very important for us to understand how it works and what is going wrong when it is not working properly.

What outputs do you think you will see at the end of this project?

A significant amount of new information will be generated during this project improving our understanding of the role of XXX in controlling gene expression and DNA replication in normal cells during development. This will allow us to better understand what is going wrong in diseases with which XXX has been linked.

We expect a number of publications will arise from this work that we will submit to respected journals.

We will also generate information on gene expression and protein modifications that will be archived on publicly accessible databases.

Who or what will benefit from these outputs, and how?

These outputs will benefit other academic and clinical researchers:

Those working on control of gene expression and its contribution to disease. Those working on understanding how DNA is replicated.

Those working on understanding how the 'inactive X-chromosome' in female cells is kept inactive (male cells have 1 X-chromosome, whereas females cells have 2 X-chromosomes. One of these is shut down to stop the cell making too many gene products).

In the long term this work might also benefit the wider public, if information is found that could help to produce new medicines or ways to identify diseases at an early stage.

How will you look to maximise the outputs of this work?

We will continue to work with other researchers (collaborators) who help us to understand the full value of our work.

We will find new collaborators who have additional knowledge who can help us develop the research in new directions.

We will present the research at seminars and conferences at the earliest opportunity.

We will use the findings to help us prepare new applications for funding from charities and research councils.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cells in a growing embryo have the ability to become all of the different cell types in the adult body. As they become more specialized they gradually switch off genes that they no longer need until they are left making only the products that they do need. For example, a skin cell produces a range of products that are very different from those in a brain cell. If these fixed gene expression patterns are disturbed, the cell can begin to lose its identity and start to behave more like a cancer cell.

Our previous work has shown that XXX plays a role in controlling signals in the cell that help to control the expression patterns of some of these genes. In this project we will use genetically modified mice that do not produce any XXX. These mice also contain a second version of XXX that we have control over when it is made, by giving the mice an antibiotic in their drinking water. Addition of antibiotic leads to production of new XXX, while removal of the antibiotic causes XXX to be shut down again.

Alternatively, new XXX can be produced in cells that have been isolated from these mice and grown in culture, by adding the antibiotic to the culture media. This means that we can investigate what happens when new XXX is made in cells that have never previously made XXX. These mice (and cells isolated from them) are therefore extremely useful for helping us to understand what XXX is needed for.

We previously showed that a complete loss of XXX causes cancer (lymphoma) through overproduction of white blood cells in older female mice. However, in young mice the only changes reported to date are very mild changes in behaviour. For these reasons we will restrict our work to using mice up to an age of 12 months. Therefore, no signs of disease are expected. Much of the work will be on cells isolated from embryos. We can grow these cells in culture and apply a wide range of laboratory techniques to support our investigation. This will allow us to look for the earliest changes that contribute to diseases with which XXX has been linked, including cancer.

Typically, what will be done to an animal used in your project?

Use of timed matings will allow us to isolate embryos at defined timepoints, most usually at embryonic day 13. These embryos will be used for producing primary embryonic fibroblast cells that can be grown in culture. Addition of doxycycline to the drinking water (of pregnant females or post-natal mice) or culture media will allow us to produce new XXX in isolated tissues and cells derived from embryos and post-natal mice, whereas injection of substances such as ethynyl deoxyuridine (EdU) will allow us to monitor DNA replication in isolated tissues and cells. Liveborn mice will also be used for isolation of tissues at later stages (new born - adult). Some mice will be kept until early-mid adulthood (3-6 months). None will be kept beyond 12 months when the adult females are more likely to show symptoms of lymphoma.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect any adverse effects during this project, but if any are observed we will notify the NACWO and NVS immediately and appropriate action will be taken.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild (100%)

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The majority of the work will be done using primary embryonic fibroblast cells from genetically modified embryos (day 12-14) after timed mating. This means that animals are essential because these cells cannot be made in any other way.

Which non-animal alternatives did you consider for use in this project?

Immortalized mammalian cell lines that are able to be maintained forever under the right growth conditions, eg. mouse 3T3, and primary embryonic fibroblasts that we have produced previously, that have been cultured over a long period of time.

Why were they not suitable?

Immortalized cells are always abnormal and very often show characteristics of cancer cells. Our own studies have shown that cells obtained directly from embryos begin to lose their 'normal' characteristics within a few weeks of growing in culture. This means that they very quickly become unsuitable for many questions we want to ask. However, the same immortalized and long-term cultured lines provide an excellent source of material to study abnormal cells. We will use these unlimited sources of material as much as possible for testing new experimental methods before working with precious primary cells, to minimize animal usage.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For the range of experiments proposed in our funded grant application (valid 2021-2024) we require a minimum of 30 female primary embryonic fibroblast cell lines of each genotype (XXX modified and wild-type). Cell lines will also be made from male embryos at the same time to prevent any wastage. All lines will be preserved and frozen for use throughout the project, and made available to other researchers. The numbers have been determined based on known average litter size from interbreeding experiments, and for experiments requiring isolated tissues. They have been calculated by estimating those needed for:

Timed matings, with optional substance administration - 30 wild-type and 30 XXX modified (60, adult) Embryos needed for experiments - 60 wild-type and 60 XXX modified (120 embryos) Isolation of tissues, with optional substance administration - 60 wild-type and 60 XXX modified (120, various age)

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We consulted the Experimental Design Assistant (https://eda.nc3rs.org.uk), MRC and ARRIVE guidelines and constructed our plans in a way that uses the minimum number of animals to achieve statistically useful data. Experimental design regarding the use of cells and tissues was calculated using GPower (Mayr et al 2007), accounting for sample sizes (number of embryos required) and statistical analyses (which include both multivariate data and single parameter endpoints), where randomization is not appropriate for our experimental considerations, and measures put in place to avoid bias.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have made a genetically modified mouse that contains two 'transgenes' (additional genes inserted into the mouse genome). These two transgenes have been put into mice that do not produce any of their own XXX.

One of the transgenes contains a second XXX gene, and we have control over when it is turned on and off. The other transgene contains an 'activator' that is needed to control the XXX transgene. In the presence of an antibiotic in the drinking water (or cell culture growth media) the activator is able to turn on XXX gene expression. When the antibiotic is removed expression of the XXX transgene is stopped.

This means that we have extensive control over expression of XXX, from zero to high level, which can be turned on and off by addition/removal of an antibiotic. Breeding animals that contain these three components together allows us to produce useful

offspring at high level, with little or no wastage. We will endeavour to share tissues and cells from these animals with other researchers to further reduce usage.

Previous experiments with this combined genetic lineage have proven incredibly useful, resulting in high profile publications.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice that contain a controllable XXX transgene on a XXX deficient background. Extensive experience shows that these mice breed well and show no evidence of harm, suffering, distress or discomfort until late in adulthood.

Why can’t you use animals that are less sentient?

We are asking questions about how cells fine tune regulation of gene expression during mammalian development and disease, so it is not possible to use non-mammalian species that are too diverged in regulatory mechanism. Focussing the majority of our investigations on primary embryonic fibroblasts derived from embryos means that we are using animals (mice) at a very immature life stage. Killing of the mother prior to embryo retrieval means that harm, distress and suffering will be kept to a minimum.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where possible environmental enrichment will be adopted, following accepted procedure. Handling of the mice will be aimed at encouraging minimal stress and discomfort, using tube handling refinement technique where possible. Animals will be examined daily and any signs of ill health dealt with promptly through discussion with the NACWO, and NVS where needed. Careful monitoring of timed matings will facilitate accurate estimation of embryonic stage which is critical for our experiments. This will keep number of timed matings required to a minimum. When plug check is inconclusive females will be weighed daily to look for evidence of rapid embryo growth, which provides good evidence of mid-gestational development.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

National Centre for the Replacement, Refinement and Reduction of Animals in Research website (nc3rs.org.uk). eg. https://nc3rs.org.uk/3rs-advice-project-licence-applicants-refinement

PREPARE guidelines: https://norecopa.no/PREPARE Laboratory Animals Science Association (lasa.co.uk)

re routes of administration https://www.lasa.co.uk/PDF/LASA-NC3RsDoseLevelSelection.pdf ARRIVE guidelines (arriveguidelines.org)

Eg. The design of animal experiments (Festing, Overend, Cortina Borja, Berdoy) SAGE publishing

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay up to date with guidance from the Home Office, including updates to the following resources:

National Centre for the Replacement, Refinement and Reduction of Animals in Research website (nc3rs.org.uk). eg. https://nc3rs.org.uk/3rs-advice-project-licence-applicants-refinement

PREPARE guidelines: https://norecopa.no/PREPARE

Guidance of the Operation of the Animals (Scientific Procedures) Act 1986

Regular interaction and feedback from the NIO, NACWO, NVS and, where required, the Home Office inspector.

Guidance will be followed at the earliest stage possible.

48. Brain development and neuronal network maturation

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

brain, development, neurogenesis, synapses

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to reveal how genes and the environment guide and modulate the formation of the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The brain is the most complex of the body's organs and its role in generating behaviours has fascinated generations of researchers. The huge complexity of the adult brain can be resolved by studying the process of brain development, when its organisation is still relatively simple. Because perturbations of the normal process of brain development result in alterations of the mature brain's structure and function, a detailed understanding of brain

development is also required to tackle the causes of neurodevelopmental disorders, such as autism, schizophrenia and epilepsy.

What outputs do you think you will see at the end of this project?

This project will lead to novel discoveries on the fundamental principles of brain development and maturation. The project will generate new data that will be published in peer-reviewed scientific journals, for the benefits of the scientific community.

Who or what will benefit from these outputs, and how?

The project will generate peer reviewed publications during the course of its implementation and in the years that follow its completion. The scientific community will benefit from the data generated by this project and use them to build new theories and experimental hypotheses, therefore moving forward the frontiers of biomedical research.

How will you look to maximise the outputs of this work?

I have in excess of 20 years of biomedical research using rodents and a track record of successful peer reviewed publications, international conference presentations, book chapters and international collaborations and exchanges with some of the major research institutes in the world working on neurodevelopment, including in Japan and the US. These activities will continue to ensure that the output of this project reaches its intended beneficiaries. At local institute level, there is high potential for synergy, with several lines of research complementary and relevant to the one presented here. Over the course of this project, we will facilitate transfer of knowledge within our local community for mutual benefit and also to avoid potential duplication of procedures. For instance, data generated on the type of genes expressed by different cells of the developing brain can be shared and used by others, often without the need to replicate the steps that involve animal handling.

Because the project is focused on the description of newly identified cell types, it is unlikely that there will be unsuccessful outcomes - any new data will be useful data and will be published, compatibly with scientific rigour in data presentation.

Species and numbers of animals expected to be used

- Mice: 5100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The primary goal of this project is to study the mechanisms that explain the organisation of the mammalian brain, hence a mammalian system is required. Genetically altered mice offer the advantage of studying well defined cells and tissues, helping to disentangle the complexity of the brain. No other mammalian system offers the same palette of genetic tools. The project is largely focused on early life stages: foetal and pre-weaning. In some cases, when information on the synaptic organisation of neurons is required, then adult animals will be used. In such cases, animals are culled within 6 weeks from the start of regulated procedures.

Typically, what will be done to an animal used in your project?

Animals carrying genetically modified alleles may be bred and culled for tissue collection. Some pregnant animals are used to perform manipulations to the embryos in utero.

Some pregnant animals and their offspring may be exposed to environmental challenges, such as non- pathogenic surrogate of viral infection or vitamin depleted diet.

Some animals are used to inject intracranially fluorescent tracers that reveal neuronal connections.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect clinical manifestations of pain, weight loss, tumours in this project. However, transient pain and weight loss may occur. Phenotypes are expected to be subtle and only detected at the microscopic level. As a result of developmental changes in teh brain cognitive and social interaction behaviours may change too, however, in this project, animals are not generated for the purpose of studying animal behaviours, but rather cellular and molecular alterations and will therefore be culled before weaning or at 6 weeks of age at the latest.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

A mild severity is expected for breeding protocols. All other protocols are expected to be moderate. Exposure to moderate procedures affects approximately 50% of the animals used in this project.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The brain is composed of hundreds of different classes of classes of cells eac each class with specific functional roles. The complex behaviours that define the ability of an animal to survive in its environment and to establish social interactions with other animals in the same group emerge from the coordinated action of the many cell classes that compose the brain.

Cell classes in the brain are defined by expression of selected genes during brain development in gestation that control their differentiation into mature neurons (the main cell type responsible for information processing in the brain). The spatial organisation of different cell classes in the brain, which results in the anatomical organisation of this organ, is of fundamental importance to enable but also to constraint brain function.

Such degree of complexity and dependence on the full 3D anatomical organisation of the brain, impose that research is performed on a living, intact organism.

We relied on the support from the Fund for the Replacement of Animals in Medicals Experiments (FRAME) to identify alternative strategies to the use of protected animals when planning our experiments, but found that no alternative in silico or tissue culture system would be available to achieve our research targets.

We feel that the use of a genetically altered mouse model would allow us to study the interactions between genes and the environment that guide brain development and maturation. the genetically altered mice that we will use allow to selectively target cells of interest on the background of an otherwise normal tissue. This approach will produce data that faithfully describes biological complexity and has the potential to truly advance knowledge in the field of mammalian brain development.

Which non-animal alternatives did you consider for use in this project?

We considered the use of in silico models and of tissue culture organoids. We have also considered the use of ex-vivo live tissue analysis.

Why were they not suitable?

In silico and cultured tissue models cannot reproduce the spatial and temporal complexity of brain development. While organoids (when stem cells self assemble in a simpler form of an embryonic tissue in a culture dish) hold promise, they are not suitable to study the establishment of neuronal networks, because development only recapitulates the early events of brain tissue specification. We plan to make use of in vitro systems when possible, for eample, we will be able to monitor the movement of cells in brain tissue for short periods of time, using ex-vivo tissue culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have estimated the number of animals to be used based in this project based on actual animal usage from the previous 2 project licences that I have held. As the general area of research, level of research funding and number of personal licence holders working under this project licence are expected to be in line with the previous years, the number of animals to be used can be estimated with a high degree of confidence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This project relies on the use of several GA mouse lines, typically, mutant alleles, cre-recombinase expressing lines and conditional fluorescent reporter gene lines. COnditional reporter lines are activated by crossing with a suitable Cre-expressing GA line. We will maintain minimal stocks of stud males with heterozygote cre and maintain the conditional reporter lines as homozygote. We will not keep these animals in breeding unless ready to conduct an experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The largest fraction of animals in this project is to be used to study small groups of cells in the brain. While targeting such small brain areas used to carry a high degree of variability and hence require many replicates, we base all our work on the use of genetically modified mice that express the cre- recombinase under cell type specific promoters and this gives a very high level of anatomical precision to our manipulations that invariably cut the number of animals needed to obtain statistically robust data. By choosing to work with cre mouse lines, we can drastically increase the specificity of our brain injections to target specific neurons of interest, as only cre-expressing neurons would respond to the treatment/manipulation.

For embryonic manipulations, in previous work we have practiced and refined techniques over the past 10 years and established protocols on the CD1 mouse strain, known to carry a higher number of embryos than C57Bl6, therefore maximising the number of experimental samples (embryonic brains) per dam. This strategy reduces considerably the number of dams and capitalises on work done under previous licences to define optimal sample concentrations and target areas for the neurons of interest.

We will perform our histological analysis on serial sections so that one biological sample will serve for multiple experiments. All spare tissue samples are stored long term in a special solution at freezing temperatures so that tissue material can be analysed months and years after the animal was culled, eliminating the need to each time generate new experimental animals.

For studies of neuronal cell migration, we have developed an ex vivo brain slice system that gives us a time window of 1-3 days to follow the migratory behaviour of fluorescently labelled neurons in vitro. This approach allows us to cut the number of mice that would otherwise have to be culled at short time intervals to obtain similar time-lapse information that we can now have with just one tissue sample (i.e. one mouse).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal model of choice is the mouse. In particular we will use genetically altered mouse lines, which provide much increased specificity of genetic manipulations, reducing the need for a high number of replicates (animals) used in each experiment.

This represents already a step towards refinement: in the past, studies that aimed at correlating anatomical brain structures with animal behaviour relied upon open scull surgery on larger mammals, such as ferrets, hamsters and cats. In these procedures large areas of the brain were damaged or removed by mechanical means including aspiration. While a small mammal, such as the mouse is ideal for our research, the use of lower organisms such as Drosophila (insect) and zebrafish (fish) does not offer the same complexity of brain circuitry for the ultimate goal of understanding human brain function.

Why can't you use animals that are less sentient?

The nature of our research is naturally focused on early life stages: embryonic, newborn and juvenile, when the nervous system is still being formed and refined and therefore the impact on an animal welfare much reduced compared to performing the same procedures on adult animals. For instance, we have developed and regularly use a protocol to perform stereotaxic brain injections at 2 weeks of age, typically resulting in the end point (animal culled) 3-6 weeks later. This represents a significative temporal compression of the procedure compared to standard methods.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have modified the standard procedure for stereotaxic brain injections to use extra-fine glass needles instead of Hamilton syringes which has the benefit of requiring only a pinhole in the skull bone and generates negligible mechanical brain damage due to the fine diameter of approx. 100 micron.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidance available on the "resources" page of the National Centre for the Replacement, Refinement and Reduction of Animals in Research at https://www.nc3rs.org.uk/3rs-resources

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will abide by the institutional reviewing procedures already in place such as periodic reviews of the project licence, regular discussions with the NVS and by regularly consulting the web page of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (https://www.nc3rs.org.uk).

49. Airway fibrosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

lung fibrosis, IPF, Pharmacology, rodents

Animal types	Life stages
Mice	adult, aged
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Understanding the biology of airway fibrosis in experimental animal systems and using that knowledge to identify and develop novel treatments for human fibrotic airway diseases

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fibrosis is the term used to describe the thickening, stiffening and scarring of parts of the body that can happen in disease. Despite decades of research, there is still a need to discover and develop new medicines for fibrosis. One serious disease of this type is called

idiopathic pulmonary fibrosis (IPF), and patients with this develop progressive lung fibrosis with a higher mortality than many cancers, and only two therapies are currently available (Ovef® (nintedanib) and Esbriet® (pirfenidone)), both of which only slow disease progression by approximately 50%. These medicines do not halt disease progression, but do provide a clear mortality benefit and yet have significant side effect profiles which impact patients' quality of life. Sadly, this position has remained unchanged since the writing of the preceding licence 5 years ago.

What outputs do you think you will see at the end of this project?

Our ultimate goal is to see new therapeutic agents progress into the clinic and be used to treat patients with fibrotic disease. The decision to move into clinical phase testing requires a great deal of information from multiple sources including human tissues, cells, safety and pharmacokinetic data as well as key data from suitable animal models. The outputs from this licence specifically could include pharmacodynamic information on the ability of the novel treatments to modulate lung fibrosis after bleomycin or TGFbeta administration, as measured using biochemical or histological/histochemical methods. Other readouts could include assessments of fibrosis relevant gene expression (such as collagen genes) or other pathways including senescence, inflammation or oxidative stress. We hope that at the expiry of this licence we will have progressed at least one novel treatments for human airway fibrosis into early clinical testing.

Who or what will benefit from these outputs, and how?

The new knowledge we will create, for example on the impact of novel therapeutics on the development or regression of lung fibrosis will contribute to the overall package of information needed for go/no-go decision making ahead of clinical stage testing. This information will also be of great use to the wider scientific community and will be promptly shared whenever possible, for example as conference abstracts, and could enable other new medicines and treatments to be generated. We would expect to share information on model development or refinement with the scientific community rapidly and without limitation. We expect the new medicines we will discover and develop to have significant positive impacts on the lives of patients, their families and society as whole. These benefits may not be tangible until 10-15 years after initial discovery, so they are unlikely to be measurable during the lifetime of this licence.

How will you look to maximise the outputs of this work?

We will share the new knowledge whenever we can through publications, conference posters and presentations. We have networks of academic collaborators with whom we share our findings and benefit from the discussion and validation of our findings. We are aware that there is a need to share negative findings as well as positive ones, and we will engage with others in the scientific community to understand if there may be ways to share non-commercially sensitive information that might reduce animal usage.

Species and numbers of animals expected to be used

- Mice: 2000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult and aged rats and mice are appropriate animals to study respiratory diseases as they have anatomically and physiologically relevant mammalian biology. Adult animals (>6 weeks old for mice, >8 weeks old for rats) are fully formed and can demonstrate representative tissue and immunological responses to inflammatory or other stimuli. Aged animals (>15 months for mice, >1 year for rats) may be used as we recognise that in some respiratory diseases (such as chronic obstructive pulmonary disease (COPD)) age itself may be a factor that limits the ability of the lung to repair or regenerate and we wish to understand mechanisms that could surmount this.

Typically, what will be done to an animal used in your project?

A typical study may involve 6 groups of 8 mice or rats, which might be identified using a subcutaneous microchip after arrival, randomisation into cages and acclimation. At least 5 days after delivery animals would have a fibrotic stimulus administered into the lungs in a small volume of liquid (under anaesthesia). Animals would be returned to their home cage once recovered from anaesthesia, closely observed to ensure they are not exhibiting any unexpected side effects, checked again at the end of the working day and then left overnight. From this point on animals would be checked and weighed daily to monitor weight loss that is expected due to the inflammation in the lungs. Treatment to modulate the fibrosis would be given, for example by a twice weekly injection or daily oral dosing, for 2-3 weeks, and at the end of the study the animals killed humanely and the lung tissues taken for analysis of fibrosis.

What are the expected impacts and/or adverse effects for the animals during your project?

Induction of fibrosis of the airways is likely to be uncomfortable and animals may exhibit clinical signs of discomfort or illness such as loss of appetite, reduced grooming and reduced social interaction.

Reduced food intake can lead to a body weight loss, and for this reason animals are weighed daily after induction of fibrosis. Animals with weight loss are expected to recover after a few days, as normal feeding resumes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice and rats:

We expect approximately 90% of animals to be classified as Moderate, the remaining 10% being Mild. This will depend on the specific studies but in many cases we will have negative (non-fibrotic) controls who will not develop fibrosis or experience weight loss, as well as positive control diseased animals (fibrotic, untreated) to enable an appropriate comparison. The remaining groups would be treated with new experimental materials (or their dosing vehicle as a control), which we would be expecting reduce the disease and thereby reduce suffering. Acute weight loss is observed in lung fibrosis models using bleomycin or TGFbeta, and the dose-response for this effect is very steep and often difficult to separate from the dose required to induce fibrosis. Weight loss is usually less than 20% at maximum (~15%) at 7-8 days post challenge, and animals will recover weight. Some animals will transiently reach the 20% limit and then recover, any animals that do not recover weigh after 24 hours are removed. The proportion of animals that reach the 20% limit varies between study, despite identical material, operators and mice source/age. In the last 3 bleomycin studies using C57/Bl6 mice the number of animals withdrawn due to weight loss was 13/32, 7/48 and 10/38 (ratio shown as a proportion of animals receiving bleomycin, not the full study size including non-fibrotic controls)

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Respiratory diseases arise through complex interactions of multiple biological, genetic and environmental factors. The structural cells of the lung tissue, the underlying vascular and nervous system components, and the immune cell populations all interact in ways which cannot yet be modelled with sufficient predictive power to replace animal studies, especially when novel mechanisms which are not fully understood are involved.

Which non-animal alternatives did you consider for use in this project?

Non animal systems are a key part of our research programmes, and animal studies are only considered when sufficient data are available to justify their use or in certain circumstances where the biology is novel and not characterised sufficiently to enable in

vitro emulation. Non-animal systems we use include cell culture models (including organoids) which can be generated from primary human tissue or immortalized cell lines. Studies in these model systems can enable early validation of hypotheses and testing of novel therapeutic approaches.

Why were they not suitable?

The in vitro systems we do use are not complete representations of the lung in health or disease. Cell culture systems, even when they have some structural homology (such as organoid culture) do not have the complex biology seen in living organisms where multiple types of cell and structure combine. Human tissue, when available, is not a complete surrogate as it lacks exposure of the lung cells to air (in submerged culture), blood circulation, innervation, immune cell trafficking and many other components.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates are based on anticipated throughput of studies and using numbers typically used in previous experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Study designs are reviewed as part of our internal statistical review system to ensure that studies are appropriately constructed to account for biases and are sized to enable robust conclusions to be drawn. Statistical techniques including power analysis are used to ensure that hypothesis testing studies are correctly sized. Studies are normally conducted for a single project to enable sufficient tissue for any project-specific assays, and to allow for a dose response design. When possible we will try to combine studies to reduce the number of control groups across the licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Much work is conducted in vitro on cells and human tissue prior to human work, which reduces animal usage for preliminary experiments. Breeding of rats and non-genetically modified mice is performed for us at a commercial supplier which enables the maximum efficiency of animal usage for these animals. Genetically modified mice are not bred under this licence but are supplied under continuous use authority. The breeding schemes for

these lines are closely monitored and for established lines with straightforward genetics (e.g. a single knockout or manipulation of a single locus) homozygous breeding is used as much as possible to reduce wastage significantly (as 100% animals have the correct genotype rather than 25% for heterozygous breeding). Where possible we will use pre-exisiting information on compounds to correctly power study designs. Due to the risk of animals being withdrawn due to weight loss, group sizes may be adjusted upwards to avoid repeat studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use belomycin and adenoviral delivered TGFbeta models of airway fibrosis in rodent species (mouse and rat). These will enable us to study the mechanisms involved fibrosis, especially in relation to human lung fibrosis, which is present in diseases such as idiopathic lung fibrosis (IPF). These methods of inducing experimental fibrosis can also cause airway inflammation which contributes to the fibrotic changes to the lung tissues and reflect what is seen human diseases, so it is likely that animals will experience respiratory changes and discomfort that cannot be avoided. However, as we are seeking to find and develop new medicines, some animals would be likely to have this suffering ameliorated by our novel treatments. We have selected airway models that are well tolerated and are expected to result in a moderate level of severity, which includes some clinical signs such as reduced food intake and lack of grooming. Where possible we will carry out studies using anaesthetised animals that can be immediately killed without recovery, to minimise suffering.

Why can’t you use animals that are less sentient?

We are seeking to identify and develop treatments for use in human lung disease and therefore although there may be some analogous systems for gas exchange in lower species such as flies, worms or fish there are large differences in anatomical structures that make extrapolation to human disease very difficult. In addition we would not expect therapeutic agents which have been developed to work against specific human receptors or mediators to have the necessary efficacy in these lower species as they are evolutionarily more distant from human compared to rodents. Rats and mice have an anatomically similar (but not identical) lung and respiratory structure to humans, and have a more similar immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are closely monitored and are kept in modern purpose built facility with highly trained and motivated technical staff. We implement many systems to improve animal welfare, including non- aversive handling (i.e. not picking up by the tail), environmental enrichments such as tunnels, nesting materials and chew sticks, as well as cage floor level access to food for animals displaying reduced activity or mobility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice, for example the use analgesics after surgical procedures will be employed to minimise suffering.

Publications such as the Handbook of Laboratory Animal Care and Welfare (Wolfenson and Lloyd), and the LASA best practice guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am in regular contact with other in vivo scientists and teams of animal welfare specialists within and outside my organisation.

50. Hypoxia, carbon dioxide and acid sensing in respiratory chemoreceptors.

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Chemoreceptor, Carotid body, Hypoxia

Animal types	Life stages
Mice	neonate, juvenile, adult
Rats	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To advance our understanding of oxygen and carbon dioxide sensing in respiratory chemoreceptors. To identify other signalling pathways and drugs that can also modulate chemoreceptor activity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Control of blood oxygen and carbon dioxide levels is essential to sustain life. This requires sensors that can measure these variables and through respiratory control centres in the brain regulate breathing.

What outputs do you think you will see at the end of this project?

We expect significant advance in our understanding of the mechanisms of oxygen sensing in this tissue and hopefully some insight into how the activity of chemoreceptors may be controlled by other pathways.

Who or what will benefit from these outputs, and how?

The primary benefit will be the advancement of science in the carotid body field. This will not only be of interest to others working in this field but possibly also in the field of hypoxia sensing in pulmonary blood vessels. Hypoxic pulmonary vasoconstriction shows many similarities to hypoxia sensing in the carotid body. Together they play a key role in helping to maintain oxygen levels in the arterial blood.

Both have implications for the understanding of hypoxemia in a clinical environment (possibly including Covid 19) and in life at altitude.

Our studies may also point the way to the development of strategies for controlling chemoreceptor activity pharmacologically. This may be of benefit in hypertension, wherein increased chemoreceptor activity leads to increased activity in sympathetic nerves which may feedback to generate a further neurogenic component of hypertension. It may also be of benefit in anaesthesiology where both anaesthetics and opiate analgesics blunt chemoreceptor responses to hypoxia and depress breathing in general. This increases the risk of postoperative hypoxemia and may limit the effective use of opiate analgesics for pain management (for fear of depressing breathing further).

How will you look to maximise the outputs of this work?

We have ongoing collaborations with other groups on the biology of chronic oxygen sensing, acute oxygen sensing and the effects of anaesthetics and other drugs on chemoreceptor function. New knowledge will be disseminated through publication of primary research, review articles, and presentation at scientific meetings. Publication of negative findings will also be presented in the same manner where it helps answer specific scientific questions and where reliable conclusions can be drawn. It may be more difficult to publish where techniques have simply failed to work.

Species and numbers of animals expected to be used

- Mice: 1700
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are chosen where we need to use gene modification techniques.

Where we do not need genetic modifications we will mostly use neonatal rats. Rats are preferred over mice as the organs we are interested in are larger and tissue from neonates is easier to dissociate into cell cultures. This means we can use fewer animals. Most of our research is conducted in vitro using cell cultures. The rat model is also better studied.

Typically, what will be done to an animal used in your project?

Removal of tissues under non recovery anaesthesia.

Administration of some agents used to induce genetic modifications. This is usually via an oral route over a period of 5 - 7 days.

Measurement of an animals breathing responses to changes in oxygen and carbon dioxide levels in the air by a non-invasive method. Over a period of 3 hours on up to 8 separate occasions.

Acclimatisation of animals to chronic hypoxia over a period of up to 2 weeks. To simulate ascent to altitude.

What are the expected impacts and/or adverse effects for the animals during your project?

Weight loss due to chronic hypoxia and/or administration of agents to induce genetic modifications. Over several days.

Increased breathing with possibility of brief dyspnoea (air hunger) during exposure to acute hypoxia (for 5-15 min).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Rats. Non-recovery anaesthesia.
- 100% Mice. Nonrecovery anaesthesia.
- 10% Mice. Mild. 60%
- Mice. Moderate. 30%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The process we are investigating involves a highly specialised function of one organ and probably only one cell type within that organ. We do not know of any cell line with the same capability.

Which non-animal alternatives did you consider for use in this project?

We do not know of any non-animal alternatives. In some cases, where we have identified a specific protein involved in chemoreception, we can study some aspects of that protein's function when it is expressed in a cell line. But as it is in the wrong cell type other components of the relevant signalling pathways may be absent. So the usefulness of such models is very limited.

Why were they not suitable?

Unable to replicate responses to hypoxia similar to that seen in native carotid body tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The vast majority of the research to be conducted involves experimentation done in vitro and so this the biggest user of animals overall. Our estimate of the number of animals used in in vitro experiments is based on the past experience of myself and others in performing these types of experiments their complexity and level of difficulty e.g.

Does it require one or more control groups or can we rely on a control measurement made in the same cell (e.g. are we comparing different genotypes).

Can the objective be achieved with a single stimulus or do we need a full dose response (e.g. defining oxygen sensitivity of mitochondrial function).

Productivity of the cell isolation process (much better in rats than mice).

Level of difficulty in applying the technique itself (success rates are much lower using electrophysiological techniques than when using imaging techniques).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The majority of research to be conducted in this project will involve removing tissue from a donor animal and breaking it up into its component cells. Experiments are then performed on these cells in vitro. With careful planning cells obtained in this manner can effectively be used for a number of different experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Given that the majority of work is conducted in vitro this is largely about productivity in cell isolation and the success rate of the in vitro techniques used to measure cellular events. We endeavour to optimise the techniques used for cell isolation to minimise the number of animals needed to generate each cell isolate (typically 2 animals). We also aim to maximise the technical success rate of each in vitro technique, this is largely achieved through experience and fine tuning of research protocols and methods. Finally, we can conduct more than one type of experiment on each cell isolate. So typically, we might plan to perform 3 different experiments, each with 2 technical replicates, using one single isolate thereby generating 3 pieces of experimental data for each animal used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are used where we can utilise genetic modifications to help understand/elucidate signalling pathways involved in the processes of oxygen sensing.

Where we do not need genetic models we mostly use rats because their carotid bodies are larger than in mice and can be used to prepare cell cultures more readily (requiring fewer animals). Most of our experiments are conducted in vitro using such cell cultures.

The main form of in vivo experimentation is measurement of ventilation/breathing. This is conducted by placing the animal in a small chamber and recording pressure changes in

the chamber as the animal breaths in and out. This technique is called whole animal plethysmography. This is a non-invasive technique which causes minimal distress to the animals.

Some animals are acclimatised to chronic hypoxia in a large chamber fed with air with a lowered oxygen content using a hypoxicator. This is a device often used by athletes to improve their performance. Animals are housed in groups in standard cages which are then placed in this chamber.

Why can't you use animals that are less sentient?

The response of the carotid body to hypoxia is blunted in new-born animals and does not show normal sensitivity to hypoxia until animals are at least a week old. There is little information on chemoreceptor function in lower vertebrates, e.g amphibia and fish, so we do not know whether they would be suitable replacements or not. Any data obtained from such animals would also have to be validated in a mammalian model so there is little to be gained by substituting these animals in this type of research.

Most of our research is conducted in vitro using tissue obtained from terminally anesthetised animals.

The main in vivo experimentation is plethysmography. We cannot measure breathing responses to hypoxia under anaesthesia because many anaesthetics depress breathing and in particular inhibit responses to hypoxia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Regular monitoring of animal health for transgenic animals and animals subject to chronic hypoxia.

Continuous monitoring of animals undergoing measurement of breathing responses to brief hypoxic and carbon dioxide stimuli for any signs of respiratory distress or loss of coordination.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will refer to NC3R, LASA, RSPCA and ARRIVE guidelines. I will also monitor published research in this area for examples of improved techniques

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will regularly review/search the NC3R's website and news letter for relevant information. I attend a regular internal animal welfare meeting (Gold Standard meetings). I also perform regular literature searches relating to this field of research.

51. Assessment of bioaccumulation in fish

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Bioaccumulation, Regulatory, Safety, Chemical, Pharmaceutical

Animal types	Life stages
Rainbow Trout	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to determine the bioaccumulation of industrial chemicals, agrochemicals, pharmaceuticals and biocides in fish such that the hazardous properties of these substances with respect to their ecotoxicological (effects on the environment) properties can be assessed. These properties are a fundamental requirement of the risk assessment process for such substances, and are there to protect humans, animals and plant life.

These studies are required by law by global regulatory authorities on behalf of governments to protect humans and animals from the potential harmful effects of these chemicals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The need for these studies is driven by regulatory requirements to provide data on the potential bioaccumulation of test chemicals in fish with the study data being used to support the registration of the new chemical or preparation, as required by the prevailing notification/authorisation scheme in the countries where it is to be manufactured or imported. These tests are required by law around the World. These tests are required to keep the environment, animals and humans safe.

The studies are conducted in accordance with scientifically relevant and internationally approved test methods so that the data will be acceptable for registration or notification of the chemical or preparation in regulatory schemes such as REACH (Registration, Evaluation, Authorisation and restriction of Chemicals) for chemical notifications, European Medicines Agency (EMA) for pharmaceuticals and European Food Safety Authority (EFSA) for agrochemicals.

What outputs do you think you will see at the end of this project?

The main benefit of this project is the development of data to support the risk assessment of chemicals such that any detrimental effects on the environment can be minimised. This will protect the environment, animals and humans.

This will allow regulatory authorities (organisations independent of governments who assess the safety of a variety of drugs and chemicals) to classify and label these substances, recommend safe handling procedures, and impose risk reduction measures if required such that the benefits provided by the substances can be safely achieved.

Who or what will benefit from these outputs, and how?

The main benefit of this project is the development of data to support the risk assessment of chemicals such that any polluting effects on the environment can be minimised.

This will benefit the environment, the public, wild animals and the people who produce these chemicals (as it will enable them to be registered and sold to the public or industry).

How will you look to maximise the outputs of this work?

The work will be shared with customers who will use it to determine their future strategy, or for submission in documents required by regulatory authorities. Whilst we have no direct control over what happens to the data after we have shared it, we trust from information given to us that it is used for regulatory purposes or to support regulatory purposes (e.g. to show that a certain chemical is safe for human exposure). Previously however, we have collaborated with customers and shared data we have produced in the form of Scientific publications that are in the public domain.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project uses freshwater fish (rainbow trout, common carp and bluegill sunfish) to assess the bioaccumulation of industrial chemicals, agrochemicals, pharmaceuticals and biocides that may end up in the environment in a living organism.

The fish chosen are based on the regulatory requirements of the test. Juvenile fish are chosen, and the age ranges of the fish are such that they are the youngest fish that have a fully functioning brain and nervous system that will allow evaluation of the specific types of data we need to fulfil the requirements of the test.

Typically, what will be done to an animal used in your project?

The individual studies undertaken involve exposure of groups of fish to varying concentrations of the chemical to assess the bioaccumulation of the chemical in the fish tissue. This can be done by adding the chemical into the water directly or adding it to the food the fish eat.

Following on from the bioaccumulation phase (where the chemical can accumulate in the tissues), a secondary phase where the fish have no exposure to the chemical is undertaken. This is conducted (where appropriate) in order to determine whether a reduction of the bioaccumulated chemical occurs in the fish tissues (this is called depuration).

Any fish that are exhibiting adverse effects which are in excess of the mild severity level will be humanely killed as soon as possible to avoid unnecessary suffering. In order to measure the bioaccumulation within the fish, fish will be humanely killed on a regular basis throughout the study to enable chemical concentrations within the fish tissue to be determined (specifically in the fat).

All fish that are killed during the study and any that remain at the end of the test will be humanely killed by a method approved by the government.

What are the expected impacts and/or adverse effects for the animals during your project?

The tests are designed to be performed at concentrations below those which are predicted to cause adverse effects on the fish and hence in the majority of exposed fish no adverse

effects will be seen. Experience suggests that in less than 5% of exposed fish will any mild adverse effects occur.

During these studies, the fish are watched closely after exposure to a chemical. We have a list of adverse clinical signs; our staff are experienced and well trained in what to look out for and noticing abnormal behaviour. If we see any adverse signs, we increase our observations until they pass, or if these signs become worse than mild to moderate, we will remove the fish and humanely kill it to prevent any further suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As we are using concentrations that are predicted to be below those that would be expected to cause adverse clinical signs, we would only expect 5% of animals to display mild to moderate clinical signs.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Current regulations, e.g. REACH, require the use of fish to assess potential environmental effects of chemicals.

Non-animal alternatives (in test tubes or using tissues from dead animals for example) have not yet been sufficiently validated for acceptance by various regulatory authorities and hence cannot be used to replace animal testing in this context.

In many cases the protocols listed in this Project will be used later in the life cycle of the testing of a chemical and in many cases, tests in test tubes will have been conducted previously (often by the Sponsors) to examine their potential toxicity in cells, before we expose them to testing in animals.

Which non-animal alternatives did you consider for use in this project?

There are no other non-animal alternatives for the work being undertaken on this project.

Why were they not suitable?

There are no adequate models to replace the whole animal experimental model, as the complexity of fish and their internal physiology and development cannot be fully replicated in a test tube.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers we have used are based on figures of previous usage from previous projects, or a projection thereof (based on estimated incidence) based on requests received from customers in the past. It is, however, impossible to accurately predict the number of studies that may be performed, in the circumstances

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals, and the number of groups of animals to be used in a particular test are usually defined within the regulatory guideline used for that test. No more animals than the numbers outlined in these guidelines will be used. The use of the specified numbers of animals ensures that the data generated will be acceptable to regulatory authorities and hence will minimise the need for subsequent duplication or supplementary testing.

Whenever possible, common control groups will be used in order to minimise the numbers of groups used.

We also have a preliminary test that helps us set exposure concentrations and test conditions, that if is successful, means we don't have to perform any more testing on fish to satisfy the regulatory needs for a chemical.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Some of the studies run in this project will automatically use data from previous experiments to inform on exposure concentrations levels for future studies. Therefore it will not be necessary to run another study, using more animals, when we already have that information. Similarly, if we have that data from other sources, we don't need to run these preliminary range finding studies.

Where possible the results of computer predictions, physico-chemical testing and non-animal tests will be used to aid in the prediction of toxicity hence reducing the number of animals required to satisfy the regulatory requirement.

We will try and get as many outputs as we can from a single animal where possible, without adversely affecting its welfare. So if we need to get a blood sample, or if we need to get a fat sample, for example, we will often do that in the same animal, rather than use separate ones, when possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The fish species selected (trout, carp, bluegill sunfish) are representative of wild species. The data generated is therefore designed to protect these representative species in the environment thereby minimising larger scale environmental effects of tested chemicals.

Our models involve exposing fish to test chemicals, by direct exposure in the test water or via their food and observing them for signs of toxicity.

Many of the outputs we use are taken after the animals have been humanely killed (to measure the accumulation of chemicals in the body). This is generally the least invasive set of procedures that can be done to give meaningful outputs to make scientific decisions about whether these chemicals are safe or not.

Why can’t you use animals that are less sentient?

The fish species used have been selected in accordance with the relevant Test Guidelines and the age ranges of the fish are such that they are of the least sentient that will allow evaluation of the specific outputs.

The species selected are representative of wild species. The data generated is therefore designed to protect these representative species in the environment thereby minimising larger scale environmental effects of tested chemicals.

Any fish that are showing a significant departure from the animal’s normal state of health or well-being will be identified and humanely killed.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When we identify that animals are showing adverse clinical signs, a “MONITOR CLOSELY” label is placed on their tank to make sure our technicians know this and increase their observations (all fish are observed at least once or twice daily), depending on the intensity of these signs. We have a list of potential adverse clinical signs within the licence which give examples of the type of things to look for that would suggest a fish is potentially unwell.

When we see that a fish is unwell, and is unlikely to recover, we humanely kill the fish to prevent and further suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

OECD Test Guideline 305 Bioaccumulation in Fish: Aqueous and Dietary Exposure.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This will be achieved by regular discussions with our Named Information Officer, colleagues in Animals Technology, and by attending appropriate training courses and conferences, or getting feedback from such events.

52. Translation of the immunological synapse

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Immunological Synapse, Tolerogenic dendritic cells, Autoimmunity, Cytotoxicity, Cancerimmunotherapy

Animals Types	Life Stages
Mice	neonate, juvenile, adult, pregnant, aged, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our research projects encompass immunological contexts ranging from tumour development (e.g. pancreatic cancer and breast cancer), infection (for example, with Listeria monocytogenes), autoimmune predisposition and induced inflammation (T-effector and T-regulator, and B cells). In all of these studies, our central objective is to further our understanding of molecular interactions that occur at the immunological synapse and their influence on the dynamics of interaction between immune cell types and on the overall immune response.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We seek to understand and characterise interactions in infection, allergic inflammation, autoimmunity and cancer, situations in which the immune system plays a large role. This involves characterising such interactions at the level of cells, tissues and whole organisms with methods that allow us to follow interactions as they occur.

What outputs do you think you will see at the end of this project?

We are particularly interested in potential translational applications of modulating molecular interactions that occur at the immunological synapse. We will gain new information about immune functions on cell-cell and molecular level that will improve our understanding of their role. This data can be used in translational research to produce new approaches to treatment for autoimmune diseases or cancer, and can help to develop new medicines. All data will be published and presented at conferences and public science fairs.

Who or what will benefit from these outputs, and how?

There are a number of groups who will benefit from this research. In the short term, we will patent (when appropriate), share preliminary findings on pre-print archives and publish our completed work in peer- reviewed journals. Members of the scientific community will use our shared and peer-reviewed published research findings as inspiration for further innovation. Within the next 5 years, publication of our patents will enable licensing of patents by companies and potentially formation of new companies that will drive valuable economic activity in the UK and abroad. Work covered by previous patents has led to approved drugs being developed. In the longer term, beyond this license life time, patients with a variety of immunologically related diseases and diseases that can be treated through immunotherapy stand to benefit from products and best practices that are developed based on, or with input, from our research.

How will you look to maximise the outputs of this work?

We share all findings with the scientific community and are active collaborators with many research groups all over the globe. All data will be made available in preliminary form through sharing through open access archives such as Biorxiv, published in peer reviewed scientific journals (open access when possible), presented at conferences and public science fairs. Where appropriate, we will deposit datasets in open access repositories to allow other scientists to make use of the information. All other data referred to in peer-reviewed publications will be made available to qualified researchers on request.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have long served as the preferred species for biomedical research animal models due to their anatomical, physiological, and genetic similarity to humans. Advantages of rodents include their small size, ease of maintenance, short life cycle, and abundant genetic resources. Immune cells (T and B cells) in mice are mature at 6 to 10 weeks of age. This is the ideal age for immunological experiments.

Typically, what will be done to an animal used in your project?

Typical procedures are

Breeding of genetically altered animals (GAA) and wild type (wt) mice.

Irradiation of mice and transfer donor cells to investigate immune relevant cells. Mice will be kept up to 8 weeks after transfer.

Injections of substances: protein, lipids, infectious agents and small molecule biological modifiers, antigen presenting cells, and implantation of tumour cells. Mice will normally receive 1 to 3 substances, and a maximum of 8 substances may be injected in rare cases. Infections are cleared after a few days. Intra vital imaging: mice will be injected with a dye or tracer right before or during appropriate terminal anaesthesia. During the procedure, mice will be monitored, kept warm and fluids are provided. Surgical procedures necessary to expose the tissue of interest to the microscope will be done with aseptic techniques. The duration of the procedure is up to 6 hours.

None-schedule 1 methods of killing: required in cases when terminal anaesthesia is provided after intravital imaging whereby an overdose of general anaesthesia is administered followed by a schedule 1 method of confirmation.

Perfusion/ fixation: is used for tissue and organ harvest for histological samples to maintain full tissue integrity and cell morphologies.

What are the expected impacts and/or adverse effects for the animals during your project?

Irradiated animals will typically show signs of moderate ill health including reduced energy, partially hunched posture, diarrhoea and reduced water and food intake in the first two weeks after lethal irradiation. We expect that when irradiated mice lose more than 10% of their body weight (occurs in approximately 75% of the mice), they will begin to regain weight within 3 days. Mice are expected to gradually regain starting weight within 2 weeks after irradiation. Lethal irradiation followed by haematopoietic rescue has a treatment-related mortality of 2%, which is related to the transient cytopenia (including low platelets, red blood cells and white blood cells), which is associated with risk of bacterial infection.

In most mice (70%), partial ablation of bone marrow is expected to cause mild symptoms of malaise for up to 2 weeks. During this time, mice may be less active and show signs of un-groomed coat. In some cases (20%), reduction in food and water intake may occur, leading to maximum of 10% loss of their original body weight.

Pruritus may develop within days or several weeks following irradiation, leading to over grooming. This is expected to occur in up to 10% of the cases.

For administration of substances such as Antigens given in the form of peptides, protein/hapten complexes, or peptide-loaded dendritic cells are harmless and are expected to cause no extra adverse effects. Cytokines (e. g. Type-1 interferon), adjuvants, TLR agonists (e. g. polyIC), and microbial components (e. g. LPS) may cause systemic inflammation resulting in fever and very rarely shock. In known cases, the dosage and route of administration will be chosen to avoid systemic ill health.

Potential local infections or hypersensitivity either due to the administered substances or local wound from injection. Intra-peritoneal injections may very rarely cause peritonitis. Tumours mostly develops at the site of implantation by subcutaneous or intraperitoneal injection. Within the limits set for tumour growth (1.2cm diameter) and duration following injection (25 days), mice are generally in good health and no sign of cachexia or terminal disease are observed. Metastases are also rarely observed within these limits. Typical signs of ill health are piloerection, hunched posture, ulceration of the skin surface, and possible interference of the tumour mass with eating, ambulating, urinating or defecating.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall, we expect the following proportion of severities: 68.3% sub threshold, 2.7% mild, and 29% moderate.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The nature of studying immune cell communication requires consideration of the local environment in which the interactions take place (microenvironment). This complex mixture of factors supplied by various cell types within a tissue shape immune responses, making it essential to evaluate such hypotheses in whole body/tissue systems.

The complexity of the diseases of interest such as autoimmune diseases or cancer cannot be faithfully replicated without a whole-animal approach.

While systems involving self-propagating, modified cells in vitro exist, these behave in a substantially different, and less physiologically relevant, way to cells that could be sourced from genetically modified animals.

Which non-animal alternatives did you consider for use in this project?

For a significant part of our in vitro studies, we used ex vivo expanded human T cells instead of mouse derived cells. This allowed us to significantly reduce the total number of animals used.

To address molecular mechanism of extracellular vesicle formation we have developed tools to genetically modify human cells (using CRISPR-Cas9) to replace the use of knock-out mouse cells cancer models and therefore avoiding the unnecessary expansion of the mouse colony.

For the study of more unique cell populations, such as those found in the mouse lymph nodes, we replace them with cells derived from human tonsils and human splenic tissue that we get from a tissue biobank.

We are replacing administration of tamoxifen via an oral gavage by administering 4OHT to a culture of isolated cells, which eliminates additional stress on the animal by gavage.

Why were they not suitable?

These methods were suitable in some instances, but cannot replace the microenvironment of various cell types, their interactions and the ability to test effects of genetic alterations and substances in other instances. The available alternatives alone cannot answer the question of the effects on a whole body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Number of mice per projects were calculated using tools such as literature search, discussion with other research groups that are in the same and or similar research fields, requirements of data points, experience and results of power calculations.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used online tools such as NC3R's Experimental Design Assistant and similar software to calculate the required number of animals that will provide sufficient statistical power to address biological questions in combination with data from in vitro work. Based on our experience with particular disease models over the last 20 years we can also include the data from earlier cohorts to assist in the planning of group sizes where we can estimate the effect size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are using both genders for experiments, use of cells and tissues from shared control animals by multiple researchers, and reviewing mouse requirements regularly to avoid unnecessary breeding. Some of the models used to address our scientific questions do not follow Mendelian ratios and more breeding is required to obtain experimental animals. By examining the use of different genotypes in terms of the phenotype we have been able to identify suitable mice of a genotype that would previously have been deemed unsuitable. Where we have a need to address antigen specific components, we have generated mice with transgenic T cell receptor (TCR) and alleles predicted to alter lymphocyte function. By using lethal irradiation and bone marrow transplantation, we can reduce the number of animals bred as a single donor animal can reconstitute 8 lethally irradiated mice.

As a secondary mean to reduce the use of animals, whenever we need mouse T cells, we expand them up to 10-fold ex vivo. This significantly reduces the number of mice sacrificed for extraction of pure cell populations. We also freeze these cells and keep the records available to all lab members.

We generate antigen specific T cell clones and use ex vivo transfection or transduction of human T cell lines with specific TCR to replace as much as possible the use of TCR transgenic mice.

The strains we don’t need to use for any active project will be cryopreserved as soon as they are no needed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use wild type and genetically altered animals. We breed mice for tissue harvest after mice are killed to investigate primary immune cells in vitro.

Mice injected with substances will be monitored for potential local infections or hypersensitivity either due to the administered substances or local wound from injection. Intra-peritoneal injections may very rarely cause peritonitis.

Animals will be exposed to irradiation to create an immune model that allow us to define effects of immune relevant genes and to determine quantitative contributions of different immune cells without resorting to complex breeding strategies. Mice will be irradiated with a maximum dosage of 1100 rads for bone marrow ablation, which will be typically split into two dosages of 550 rads each, separated by 4 hrs in order to induce total ablation of bone marrow. Irradiation will only be applied on adult mice.

Irradiated mice will receive haematopoietic precursors from different mice, which will be injected intravenous or intraperitoneal routes. Reconstitution will be performed within 24h post irradiation. Irradiated mice will not be subjected to other procedures until their full recovery.

For intra-vital imaging lasting for an hour or more the surgery will be carried out aseptically. All mice under a procedure will be monitored daily and will be killed immediately when any adverse manifestation such as ocular or nasal discharge, piloerection or hunched back appears.

Where the possibility of adverse effects is not known (e. g. administration of novel compounds), pilot studies involving small numbers of animals will be undertaken, starting with the smallest dose. The dose will be increased if innocuous and necessary.

Why can't you use animals that are less sentient?

Mice are the least sentient model that can mimic the mammalian whole body system.

We use adult mice that have mature immunological cells (T and B cells) that happens in mice between 6 to 10 weeks of age.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We import any strains of interest as sperm or embryo in case we can develop an in vitro experiment instead by the time the samples arrive and won't have to use them.

We consider the volume and route of injections, and where multiple routes are possible use the least painful and invasive route. We use of inhalation anaesthetic to reduce temporary discomfort during a procedure.

To tail vein bleed mice to collect blood for genotyping, we replaced the use of a scalpel with a needle. The needle puncture results in a smaller incision and therefore less stress for the mouse.

We will do pilot studies with primary cells in vitro for cancer models. We will use inducible conditional models that allow genetic modifications in specific cells at specific times, so the onset of disease phenotypes is highly controlled and limited to specific cell types.

To reduce the risk of infection in irradiated mice, antibiotics may be given in drinking water for 2 weeks post irradiation. Where possible, primary cells will be used in vitro instead.

We are picking up/ moving mice with the use of the tunnel in the cage when appropriate, e. g. setting up breeding, moving mice to different cages, or removing mice from the cages. We use of environmental enrichment and reducing social isolation of mice to a minimum by co-housing where possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3R's guidance and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend conferences and meetings organised by NC3Rs and other organisations. New methods that don't require animals and non-animal replacement protocols can be found in the scientific literature and implemented immediately.

53. Control of worm infection by the immune response and drugs

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Helminth/worm, Anthelminthic, Mast cells, Inflammatory disease, Microbiome

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to understand the interaction between parasitic worms (nematode helminths) and immune cells (mast cells) and how this influences immune responses in disease. This can lead to a better understanding of how infections can alter immune responses to vaccines or in non- communicable diseases such as diabetes and arthritis and thus lead to the development of new medicines. We will carry out research into the basic mechanisms by which worms trigger or control inflammation and the role that mast cells play in this. It is also important to develop new drugs to control worm infections for both humans and livestock and thus we will also aim to evaluate new compounds for anthelmintic activity and assess how elements of the immune response contribute to their effectiveness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Parasitic worms infect more than a quarter of the world's population and while they can be detrimental to health they may also play a role in protecting us from the development of autoimmune diseases and allergies. Autoimmune diseases affect more than 5% of the global population and costs greater than $100 billion while allergies affect more than 20% of the world with costs of $18 billion, with costs and incidence of both diseases increasing.

Understanding how worms interact with the immune response and vice versa is important to understand how inflammatory responses develop (an inflammatory response is when the immune system gets out of control and can result in allergies, autoimmune diseases, such as diabetes and rheumatoid arthritis, as well as cytokine storms like that seen in COVID infection). Therefore, worm infections have the possibility of altering the development of inflammatory diseases, asthma and cytokine storms.

Worm infections are also a considerable health and economic burden. More than a quarter of the world's population are infected with worms at a cost of €1.7 billion to the EU livestock industry. Further, there have been no new anthelminthics drugs on the market for over 20 years and resistance is increasing to those currently available. Therefore, the development of new anti-parasitic drugs using mouse models is essential.

What outputs do you think you will see at the end of this project?

The primary output will be to publish the findings in high ranking academic journals and at international conferences. This in turn will support applications for research funding and will provide employment for research scientists in the field.

The identification of novel anthelminthics would be of enormous potential benefit to human health, animal welfare and the economy.

The scientific information of the effect of the worms on the immune response is likely to be of interest to pre-clinical scientists interested in infectious, inflammatory and allergic immune responses.

The project will further our understanding of the underlying mechanisms involved in the expulsion of gastrointestinal helminths and the induction of inflammatory and allergic diseases thus informing rational design of novel therapeutic strategies for these diseases, all of which have enormous impact on the economy and the health care of humans. Experiments in this PPL using specific techniques such as imaging in live animals (IVIS) will provide novel data of the interaction of cells and parasites in the gastrointestinal system, and give additional insights of the role of mast cells in the induction, polarisation and amplification of allergic Th2 type responses. Studies using IVIS will also avoid the sacrifice of animals at various time points to study the biodistribution of reagents in organs, therefore reduce the number of animals used for research.

Who or what will benefit from these outputs, and how?

As this licence is for 3 years the long term outputs are a contribution to the body of knowledge in the area.

Infections with helminth remain a challenging health problem with global health, economic and societal impact. The new knowledge we learn from these studies will help us to understand the role of immune responses in controlling infection but also how they may affect the generation of inflammatory and allergic responses.

In the short term we anticipate identifying new therapeutic candidates for treatment of helminth infections which in the long term may lead to the development of new pharmaceutical products for clinical intervention of these diseases.

In the medium term the information is likely to be of interest to pre-clinical scientists interested in how immune responses are modulated by infection.

The new knowledge we learn from these studies will help us to understand the role of immune responses in controlling infection but also how they may affect the generation of inflammatory and allergic responses.

How will you look to maximise the outputs of this work?

I collaborate with colleagues within the University, in UK and internationally to promote the research in understanding the generation of immune responses associated with helminth infection and development of novel anthelminthics. The findings of our studies will be published in peer-reviewed journals for other researchers in the field, in addition we will disseminate our findings through presentations at national and international conferences, and thus there are ample opportunities to share data and results with the international community. We also aim to promote public understanding of immunology and helminth via our outreach activities.

Species and numbers of animals expected to be used

- Mice: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Normal naive mice or genetically altered mice with modifications of specific genes or cells of research interest will be used in this study. Animal models for parasite infection have been the essential tools used in research in our understanding of the underlying protective and pathological immune responses accompanying helminth infection. Recent development of the understanding of these immune responses demonstrate that they closely resemble responses in humans. Mice are the lowest vertebrate group where models of parasitic infection have been developed and refined and give repeatable results of low variability and high quality. The models have also been refined to reduce suffering to the minimum levels whilst still giving satisfactory result. Only adult animals can only be used as the immune system of younger animals is not sufficiently mature to generate appropriate responses

Typically, what will be done to an animal used in your project?

Infection with gastrointestinal helminths is induced by the oral administration of infective larvae. The dose given has been adjusted to ensure that adverse effects are as low as possible without compromising the induction of protective immune responses. A typical experiment would compare genetically altered and normal naive and infected animals which are untreated or treated with drugs against the parasite or immunomodulators (compounds which alter the immune response) and examined at two time points. Assessments of these effects on parasite expulsion and development of protective and pathological immune responses will be carried out post mortem. Mice will then be monitored closely and weight will be recorded. Depending on the specific research aims, experiments often last 2 to 6 weeks, at the end of which mice will be culled and tissues analysed.

For evaluation of novel anthelminthics normal naive mice will be infected with the parasite followed by administration of novel anthelmintics which have been identified in in vitro studies. Mice will then be monitored closely and weight will be recorded.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effect for each genetic modified mouse colony will be dependent on specific genetic modification of the mice. The majority of mice have no gross phenotypic abnormalities, reproduce normally and mature to full age, just as wild type mice do. Some strains have mild phenotypes involving altered behaviour or activity, or susceptibility to disease due to immunomodulation. The information for the adverse effect for each colony will be obtained from the suppliers and/or from literature if published already. Other potential minor adverse effects associated with breeding and maintenance are: ear notching should involve only very slight and transient pain, and no healing problems. Haemorrhage after blood sampling is very rare and will be controlled by local pressure. Parasite infection may result in mild gastrointestinal discomfort for a maximum of three weeks (mild weight loss, slight hunched posture and mild piloerection), but it often lasts just a few days or even goes undetected. Moderate muscle discomfort may result (altered gait, reduced movement and abnormal posture) however these effects should be very rare. Possible adverse effects also include pneumonitis (shallow, fast breathing) from migration of larval stages of the parasite. This effect should be transient (< 48 hours) and rare.

Normally the adverse effects associated with imaging are not expected to result in any lasting harm. Possible adverse effects include: transient stress/discomfort associated with anaesthesia, plus dehydration and hypothermia. Repeated anaesthetic sessions may have a detrimental effect on the animals, but this will be minimized by using short-acting inhalation anaesthetics and making the imaging sessions as short as possible. Fluid support will be provided where appropriate. Mice will be kept warm throughout imaging sessions.

Potential adverse effects associated with dosing regimes of novel anthelminthics (e.g. different routes of injection) are not expected to cause any lasting harm, but may include distress or discomfort due to restraint as well as transient, momentary pain during injections. Some signs of discomfort e.g. listlessness, hunching, may be observed after injection of some of the agents to be used. This is normally mild and transitory (2-48 hours). Animals will be monitored regularly after injection and if any of the mentioned signs persist or deteriorate, humane end-points will be applied as described previously.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

The adverse effect for each genetic modified mouse colony will be dependent on specific genetic modification of the mice. The majority of mice have no gross phenotypic abnormalities, reproduce normally and mature to full age just as wild type mice do. The expected severity is mild (> 95%).

Mice infected with helminths are expected to develop clinical signs resembling human helminth infection, thus may reach a moderate severity (about 20%). However, control animals without infection will not reach such a level of severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed studies investigate the underlying the mechanisms of generation of protective and pathological immune responses to worms. The complex interactions between the host and the parasite cannot be modelled in vitro and the parasites cannot be produced or maintained in vitro. These studies require an animal with an intact immune system and gastrointestinal system. The complex interplay of cells and cytokine (immune molecular messengers) interactions between the gut and immune organs in vivo simply cannot be replicated or replaced by any available in vitro models. It is absolutely critical that the functional studies are analysed in vivo. Mice are the best animals for this work because of their structural and physiological similarities to the human immune system. Mice are used as they are the lowest vertebrate group where models of parasite infection have been developed. There is no good alternative model than the use of mice that can answer the specific questions of the proposed project.

Which non-animal alternatives did you consider for use in this project?

Whenever possible we will use non-animal alternatives in this project. For example, in vitro studies will be conducted to initially inform the interaction between T cells, dendritic cells and mast cells and helminth infection. Cell cultures of mast cells with T cells with or without antigen presenting cells (APC) in the presence of helminth products will be conducted to assess the effects of cell activation and polarisation. However these in vitro studies cannot adequately model the complete and complex array of immune responses, such as the role of epithelial cells and the effects on the parasite, involved in the generation of protective and pathological responses.

We have previously developed in vitro culture system in the previous project licence and have successfully used this for the evaluation of anthelminthic activity. Although this allows us to identify candidate anthelminthics it does not evaluate their efficacy and safety. Therefore in order to achieve this we will then progress the most promising compounds to pilot in vivo studies before more extensive in vivo analysis is conducted.
We keep up-to-date with developments in the field (including non-animal alternatives) and check relevant databases on alternatives.

Why were they not suitable?

In vitro studies cannot adequately model the complete and complex array of immune responses involved in the generation of protective and pathological responses, particularly when assessing multi- system pathological responses.
For analysis of anthelminthic activity the parasite must be maintained in animals. In vivo studies are essential in determining activity of drugs since in vitro studies cannot assess the bioavailability of drugs or how they may be metabolised.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies.

Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals to be used in each protocol below are projections based on current usage and potential research interests through collaborations. They are based on years' of experience with the models we use and regular consultations with our establishment's biostatistician.

Protocol 1: Breeding and maintenance of genetically modified mice, 600;
Animals bred under protocol 1 will move onto 3 & 4 as required.
Protocol 2: Maintenance of parasitic nematodes, 70;
Protocol 3: Assessment of anthelminthic activity, 180;
Protocol 4: Infection with gastrointestinal helminths, 250

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will take the following measures to ensure that minimum number of animals used in this project:
Use of minimum numbers in each experiment: The experimental designs and methods of analysis of the results have been discussed with the Statistical Services Unit at the University. Experiments will be designed to use the minimum number of animals per group consistent with obtaining data that can be tested statistically. These numbers are based on our considerable collective previous experience of the numbers required and power projection of numbers required for our future needs. For qualitative experiments, the amount of material required is the minimum necessary to provide an adequate description

(e.g. good quality histological samples). We have also planned to reduce the animal numbers by harvesting multiple organs for analysing. We will continually review our results to adjust the number of animals used in experimental groups so that we use the minimum number of animals to have statistically valid data.

Use of optical imaging (Protocol 4): Animals that have received bioreagents may be imaged to determine the biodistribution of reagents in the organs, and thus provide additional insights of the action mechanisms of the reagents in vivo. This will avoid the sacrifice of animals at various time points to study the biodistribution of reagents in organs, therefore significantly reduce the number of animals used for research.
NC3R's Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) will be employed to generate experimental workflows that lay out the design of core experiments. This will assist in planning, from group randomisation, through consideration and minimisation of nuisance variables in design/measurement/analysis stages, to the most appropriate statistical tests and required group sizes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use other measures to optimize/reduce the number of animals used in this project: We will work closely with staff at the animal unit for efficient breeding of mice in Protocol Small pilot studies will be performed for any new project to ensure the success of following in vivo experiments and reduce any unnecessary waste of animals. Following that power calculations will be performed to calculate the animal group size for subsequent experiments.

We plan to reduce the animal numbers by harvesting multiple organs for analysing and for isolation of infective larvae.

We will use non-invasive IVIS imaging to follow the course of infections and biodistribution of reagents over time in the same animals, obviating the need to cull animals at different time points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the lowest vertebrate group where models of parasitic infection have been developed and refined and give repeatable results of low variability and high quality. The models have also been refined in previous project licences to reduce suffering to the minimum levels whilst still giving satisfactory results, by – for example - reducing the infective dose.

Why can't you use animals that are less sentient?

The project aims to investigate how protective immune responses are generated in parasitic nematode infection and develop potential therapies for patients and for livestock. The animal models used require the intact complexity of the immune and gastrointestinal systems in order to analyse the interactions between molecules, cells, tissues and organs in vivo which are important in the initiation, development and resolution of protective and pathological immune responses in helminth infection. The parasite can only develop to maturity in adult mammals, mice are the lowest group which can be infected and where effects on the immune responses can be analysed. Therefore, in vivo work using the proposed animal models is required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We use the following steps to refine our experimental procedures:
The experiments (all using mice) of helminth infection often last 4 weeks, from infection day to finish, although some will be up to 8 weeks or more to study the long term infections. All experiments will be kept to the minimum length needed for the experiment to acquire the necessary data.

We use an improved administration protocol (cleaning the injection site and using new needles, prior to administration of substances & carefully avoiding the leakage of injection reagents)

We use the least infective dose of parasites necessary to induce the necessary immune response whilst having the least adverse effects possible.
Mice are closely monitored after infection and supported by, for example, offering food treats such as baby food and extra nesting material.

The use of in vivo imaging systems (IVIS) will allow us to determine disease onset at earlier time points and thus terminate procedures before the disease reaches a more advanced stage.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?
Guidance from the NC3Rs of animals in research, LASA good practise guidelines and advice from RSPCA for laboratory animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will learn advances in the 3Rs through various opportunities such as the University annual 3Rs symposium, and information from NC3Rs and from our own NIO.
We aim to implement advances in the 3Rs in our research whenever we can. For example, using one needle per animal, handling animal by cupping rather than picking up by the tail and positive reinforcement (with treats) when using the IVIS. We also liaise closely with NACWO and NVS.

54. Defining immune mechanisms that promote inflammatory arthritis and associated co-morbidities to identify new therapeutic targets.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Inflammation, Arthritis, Immunotherapy, Multimorbidities

Animal types	Life stages
Mice	pregnant, adult, aged, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to characterise the immunological mechanisms that promote joint inflammation in arthritis as well as co-existing inflammation in other tissues and to evaluate immune-modulating drugs as novel treatments for inflammatory arthritis and its co-morbidities.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Rheumatoid arthritis represents the most common type of inflammatory arthritis and affects ~1% of the world's population. While the clinical management of rheumatoid arthritis has improved in recent years, it remains a disease with significant unmet clinical needs. There is no cure and approximately 40% of patients do not respond to current frontline therapies that aim to reduce joint inflammation (e.g., anti- TNF and anti-IL-6R therapies). Patients with inflammatory arthritis also experience severe co- morbidities (e.g., uveitis, cardiovascular disease, depression) that impact their quality of life and mortality. Ultimately, the proposed work aims to advance understanding of the immune mechanisms that promote inflammatory arthritis and its co-morbidities so that we can exploit this knowledge to improve the diagnosis and treatment of patients.

What outputs do you think you will see at the end of this project?

The data generated during the project will provide new information about the immunological relationship between inflammatory arthritis and its associated co-morbidities, including identifying the immune cells involved, their interactions and pathogenic behaviours within inflamed tissues. We aim to use this information to identify potential diagnostic biomarkers and to establish whether targeting specific immune mediators is effective in the treatment of arthritis and its co-morbidities. The outputs will be disseminated to the scientific community through presentations at national and international conferences and publication in peer-reviewed journals.

Who or what will benefit from these outputs, and how?

The ultimate long-term objective of the project is to identify treatments that will benefit patients with inflammatory arthritis. This will also reduce the socio-economic burden of the disease. Before this, the project will have short- and medium-term impact.

Immediate to short-term impact:

The data generated will address a knowledge gap that will benefit scientists working in the fields of immunology and rheumatology, and inform future studies. Investigators working on the project will gain skills in applying cutting-edge research methodologies to identify mechanisms that drive chronic disease. Publication of the outputs will enhance the research profile of the investigators, the group and the University.

Medium-term impact:

Our research aims to drive a step-change that leads to better patient treatment. Newly identified biomarkers and therapeutic targets that have the potential to improve patient care will be of benefit to pharmaceutical companies that have expertise in developing diagnostic markers and drugs for immunological diseases.

How will you look to maximise the outputs of this work?

During the project, research outputs will be disseminated via presentation at national and international scientific meetings (e.g., British Society of Immunology, American College of Rheumatology, British Society for Rheumatology, International Cytokine and Interferon Society). We also aim to publish the data in peer-reviewed international journals (e.g., Journal of Experimental Medicine, Nature Immunology, Arthritis and Rheumatology). To support future research, large datasets will be made freely available to the scientific community via public access repositories.

Established cross-disciplinary collaborations with fundamental and clinical scientists specialised in immunology, rheumatology and ophthalmology will provide an opportunity to clinically validate and translate our basic research outcomes. Our group collaborates with several industrial partners focused on developing novel immunotherapies. Thus, a framework is in place for our research outcomes to inform the design of clinical trials in patients with inflammatory arthritis.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the species with the lowest neurophysiological sensitivity suitable for these studies. Pre- clinical models of inflammatory arthritis in adult mice are well-established, highly reproducible and provide a proven platform to test and develop new drugs. Mice have been extensively characterised in immunological research and the reagents needed to track immune responses are readily available.

Typically, what will be done to an animal used in your project?

Mice will be used in studies to characterise the immune response during inflammatory arthritis. Upon arrival at the facility, mice will be allowed to acclimatise for one week. Mice will be administered substances that promote an inflammatory response resulting in arthritis. These will be mostly administered by injection under the skin or into the knee joint while under general anaesthesia. Mice will be monitored for clinical signs of arthritis. In some experiments, we will test potential therapeutic targets by administration of immune-modulating agents, typically via injection or by oral gavage. Some mice will have a small blood sample taken from a superficial vessel to track immune responses. Most experiments will last 1-2 months before mice are killed using a Schedule 1 method or by exsanguination or perfusion fixation performed under general anaesthesia and tissues recovered for analysis.

For experiments that will determine whether induction of inflammatory arthritis results in early signs of ocular inflammation, a small number of mice will undergo medical imaging techniques (e.g., optical coherence tomography) under general anaesthesia that will allow us to track structural changes in the eye.

To allow us to determine the roles of specific immune mediators involved in inflammatory arthritis, genetically altered mice will be bred and used in arthritis studies. These mice will typically be deficient in a gene, or genes, the regulate immune function. There are no adverse phenotypes associated with these genetically altered mice. As well as being used in models of inflammatory arthritis, mice generated under the breeding and maintenance protocol will be used for in vitro studies to understand cellular mechanisms that determine their functions.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will be administered agents that will promote arthritis, resulting in joint inflammation and leading to cartilage and bone erosion. As a result, mice will experience joint swelling. During this time, they may show a slight loss of mobility and normal exploratory behaviour. The vast majority of mice will be used in a self-remitting and resolving model of arthritis in which joint swelling begins to resolve (after 2-3 days).

Some mice will be used in a model of chronic inflammatory arthritis, where they typically experience joint swelling for approximately 10 days before they are killed for tissue analysis. As far as possible, suffering will be minimised by the use of analgesia and close monitoring of the mice for any clinical signs of suffering (e.g., behaviour, piloerection, weight loss). Rarely, mice may experience an adverse response to reagents administered to promote arthritis, such as skin irritation at the site of injection. For all studies mice will be carefully monitored for unexpected adverse events and should these signs persist and not be ameliorated by mild veterinary intervention, they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice (up to 2000 mice) will be used for breeding to maintain genetically altered lines and their tissues will be recovered for in vitro studies. These mice will therefore only experience the mild severity category.

Up to 1500 mice will be used in experimental protocols and are in a moderate severity category. Approximately 90% of mice used in these experiments will develop arthritis and the maximum severity of these studies is moderate. Approximately 10% will be used to track immune responses in the absence of arthritis, or before clinical signs of arthritis

appear and therefore experience mild severity. As far as possible, suffering will be minimised by the close monitoring of mice, use of analgesia and humane endpoints.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Reliable alternatives that can replace animals to study complex immune interactions during inflammatory arthritis, as well as disease interactions in co-morbidities such as arthritis-associated uveitis, are unavailable. This is because the complexity of a process that involves immune cell activation, cell interaction and communication, and cell movement from organs of the immune system to inflamed tissues, cannot be modelled in culture systems.

Which non-animal alternatives did you consider for use in this project?

Where appropriate, we use in vitro cultures to support our studies in mice, which can provide information about cellular mechanisms associated with the disease. For example, in understanding how individual cells respond to a specific inflammatory stimulus found in joint tissues. Studies involving human samples has also informed the clinical significance of the pathways we will investigate. While these approaches complement our in vivo studies, they cannot replace the use of experimental arthritis models in mice.

Why were they not suitable?

While cell culture systems can help understand cellular mechanisms associated with disease, they cannot replicate the complex microenvironment found within inflamed tissues such as the joint that are critical for disease progression. Many of the immune processes responsible for arthritis also occur before patients present with clinical symptoms that lead to a diagnosis. This early phase of arthritis is extremely difficult to track in humans. Current in vitro systems also cannot be used to investigate disease interactions (e.g., multi-morbidities such as arthritis-associated uveitis and cardiovascular disease) which is an important aspect of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Group sizes for experiments are based on data generated in our previous experiments (i.e., previously observed effect sizes) or a standardised effect size (e.g., Cohen's d of 1.5) for pilot studies where no previous data are available. Depending on the outcomes being measured, typically our experiments require between 6-10 mice per group. We estimate experimental usage at 300 mice per year. This is based upon the scientific objectives of our current grant-funded projects and grant applications currently being prepared and equates to approximately 10 experiments per year (with 2 independent repeats).

The number of animals used for breeding and maintenance is estimated at 400 animals per year. This is based on the number needed to maintain transgenic lines and supply genetically altered mice required for experiments. These mice will also provide tissues for in vitro studies that we will perform alongside in vivo models of arthritis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure that experiments are sufficiently powered to identify biologically relevant changes while also avoiding using too many mice, we use online experimental design tools. Experiments will be designed using the NCR3s experimental design assistant (EDA) and its power calculator tool. We also consult the statistical software tool G*Power (gpower.hhu.de) when power calculations for more than 2 groups are needed, or where non-parametric analyses are used.

The use of serial clinical imaging (e.g., optical coherence tomography) will allow us to track clinical disease over time in individual mice. This reduces the number of endpoints where mice need to be killed for immunophenotyping, thus reducing the number of mice needed for the study. This also allows us to identify high-value timepoints for analysis (e.g., peak of inflammation, or resolution phase of inflammation) thus ensuring that mice are not subjected to procedures for analysis at less valuable time points. The use of omic technologies will also allow us to generate more information per experiment about the immune processes involved in inflammatory arthritis, which significantly reduces the number of mice used in studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use efficient breeding strategies, where possible breeding homozygous mice to reduce the number of animals required. Our genetically altered mice have been registered

with the University's Genetically Altered Animal Register and Tissue Sharing Network, which promotes sharing of tissues between research groups, thus maximising the information gained from research involving animals without increasing the number of animals used. Ad hoc tissue sharing between research groups has already resulted in novel observations and funding to pursue research into co-morbidities associated with arthritis. Mouse tissues from experiments are archived so that we can revisit the tissues to investigate new immune pathways that become of interest, as well as optimise new methods.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used as they provide an excellent model system to study inflammatory arthritis. The immune system of mice closely resembles that of humans and arthritis models have been established that closely replicate the human condition. Mice are also amenable to the genetic alterations needed for the study and numerous genetically altered lines deficient in immune genes of interest are already available. Reagents (e.g., antibodies) that can be used to test the therapeutic potential of blocking immune mediators are also widely available for mice.

While the procedures used in the study will themselves cause no more than mild transient pain or suffering, the majority of mice will go on to develop inflammatory arthritis as a consequence of these procedures, which is classed as moderate severity. Here, we preferentially use an arthritis model of lower severity. For example, >90% of mice that develop arthritis will be used in a model where mice develop self-remitting and resolving joint inflammation only in an injected knee, without the more progressive and systemic (affecting multiple joints throughout the body) joint involvement seen in other models. For this model, incidence is 100% with immediate and synchronous onset and a relatively short experimental time-course that minimises any lasting pain or suffering. Development of arthritis is monitored closely and does not impede the animals' ability to feed, drink and explore their environment. Some mice that develop arthritis (<10%) will be used in a more systemic poly-articular model of arthritis (i.e. affecting multiple joints). Here, the development of arthritis is closely monitored, does not impede the animals' ability to feed and drink, and mice are given analgesia at, or prior to, clinical onset.

Why can't you use animals that are less sentient?

Mice have the lowest neurophysiological sensitivity of the animals suitable for these studies. It is not possible to conduct this study in less sentient species as they either do not have an immune systems comparable to humans or the species specific reagents needed to undertaken the study are not available. Our studies are designed to gain insight into the immune mechanisms that promote inflammatory arthritis in humans and to test potential treatment approaches. Inflammatory arthritis predominantly affects adults and some children therefore it is not possible to investigate relevant mechanisms that promote the disease at more immature life stages.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures used to study the immune system and measure clinical signs of inflammatory arthritis (e.g., measuring joint diameters) themselves cause no more than mild transient pain or distress.

However, in mice with active arthritis there is potential for pain and discomfort associated with these procedures to be exacerbated. Where appropriate, this will be minimised by the use of general anaesthesia. We have introduced several further refinements based on published guidance and literature reviews. These include the use of tangle-free bedding to minimise arthritic limbs being caught, handling of mice with arthritis on soft surfaces (e.g., VetBed), the use of analgesia in systemic poly- articular arthritis models, providing environmental enrichment (e.g., tunnels, nest boxes, effortless access to food) for the animals, and tunnel or capture handling. All animals will be assessed daily for any signs of adverse effects. Monitoring regimes will be adapted as necessary to be proportionate to the anticipated or observed effects. For example, mice with clinical signs of inflammatory arthritis are monitored daily using welfare assessment scoresheets. Similarly, mice displaying any adverse effects will be closely monitored and the named veterinary surgeon (NVS) and Named Animal Care and Welfare Officer (NACWO) consulted where any advice may be needed. In the event that animals reach certain pre-defined clinical scores (e.g., joint swelling) or display unexpected adverse responses, they will be killed by a Schedule 1 method or other method specified in the protocol to avoid pain or discomfort.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

My group participates in regional 3Rs symposiums and 3Rs events to share and learn about approaches being implemented by other groups. The AWERB committee at my institute review current best practices and informs researchers on these by e-mail and newsletter.

As well as consulting online resources such as the NC3Rs website, we will keep up to date with published protocols in peer-reviewed journals that describe animal models of inflammatory arthritis, including recommended refinements. In this regard, our group has published methodologies in books that describe animal models for inflammatory arthritis

including considerations on how to improve experiments by implementation of 3Rs initiatives.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My research group attends 3Rs events and the annual regional meeting organised by our NC3Rs coordinator, which provides a forum to learn about new 3Rs approaches used by invited external participants and other groups in the University. We will continue to stay informed by using the NC3Rs website and e-learning resources as well as consulting other resources available from LASA (Laboratory Animal Science Association) and FRAME (Fund for the Replacement of Animals in Medical Experiments) when appropriate. Postdoctoral Researchers and students within the group are also encouraged to join the early career researcher's 3Rs group to learn and share best practices

55. Development of vector control strategies and intervention methods concerning the spread of malaria

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

mosquito, vector control, malaria, parasite, Anopheles

Animal types	Life stages
Mice	Adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

There is an urgent need to develop alternative control measures against the spread of malaria as well as other vector-borne diseases. By developing and applying our technologies, we hope any successes will lead to the provision of low-cost measures for vector control in countries where malaria is common, on a continent-wide scale.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vector-borne diseases are a growing threat to public health in many countries, a development that may be compounded by climate change and invasive vector species such as Aedes albopictus. This is also reflected by the current worldwide malaria situation

as malaria is still one of the world's most devastating diseases. Malaria is an infectious disease transmitted by female Anopheles mosquitos caused by a small parasite of the genus Plasmodium. 200-400 million people are infected with human malaria per year, making it one of the most important diseases in the world with half of the world's population still at risk. It claims half a million deaths per year, with children below the age of five being the primary victims. These figures underline the importance of gaining in-depth knowledge of the disease to come up with effective countermeasures such as a vaccine, drug or vector control measures.

These tools are based on altering mosquito genes to determine how effective these genetic changes spread through mosquito populations as well as how any resulting offspring are affected. Female mosquitoes have the ability to bite and feed on human blood, therefore our main focus is genes that affect fertility and female biting capabilities in order to reduce the number of disease-carrying vectors in the wild that can infect humans, thus ultimately reducing malaria.

What outputs do you think you will see at the end of this project?

In regard to the project, my group’s main focus is to contribute towards new approaches to vector control in a bid to eradicate malaria.

The main mode for vector control is currently the use of indoor residual spraying (IRS) and physical barriers. Unfortunately, these tools are limited and often result in mosquito populations developing resistance. To provide efforts in expanding potential solutions, this project aims to continuously identify and test elements involved in determining the sex of mosquitoes as well as critical genes associated with mosquito physiology. This will provide better insight into basic mosquito biology.

In doing so, we also aim to continue generating genetically modified mosquitoes as well as preserving our current stock. Various mosquito lines with different genes will be tested and evaluated in small, caged experiments by my team in specialised enclosed facilities to assess behavioural changes and their ability to continue spreading malaria, for which we hope to see a reduction.

With all this, I hope to continue exhibiting promising research through public forums and scientific publications that illustrate new findings. Any positive outcomes are often shared with our collaborators for further studies.

Who or what will benefit from these outputs, and how?

With 3.4 billion individuals, up to half the population, at risk of malarial infection, there is a pressing need to wipe out this disease. Current strategies used include diagnostic management, drug discoveries and surveillance or contact control with parasitic carriers. This research is part of a large research consortium with any technologies that stem from our work being made publicly available.

In regard to my project, my main focus is to contribute towards new approaches of vector control as well as furthering our understanding of key features of mosquito biology essential for its strong success as a vector of diseases. Our short-term goals are to continuously identify key mosquito components in addition to manipulating these elements. Resulting genetically altered (GA) mosquitoes will then be tested in caged experiments and assessed to identify potential strains that; 1) deviate from the behavioural norm; 2) have altered reproductive capabilities; and 3) potentially lack the ability to carry or transmit the malaria parasite. We also aim to develop and test methods that identify the occurrence of resistance in our gene-drive systems (promotes biased inheritance to produce a population of mosquitoes with a particular genetic make-up) as well as ways to minimise this.

The study of malaria as a model for infectious vector-borne disease has revealed the relationship between parasites and their hosts as well as furthering the understanding of how genetics and biology reflect the behaviours of these carriers. For example, as a consequence of understanding the life cycle of the parasite within different hosts, other researchers are able to elucidate new drug target sites which could translate into prospective new treatments.

In the long-term, promising results can be expanded by our collaborators in endemic countries whereby small subsets of modified mosquitoes are released in a controlled manner and are subsequently evaluated in the field. These are major steps towards eliminating the spread of malaria.

As a result, my research is largely shared amongst scientists and fellow researchers via conferences, publications and collaborations. This aids the expansion of novel control methods in endemic countries through technologies that rely on interfering with typical mosquito behaviour or the infectious relationship of the parasite within the insect.

Overall, successes in this project could lead to improvements in vector control for the general public, and thus the spread of malaria, on a global scale.

How will you look to maximise the outputs of this work?

My funding and scientific investigations are largely based within the network of multiple institutions and researchers from across 3 continents where we are able to develop innovative ideas and disclose potentially world-changing research. My work is often published in open-access journals.

Many of our smaller cage trials are expanded to larger populations and therefore, my group frequently collaborate with universities and specialised centres across the globe. On top of my expertise, the sharing of data, transgenic strains and state-of-the-art research facilities in addition to frequent forum updates and conferences enable me to greatly increase the chances of successfully meeting my objectives.

Under our funder's mission statement, we also aim to continually improve community awareness at home in the UK as well as abroad in sub-Saharan Africa where my research will directly affect, or at the very least, involve these communities.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

There are over 100 species of Plasmodium, a malaria-causing parasite, with 5 that have the ability to infect humans and many others that infect other animals, thus are considered to be zoonotic (i.e. can transfer between animals and humans) or species-specific malaria.

Plasmodium berghei is a strain of the parasite in rodents that has been deemed suitable for malarial studies using rodents as appropriate models of disease. Genetic processes and crucial molecules required for parasitic invasion are largely preserved. Here, we can study the underlying mechanisms and interactions between the host (mice) and parasite.

P. berghei is safe and easy to handle at all developmental stages and requires a live rodent host to establish and increase levels of the parasite. Previous investigations into culturing the parasite through non-animal alternatives (in vitro) have proved to yield unsatisfactory results; including limiting the parasitic lifecycle stages required for the project. Furthermore, a regular supply of infected blood is required for the mosquitoes to feed on. Ultimately, mice were selected as our chosen least-sentient rodent species.

As mentioned, the establishment of new mosquito lines as well as the maintenance of our current, more difficult strains will need to be maintained through regular delivery of blood meals. Though we are currently utilising new methods to reduce the number of mice, this blood feeding is best done on live animals due to characteristic mosquito behaviours.

Additionally, as a result of biological and physiological changes that occur with age in rodents, we have selected to use adult mice to reduce any experimental impact such variables would introduce.

According to Jackson et al. 2017, key immunological markers signify various developmental stages within mice, and it is understood that neonates do not possess an established immune system or the bodily/ blood composition required to safely and successfully propagate malarial infections within the first few days without potentially developing severe reactions. Due to the fragility of their systems, this would place unnecessary biochemical stress on young mice.

Additionally, mice nearing senescence may also respond differently.

Typically, what will be done to an animal used in your project?

The entire process for general blood feedings can take between approx. 30-90minutes, depending on the number of cages needed to be fed in relation to the number of mice under general anaesthesia.

Here, one mouse can feed multiple cages. The animals are initially weighed before the correct dosage of anaesthesia is administered via an injection in the abdomen cavity (IP). Once anaesthetised, the mice are placed on top of mosquito cages with solely the abdomen being exposed, ensuring more sensitive areas such as limbs, face and genitals are protected from mosquito penetration. Once mosquitoes have been adequately fed, mice are then humanely killed.

For infection of the malarial parasite by IP injection, animals are infected for approx. 3-5 days and monitored daily including regular weighing. Blood samples from superficial blood vessels, tail smears or punctures are routinely taken every 2-3 days to observe the levels of the parasite within the blood under a microscope.

Once sufficient parasite levels are achieved, mice are put under general anaesthesia and blood is either collected via cardiac puncturing (directly from the heart) and exsanguination (draining of blood) or mosquitos blood-feed on the infected mice. This is followed by the humane culling of the animal to reduce unnecessary suffering.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected for mice used solely for mosquito blood feeding as the animals will be anaesthetised for the duration of the procedure and then humanely killed.

All animals regardless of their infection status will be checked daily. The weight of the animals will be recorded on the day of infection and as mice are only infected for a few days before being anaesthetised for blood collection or mosquito feeding, clinical signs of malaria should not occur for the duration of this project.

Regardless, very few animals (<1%) can suddenly die from malaria infection. Therefore, any of the following reactions require symptoms to be reduced with some form of treatment and monitored 24- hours prior to killing via a Schedule 1 method if there is no improvement: piloerection, pallor, shivering, hunched appearance, reduced activity, elevated heart rate or distress.

More specific clinical signs of malaria include, but not limited to, respiratory distress, reduction in mobility or 15% loss of body weight compared to the day of infection. Neurological symptoms include convulsions, reduction in coordination and, worst case

scenario, paralysis followed by death. Any one of these symptoms and the mice will be killed by a permitted method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)

The expected severities that mice used in our project will experience will vary. Approx. 30% will be non- recovery, 50% of mice will experience a mild severity and the remaining 20% will experience a moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

At present, we require the use of animals in order to meet the objectives of my research. Maintenance of mosquito colonies require regular provisions of a blood meal for egg production, and this is best done on live animals due to mosquito behavioural biology. Direct feeding on humans poses a health and safety risk and therefore, mice are required for some procedures such as the establishment of new GA mosquito strains, which require high feeding rates and a large number of progenies, or simply for malarial infection of mosquitoes through blood meals.

Because genetic processes and essential molecules of the invasion strategy are largely preserved among mammalian parasites, we will continue exploiting the parasite, Plasmodium berghei, as a model for malarial infections, a safer alternative to the human malaria, P. falciparum. Additionally, the culturing of specific-life stages of the parasite in vitro (using non-animal alternatives) has yielded unsatisfactory results while the regular supply of fresh red blood cells present in live rodents allows for sufficient natural replication and subsequent infection of mosquitos that require blood meals. Conversely, initially cultivating the parasite in vivo (in mice) can help with culturing it in vitro (i.e. petri dishes) for short periods of time to perform specific experiments.

Which non-animal alternatives did you consider for use in this project?

We have largely reduced the number of animals we expect to use due to the measures put in place to replace animal feedings during our previous project. Where possible, we had initially moved from maintaining our large stock of mosquito colonies with mice to

membrane feeding using donated human blood. We have more recently moved towards using cow blood as a more sustainable and effective option.

We have also taken to experimental modelling to identify the nature of some of our GA lines under various conditions. Statistical and genome-wide transcriptional approaches allow us to characterise these mosquitoes all the while reducing the need for larger population experiments, and consequently the need for live animals.

Why were they not suitable?

Unfortunately, generating new mosquito strains with altered genes can prove difficult. When moved to membrane feeding, a number exhibited a fitness cost, meaning typical mosquito behaviours such as feeding, egg production and fertility rates were affected.

Additionally, parasites grown in vitro show altered genetic patterns related to factors produced by disease-causing organisms, metabolism and reproduction, in turn affecting any follow-up experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our main aim is to establish and maintain mosquito lines in addition to qualitatively assess the function and limitations of these lines via malaria infection and observation. Due to the replacement measures that have been inaugurated within our lab, i.e. artificial hemotek feedings, the number of mice estimated reflects the numbers required to meet our scientific objectives.

This is largely determined by the number of lines that need to be generated throughout the duration of the project licence which is largely based on my projects in previous years and will also correlate with any additional funding my research may receive.

Furthermore, the number of mice required is dependent on our findings from our infectious experiments including that stated in protocol 2 and thus, there is the possibility we may need to further investigate our results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted with the Named Veterinary Surgeon (NVS) and Named Animal Care and Welfare Officer (NACWO) in many instances concerning reducing the numbers of

animals in past licences. We have reviewed our experimental procedures as well as the actual animal work performed under the current and past projects. The number of animals proposed to be used under this licence will be reduced by continuing to implement the use of membrane feeding over more GA strains, including newly generated lines.

We will continue to fully transfer mosquito colonies to membrane feeding so that mice are only used in cases where membrane feeding proves prohibitively inefficient. We will also continue to reduce the number of mice used by using the whole mouse blood to maximise the number of mosquitos that can be fed per animal as well as replenishing our stock of the parasite.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to abide by the NC3Rs in addition to any updates or advice.

When possible, we aim to preserve the parasite by freezing blood obtained via cardiac puncturing to avoid animal wastage as the parasite strains do not then need to be maintained by continuous breeding.

As mentioned, we will also continue to use the whole mouse blood to maximise the number of mosquitos that can be fed per mouse as well as utilising transcriptomics (a terminology for the study of active genetic sequences which can help give us a broad view on which processes in the cell are active, and which are dormant) and statistical modelling where appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are commonly used as models for human diseases to provide insight into these mechanisms, providing validity and reproducibility.

Animal suffering is minimised by conducting blood feedings of mice to mosquitoes under terminal anaesthetics, thus culling is the end-point in both protocols. During this time the depth of anaesthesia is monitored by pinching the toes, observing any reflexes and re-administering additional drugs where appropriate.

To minimise suffering, injections and blood samplings are carried out under sterile conditions by competent scientists and mice are then monitored daily for any signs of

suffering or distress. Infected blood is either obtained through exsanguination or used to feed and infect mosquitoes whilst mice are under terminal general anaesthesia, to reduce pain and suffering, before culling.

Why can’t you use animals that are less sentient?

Mice have been selected due to being the least sentient species that still exhibit similar responses that provide a proof of concept in our field of study when observing malarial infections within humans and rodents. All mice used for mosquito feedings will be terminally anaesthetised and humanely killed.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As mentioned, we have previously made several refinements to the protocols to ensure minimal pain and distress during procedures. Animals will be monitored daily for signs of any adverse effects and aseptic techniques will be used to minimise the potential for infection. Animals showing signs of adverse effects will be killed using humane methods to minimise suffering and where appropriate, investigated and relieved under veterinary advice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We continue to follow ASPA, NC3Rs and LASA guidelines to ensure experiments are conducted in the most refined way possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We aim to continue keeping in contact with animal technicians regarding any notices or changes. We will continue to discuss current and new approaches to procedures, opportunities and ultimately the welfare of our animals with our network of NACWOs, veterinarians and animal technicians. Where appropriate, nominated PIL holders will attend NC3R’s workshops, webinars and courses throughout the course of this project.

56. Novel drugs for intractable cancers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Drug discovery, G protein-coupled receptor

Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We wish to develop new chemicals, antibodies and other drugs that slow, stop or reverse the growth of cancers that currently have no or few life-extending treatments. Our principal targets are receptors for hormones that provide benefits for cancer cells to grow and spread around the body. We make chemical compounds and antibodies that are very selective - that is they target specific hormones or subsets of receptors for a specific hormone to provide benefits with minimal side effects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The outlook for most cancer patients has improved dramatically in the last 30 years, and mean survival after diagnosis is around 10 years. However, these figures disguise a marked polarisation of treatment efficacy. Some cancers have just as poor outlook as they did 30 years ago and there are no treatments that extend life for a significant time. Our targets include pancreatic cancer, a devastating disease that usually results in a terminal prognosis at first diagnosis and 1-year survival of under 25%. We also hope to address cancers that are responsive to treatment but become mutated at which time they have a short terminal course. Such cancers include "hormone refractory" prostate cancers that lose their response to anti-testosterone drugs. Other targets include "triple negative" breast cancers which do not respond to drugs that save the lives of the majority of breast cancers patients. Finally, we wish to target rare cancers. One example is a very rare lymphoma (Sézary syndrome) whose 5-year survival is under 20% and in which the only effective treatment works in just 28% of patients and extends life by only around 7 months. While some of the patients in these cancer diseases are older, there is significant representation among the working-age population.

What outputs do you think you will see at the end of this project?

Outputs from this work will include information in the form of new knowledge, which may be published in the scientific literature and disseminated at learned society meetings. We are focused on translational research, so patent filings may be made prior to publication and they are outputs with tangible value for the development of novel therapeutics. Naturally, drug development requires both significant time and funding, but our programmes have developed and the University has approved formation of a spinout company to progress its activities. Outputs may also include the development of new drugs - for example, our current research programme has resulted in a clinical candidate.

Who or what will benefit from these outputs, and how?

Publications benefit staff career development and increasing the sum of knowledge in the public domain. That usually leads to academic contacts, collaborations and further advances with their own outputs.

Patents provide the opportunity for novel inventive science to be developed by biotech and pharma companies with a route to recover research costs through the sole rights to manufacture and sell drugs during patent life. This provides commercial benefit to the companies, with revenue shares flowing back to supporters of earlier research. Supporters in this case include funders - where income supports new science - and the University, where income not only provides for growth of academic activities but also increases the institutional reputation within the national and international communities.

Patients will benefit from our novel efficacious therapeutics with extension of life and improved quality of life. Our approach is to target disease precisely so that drug effects are tailored to the appropriate population of patients who should receive benefits without the level of toxic side-effects experienced with less selective cytotoxic therapies. Even if a cure is not possible, acceptable life-extending therapies have great value for some cancers that are currently very intractable to treatment.

The families of patients with intractable diseases have to come to terms with their relatives' illnesses and in some cases the brevity of life after diagnosis can make this a very traumatic experience.

Increased lifespan can allow more time for families to come to terms with what are still ultimately fatal diagnoses.

Healthcare providers (NHS in the UK and equivalent state healthcare providers in other countries, insurers in other countries without state provision of medicine) would benefit from reduced costs for treatment and palliation of protracted disease and reduced pressure on bed space. Even medicine that do not extend life greatly, but allow for acceptable quality of life in the home setting reduce healthcare costs and improve patients experience.

The national economy would benefit from UK drug discovery processes through employment, taxation and would also gain international recognition for the quality of UK science .

How will you look to maximise the outputs of this work?

Our experience in taking a research programme from academic basic science through drug discovery research and into a spinout company seeking major investment has been a very educational experience from the start. The interactions with medicinal and synthetic chemists, molecular designers, clinical development experts and commercialisation professionals has given me insights into the process from basic science to the clinic that has influenced my outlook greatly. I understand the need for professional industry-standard data packages, and in this context, our experiences with the translational aspects of drug development beyond efficacy models (PK, DRF and MTD studies) has been transformational. One specific issue may appear counter-intuitive, but it is clear that publication too early can corrode the value of IP, so we do not rush into dissemination of information into the public domain without proper protection as that would reduce the likelihood of successful development of a clinical therapeutic.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice represent the appropriate mammalian species for these studies. Commercial development of novel agents is unlikely if an industry standard data package (i.e. one using mouse models) does not support mammalian efficacy. (We are not proposing to work to GLP standards for discovery research, but to use GLP-like standards which will aid later translational and commercialisation activities).

Mouse models are also well developed, characterised and refined.

Typically, what will be done to an animal used in your project?

During the studies, animals will receive vehicle or drug agent treatment, usually by injection (but possibly by addition to the water) so that injection constitutes a relatively minor harm in these studies. Studies will generally last no longer than 28 days after the start of treatment. In most cases tumours establish and can be treated within a week of implantation of cells.

Subcutaneous xenograft models

Inhalation anaesthesia, subcutaneous injection of cells, measurement of tumour sizes with vernier callipers. (Optional IVIS visualisation, if appropriate)

Orthotopic pancreatic xenografts

Inhalation anaesthesia, laparotomy, intrapancreatic cell injection, wound closure, up to twice weekly inhalation anaesthesia for IVIS visualisation.

Orthotopic breast cancer

Inhalation anaesthesia for cell injection into the mammary fat pad, measurement of tumour sizes with vernier callipers. (Optional IVIS visualisation if appropriate)

Systemic injection of lung tumour cells

Intravenous injection of lung tumour cells to the tail vein or by intrathoracic injection under brief general anaesthesia, up to twice weekly inhalation anaesthesia for IVIS visualisation.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts and/or adverse effects

Effects due to tumour presence - subcutaneous models: ulceration, orthotopic models: pressure on local organs or tissues causing pain or interference with normal function (e.g. gut transit for pancreatic cancer model).

General health adverse effects:

- Weight loss of 10 - 15% of the animal's average stable weight
- Hunched posture
- Piloerection
- Altered behaviour/activity, which may include abnormal locomotor activity, under-activity, hyperactivity, under-grooming, over-grooming, scratching, licking, or self-mutilating
- Dehydration
- Abnormal vocalisation
- Persistent hypothermia
- Enlarged lymph glands
- Anaemia
- Eating/drinking difficulties
- Mild dyspnoea

If any one of these endpoints is severe or prolonged (>24 hours), the animal will be culled immediately.

Mice will be humanely killed, by Schedule 1 method, in the unlikely event that they show any one of the following signs:

- Body condition score ≤2/5
- Weight loss of >15% of the average stable weight, if not improved within 24 hours
- Internal tumour growth begins impeding normal function
- Serious clinical signs (e.g. incontinence, diarrhoea, >mild dyspnoea, bleeding/mucopurulent discharge from any orifice, hindlimb paralysis/weakness, tremors or convulsions)
- Pain which cannot be promptly relieved
- Hind limb paralysis/weakness/'flippering' gait
- Signs of being moribund (lethargic, failure to respond to gentle stimuli) Duration

We expect adverse effects to be short-lived as we will euthanase any mice experiencing significant suffering. We expect the incidence of adverse effects are also likely to occur towards the end of the experimental period as tumour sizes increase.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We propose that all the studies will be of moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

During the process of development of a new chemical compound, we first test in computer models (in silico) with protein models that mimic the structure of our target hormone receptor. Then we test in cells (in vitro) that express the target receptor, by measuring the effect of compounds on hormone signaling to induce changes in growth and proliferation of cancer cells, as well as their ability to migrate and invade new tissues. Once we have exhausted the range of tests in cells (in vitro), we must measure the effects of potential new drug compounds on tumours in a living organism (in vivo). This means implanting tumour cells into mice so that we can measure the growth differences between in groups treated with drug candidate molecules compared with groups given the same vehicle solutions without the drug compound. It is currently impossible to replicate the complex interplay of effects that act on tumour cells in a living organism within a 2D/3D cell culture, so the studies we propose are an essential for development of new drugs. Additionally, animal models are currently an industry standard for a data package to be used to support preclinical development and clinical trials in humans.

Which non-animal alternatives did you consider for use in this project?

In addition to considering alternatives, we do in fact use them in the earlier stages of drug discovery.

We model our receptor target using sophisticated computer methods, and design drug molecules to fit the structure. We then virtually screen these molecules to determine which are likely to bind to the target receptor. Thereafter, we synthesise and test the selected compounds in in vitro cell models in all cases to measure the effect of compounds on signalling pathways and specific cancer hallmarks (proliferation, apoptosis, migration, invasion etc.) before performing animal studies.

Why were they not suitable?

They are suitable to identify compounds that block the receptor and to determine the nature and mechanism of those effects, in the early stages of drug discovery. However, they lack the complexity to allow us to determine their likely effect in humans, so we must move on to animal studies when all these other tests have been performed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We know the group sizes for the studies we expect to perform and those have been chosen to be the minimum to provide robust statistically relevant results. Depending on the minimum detectable effect and availability of historical data, group sizes are typically 8-10 mice. Within the oncology community, there is wide use of relevant animal models. We do not originate them, but use those which are recognised as well as characterised, refined and ethically acceptable in numbers that lead to identification of changes of magnitudes that are scientifically and clinically relevant.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We take advice from the local statistical professionals to design experiments that use the smallest number of mice appropriate. We use groups of mice that are very closely or identically matched in age, sex genetic strain and size, because that reduces the spread of results. As we generate more data, we will also incorporate the use of NC3R's Experimental Design Assistant to determine sample size calculations for future experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to consult statistical professionals and to keep abreast of the scientific literature relating to use of mice in order to benefit from advances that lead to reductions in numbers. We incorporate many non-animal methods in our drug development pipeline such as in silico screening (docking/binding), in vitro screening (potency/selectivity), in vitro cancer models (proliferation, apoptosis, migration, invasion, angiogenesis and more), in vitro ADME and pharmacokinetic studies. From these methods, we select only a handful of lead compounds to test in mice from a long list of more than 1000 compounds.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use several different types of cancer models (Workman et al Br. J. Cancer 2010).

Subcutaneous xenografts

Human cells are implanted under the skin of the flank (side of the body) of mice so that they grow into tumours. The mice would normally reject human cells so we use natural or artificial mutant mice that lack a complete immune system so that they tolerate non-native cells. Those mice are reared and kept in very clean conditions to prevent infections (because of their reduced immune status) and all our experiments are performed in those clean conditions with staff wearing gowns, gloves and masks to protect the mice. The procedures are not painful, as the implantation of the cells is an injection performed at the loose skin of the flank after carefully restraining the mouse. Short term anaesthesia will be used if it is required to minimise duress and duration of procedure. The most likely reason for this is that some mice are temperamentally less calm about handling and injection, so it is more humane to anaesthetise them to reduce the stress experienced. As the tumours grow, they do not cause pain, and if the size reaches a limit specified in the protocol, the mice are euthanased.

Orthotopic xenografts

Here, the cells are implanted into the tissue or organ in the mice in which the human cancer originated. For example, human breast cancer cells are implanted into the mammary tissues of the mouse. Where the tumours can be assessed by looking at the mice, we measure their size and can assess their progress towards an end-point size limit or whether there is any pain, suffering or distress. If cells are implanted into internal organs, the tumour cells may be altered genetically so that we can see them through the body wall, by virtue of their ability to emit light under specific conditions (e.g. luminescence, fluorescence). This allows us to assess size of tumours within the body.

Syngeneic orthotopic models

In these studies, we inject mouse cells into the tissue of origin of the tumour. This allows us to assess tumour growth in mice with a complete immune system, which is a more realistic model than the studies in immunodeficient mice. These models may provide closer approximations of cancer in that they can spread to other parts of the body, so observation of the mice, assessment of tumour sizes (and any secondary tumours) is even more thorough and signs of distress are watched for very carefully.

For all these studies, at the end of the experiments mice are all euthanased painlessly. We also keep a close check on the mice with a team including vets, and highly experienced animal care workers who can tell if mice are generally unwell or showing signs of any distress.

Why can’t you use animals that are less sentient?

We need to use mammals to provide systems that work in the same general ways as in humans. Mice are the least sentient mammalian species that we can use. While non-mammalian models for in vivo research in cancer biology are available (e.g. zebrafish models), they are not widely accepted in the same way as mammalian models in their perceived power to predict human responses. Therefore, to aid translation/commercialisation of our research into practice and eventually patient benefit, we propose that mouse models are the most appropriate ones.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We perform studies for the shortest time to provide robust data. We choose models and techniques that cause the minimum of harm discomfort or suffering. Pain will be controlled during surgery by general anaesthesia and post surgery by analgesics. Surgical sites will monitored daily for signs of inflammation and infection. In the event of post-operative complications, mice will be killed unless, in the opinion of the Named Veterinary Surgeon, such complications can be remedied promptly and successfully using no more than minor interventions. If an orthotopic tumour’s presence is associated with signs of pain or suffering we would consult the NACWO and/or NVS for advice over continuation and/or analgesic treatment, and euthanase mice if those signs are maintained for more than 24 hours.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs website contains a vast range of guidance for best practice across the spectrum of animal research activities. (https://www.nc3rs.org.uk/3rs-resources). CAAT-Europe also disseminates information about developments within 3Rs in the European network, which NC3Rs is part of.

PREPARE guidelines (produced by a group of experts from the UK and Norway) for planning animal experiments is also used as a guide to plan individual experiments. All surgeries will be performed in line with the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We attend scientific meetings and relevant training courses in the UK and abroad. We read the scientific literature. We discuss the 3Rs with staff in the animal facility. We Also consult our NC3Rs regional programme manager. Where advances are made, it is ethically indefensible not to implement them.

57. Establishing the pathophysiological impact of cigarette smoke extract in mice as a model for chronic obstructive pulmonary disease (copd)

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Cigarette smoke extract, Chronic Obstructive Pulmonary Disease, Underlying mechanisms, Disease progression

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To establish a mouse model of cigarette smoke extract-induced Chronic Obstructive Pulmonary Disease (COPD) with which to determine the underlying pathophysiological changes to health.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic Obstructive Pulmonary Disease (COPD) represents a significant burden to public health with an estimated cost to the NHS of £800m. The hallmark of COPD is chronic inflammation that affects central and peripheral airways, lung tissue and pulmonary

vasculature. Repeated injury and repair leads to structural and physiologic changes. The inflammatory and structural changes in the lung increase with disease severity. The main components of these changes are narrowing and remodelling of airways, increased number of goblet cells, enlargement of mucus-secreting glands of the central airways, alveolar loss and finally, vascular bed changes leading to pulmonary hypertension. Evidence suggests that the host response to inhaled stimuli generates the inflammatory reaction responsible for the pathophysiological changes. Activated macrophages, neutrophils, and leukocytes are the core cells in this process. Oxidative stress and an excess of proteases amplify the effects of chronic inflammation. Hyperinflation and destruction of lung parenchyma predispose patients with COPD to hypoxia.

Progressive hypoxia causes vascular smooth muscle thickening with subsequent pulmonary hypertension, which is a late development conveying a poor prognosis.

Current COPD therapies are largely inadequate due to their modest improvements on symptoms and long-term mortality. Therefore, the development of better models for COPD with which to develop new therapies is essential. In mice, many of the hallmark features of human COPD, namely (i) lung inflammation, (ii) impaired lung function; (iii) emphysema; (iv) mucus hypersecretion and (v) airway and vascular remodelling can be induced in response to cigarette smoke. However, while rodent cigarette smoke extract models of COPD exist, their design and ability to address the underlying pathophysiological mechanisms are limited for several reasons. First, the majority of studies assess the impact of COPD in only a single tissue, typically the lung, failing to acknowledge the effects of this disease in other tissue types or on a systemic scale. Indeed, systemic inflammatory mediators may contribute to skeletal muscle deterioration, and initiate or worsen cardiac, metabolic, and skeletal comorbidities. Indeed, comorbidities are frequently reported in COPD patients, and it is important to understand whether or not the onset of these comorbid conditions are as a result of immuno-pathogenic mechanisms of COPD in additional tissues. Therefore, new models which adopt a whole body, multiple organ/tissue analysis approach are needed in order to gain new insights into how the disease progresses, whether tissues separate to the lungs are also predisposed to developing additional pathogenic phenotypes and the role of the peripheral immune system in driving them.

Additionally, existing studies typically only focus on the impacts of COPD in a single sex. In humans, studies have shown that the impacts of COPD are different in men than women, with women typically presenting disease characteristics sooner than men and at a more severe level. As such, understanding how the disease develops and progresses in both sexes is critical for developing new sex-specific therapies for men and women.

Furthermore, existing studies predominantly examine the pathophysiology of COPD at a single time point only, ignoring the fact that COPD is a progressive chronic disease that will develop over time. Typically in a human context, COPD is only diagnosed once a patient reaches a specific degree of morbidity, preventing a detailed analysis of how the

disease starts and progresses. Using animal models, an understanding of how the disease develops, even prior to clinical manifestations, can be obtained.

In order to develop new, preventative therapies for COPD patients, it is critical that an understanding of the initial stages of immune system activation and recruitment to the lungs and other tissues is established. As such, a model in which the progression of the disease over time, on a whole-body and multi-organ system approach and that studies the pathophysiology in both males and females represents a significant development and enhancement of existing models which typically only focus on a single tissue, sex and time point.

Data from this study will identify the key biological mechanisms involved in the development and progression of COPD in a valid mouse model. At the centre of this proposal will be a study of the immune system, its activation and its influence on multiple organ systems in the body. Findings from this study may allow for the future replacement of animal models with appropriate in vitro cell lines, whole organ and/or in silico models. In addition, following identification of key molecular and biochemical pathways involved, data from this proposal can be translated from the mouse into human samples.

What outputs do you think you will see at the end of this project?

Although COPD is a significant global health burden, the mechanisms underlying disease progression and persistence are poorly understood. Furthermore, current therapeutic interventions for COPD typically rely on smoking cessation and management of symptoms. The development of this novel murine model will provide researchers with a new model that accurately reflects human COPD in a more three-Rs friendly manner, and will maximise their data outputs in comparison to models currently in use. Although this model is designed with the investigation of immunopathogenic mechanisms of COPD in mind, the model has additional potential future applications for researchers investigating other pathological mechanisms or developing novel therapeutic interventions and treatments of COPD. The model will help to further define and identify immunopathological mechanisms of COPD, providing additional characterisation of immune cell and cytokine profiles to further solidify current understanding and research of COPD immunopathogenesis.

Throughout the duration of this project, several publications including primary research articles and review papers will be produced. Data will also be presented at relevant national and international (where possible) conferences by the principal investigators and PhD and graduate students. We are currently in the process of publishing a systematic review paper of current cigarette smoke exposure murine models of COPD that investigate immunopathological mechanisms.

The generation of a tissue bank throughout the project will provide research materials for future PhD students, graduate students and collaborators, as well as provide data for future grant applications relevant to follow on projects. Samples from this tissue bank as

well as directly from mice utilised throughout the project may also be used for additional analyses that will provide further insight into additional mechanisms of COPD or for additional investigations to elaborate on data gained throughout the project, therefore reducing the number of animals needed for further research.

Who or what will benefit from these outputs, and how?

The findings and results from this project will have many benefits to a multitude of groups within the academic and health care communities over both short (5 years) and long-term (10-15 years) time scales. First and foremost, the project will provide COPD researchers with a more refined and characterised murine model with which to conduct research that will maximise potential outputs as well as better reflect human COPD and the three Rs of animal research. As indicated above, there is a paucity of well-described and characterised models which explore the development of COPD over time, on a whole body basis and in both sexes. As such, this model will be of benefit to other research groups in this area. Upon presentation of our data at appropriate conferences and publication of our results, our model will act as a comparator against which other research groups could refine their own models to improve the welfare of their animals and the validity of their data. We anticipate the establishment, validation and publication of initial results from this novel model will occur within a comparatively short (3-5 years) time scale.

Findings from our project will aid in the further characterisation of pathological mechanisms of COPD. These findings will be of clinical relevance and may aid in the development of new approaches for the management of COPD patients. Such translational outcomes will occur on a medium- to long-term time frame (10-15 years). However, following the identification of clinically relevant mechanisms in our mouse model, we anticipate the development of a range of in vitro and in silico models. These will be based on using human samples and that will aid in the translation of our findings from the mouse to humans. These are likely to occur on a medium time frame of 5-10 years after initiation of the research.

How will you look to maximise the outputs of this work?

To maximise the output from this project, we will publish the research data in high-impact, open-access journals. Furthermore, data collected under this project will be presented at international, national and institutional conferences, meetings and seminars. In addition, we will use publicly accessible outlets such as the Conversation UK to discuss research originating from this project. Where ever possible, we will also collaborate and share resources (samples, knowledge, technical skills) with other researches (both within and outside of the University) to maximise the scope and impact of our research. It is our anticipation that all data generated under this project (both positive and negative) will be made available.

Species and numbers of animals expected to be used

- Mice: 510

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice represent the most appropriate animal model for these studies for a number of specific reasons. Firstly, patterns of COPD pathophysiology in mice in response to experimental insults (e.g. cigarette smoke and/or extract) bear significant similarity to that in humans. Furthermore, mice are the lowest vertebrate order that develop the significant lung changes associated with COPD. This means that mice represent the optimal model with which to study COPD disease progression.

Second, the un-surpassed genomic annotation of the C56BL/6 strain permits analyses into the underlying molecular and epigenetic regulation in tissues isolated from our mice, maximising the level of data retrievable from each animal. Additionally, the array of genetically manipulated mouse strains means that upon identification of potential therapeutic targets, appropriate mouse knock-out models can be investigated, providing more insight ahead of subsequent human focused studies.

Finally, the use of rodents allows for the isolation, culture, manipulation and cellular analysis of somatic and reproductive samples. As such, by using rodents it is possible to understand the entire aetiology of COPD development and progression as well as studying the impact the condition on the whole body.

Such an integrated, whole-organism approach would not be possible in humans or non-mammalian species.

Typically, what will be done to an animal used in your project?

Under this project, we will study the pathophysiological development of COPD pathophysiology in adult male and female mice in response to a cigarette smoke extract. Typically, male and female C56BL/6J will be exposed to a cigarette smoke extract created in our laboratory via an intranasal route. We have performed a systematic review of the existing literature (which is being prepared for publication) on the different animal models of COPD. Of 217 papers compiled during our literature search, only 3 studies that used a cigarette smoke extract to induce COPD in mice. None of these studies characterised disease progression over time, examined the impacts in both sexes or looked on a whole body basis.

As such, there is currently no existing data indicating what an optimal concentration or exposure duration to cigarette smoke extract is to mimic the progression of disease in humans. Furthermore, none of the studies we identified reported on the adverse effects of their models for the welfare of the animals used.

In light of the lack of detailed published literature on which to establish an optimal experimental set of concentration and dose parameters, we propose to conduct an initial pilot study. The aim of this pilot study will be to define the minimal dose necessary to observe pathophysiological changes in line with patients presenting with moderate COPD. Specifically, we will use a set of experimental endpoints typically consisting of (i) elevated lung damage (as defined by significant increases in histological assessment of alveolar mean Linear Intercept (Li) and Destructive Index (Di) parameters); (ii) statistically significant remodelling and extracellular matrix deposition of the lung vasculature; (iii)

decrease in blood oxygen saturation to 85%; (iv) significant infiltration of lung immune cell populations into the lung tissue and; (v) elevated peripheral immune cell activation and inflammatory mediator profiles.

To ensure our pilot study has the minimal impact on animal welfare, we will adopt a system in which mice (males and females) are initially exposed to the lowest concentration of extract (typically 1%) and for the shortest duration (typically 1 week). Animals will be exposed to the cigarette smoke extract three time a week via an intranasal route and will be compared again control (culture medium only) animals. Once a week, mice will be restrained for the conscious measurement of blood oxygen saturation and heart rate using a pulse oximeter. At the same time, we will collect a tail vein blood sample for the measurement of circulating inflammatory markers and immune cells using a multiplex protein microarray and spectral flow cytometry within our laboratory. Our new spectral flow cytometer will allow us to characterise and identify the differentiation of key immune cells involved in COPD pathogenesis (NK/NKT/CD8+ T cells, Macrophages and Th17/Tregs) using up to 40 key markers in a single sample. We are currently validating this novel flow panel in vitro, and will apply it to blood samples obtained from the in vivo murine model. In addition, multiplex protein microarrays will allow us to analyse and quantify the presence of inflammatory modulators such as cytokines within the blood samples. Both of these techniques will allow us to characterise immunopathogenic mechanisms beyond what has already been previously identified in literature and within our own in vitro studies, and require a minimal amount of samples to obtain a significant amount of data.

At the end of the defined exposure time, mice will be culled for the collection and study of a range of tissues. Typically, after humane killing by a schedule one technique, lungs will be flushed using sterile phosphate buffered saline for the collection of bronchoalveolar lavage fluid (BALF) and analysis of immune cell populations. Lung tissue will then be fixed and processed for histological assessment of vascular smooth muscle remodelling and alveolar damage. Other tissues such as the liver, kidney, heart and reproductive tissues will also be collected, processed for histological assessment. Peripheral blood will be collected for analysis of immune cell and inflammatory mediator profiles as described above. If no change in the experimental and physiological endpoints described above are noted, in addition to no detrimental effects on animal welfare (see comments below), the dosing regimen will be increased incrementally (typically by an extra 2% concentration of the extract and for an extra 2 weeks of exposure). Based on existing evidence that onset and severity of COPD displays sex-specific differences, it is conceivable that to establish

the same COPD pathophysiological status, the dosing regimen between males and females may be different.

During this Pilot Protocol we will monitor closely the welfare of the animals (with supervision from the NVS and NACWO, or appropriate deputies) for signs of weight loss, changes in body condition and breathing difficulties. Under this pilot study our humane endpoints will be a loss of body weight of ≥20%, a body condition score of 2 or any animal found to be making significant respiratory effort with no improvement in symptoms over the course of 4 hours. In addition, animals will be scored for clinical symptoms on a 0-3 scale (where applicable) and a cumulative score of 12 will result in the animal being humanely killed. The findings from this pilot will inform on the dosing regimen required to induce a phenotype reflective of moderate COPD in humans, and to ensure our experiments are maintained within a ‘Moderate’ severity limit or lower.

Under Protocol 2, male and female mice will be exposed to the defined, optimal dosing regimen, as established under Protocol 1. Here, the aim of this Protocol is to define the biological mechanisms driving the progression of COPD and to understand the potential recovery of the mice once administration of the extract has been stopped. As under the Pilot protocol, mice will be exposed to the cigarette smoke extract three times a week. Mice will be subjected to regular (weekly), non-invasive monitoring of blood oxygen saturation and heart rate via pulse oximeter as well as tail vein blood sampling. At the end of the dosing regimen, one group of the animals will be culled for the collection of tissues for molecular analysis and in vitro characterisation of isolated cells e.g. vascular smooth muscle cells.

As sex differences in respiratory physiology and predilection for developing COPD have been documented, there may be connection between sex hormones, reproductive health indicators and disease pathogenesis. A separate group of experimental males and female will be mated to control animals for the analysis of reproductive health and correlated to extent of disease progression. Here pregnant females will be culled at distinct stages of gestation for the collection of reproductive, embryonic and fetal tissues. All pregnant females will be culled prior to term.

Finally, to address whether the induced tissue damage and activated immune cell profiles can return to a more normal profile once the exposure to the cigarette smoke extract stops, a second group of animals will be kept and monitored at either 1, 5 or 10 weeks after their last exposure to the cigarette smoke extract. Analysis of these animals will be in line with the experiments detailed above and will inform on how their physiology responds after cessation of exposure to the cigarette smoke extract.

What are the expected impacts and/or adverse effects for the animals during your project?

The intention of this study is to induce pathophysiology symptoms in line with moderate COPD in humans. Our Pilot protocol has been designed to ensure the welfare impact on the animals is minimised and remains within a ‘moderate severity’ limit.

During this program of work, we will monitor closely the welfare of all animals (with supervision from the NVS and NACWO, or appropriate deputies) for signs of weight loss, changes in body condition and breathing difficulties such as an increased respiration rate and breathlessness. Under this pilot study our humane endpoints will be a loss of body weight of ≥20%, a body condition score of 2, any animal found to be making significant respiratory effort with no improvement in symptoms over the course of 4 hours or a drop in oxygen saturation below 85%. In addition, animals will be scored for clinical symptoms on a 0-3 scale (where applicable) and a cumulative score of 12 will result in the animal being humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As indicated elsewhere, there is a significant paucity of published data on the welfare impacts of administering a cigarette smoke extract to mice. As such, it is difficult to anticipate precisely the likely severities that animals on this application will experience. However, to mitigate this lack of prior knowledge, the humane endpoints associated with our protocols have been set to ensure that all experiments will not exceed a 'moderate' severity limit.

Our pilot study has been designed such that animals will be exposed initially to the lowest concentration of the extract and for the shortest time. Dependent on the experimental endpoints observed, in conjunction with our humane endpoints, the dosing regimen may then be increased if minimal changes are observed. As such, it is possible that our experimental endpoints are achieved with minimal impact on animal welfare. However, it is also possible that the anticipated changes in lung and vascular histology, oxygen saturation and inflammatory status may impact to a moderate severity in those animals receiving the higher doses and for long durations. It is anticipated that under Protocol 1, 25% of animals may experience Moderate severity effects in response to the higher doses of cigarette smoke extract. If it is the case that we establish a regimen that achieves our experimental endpoints but which are associated with Moderate severity effects, then all animals under protocol 2 will experience Moderate severity effects. These are anticipated to be weight loss (no more than 20%), decline in body condition (no lower than 2), respiratory impairment (laboured breathing and/or increased respiration rate lasting no longer than 4 hours) and/or a decline in blood oxygen saturation (no lower than 85%).

Separate to the impact of the cigarette smoke extract on animal welfare, we anticipate mild severity short-term effects on animals from regular restraint, sampling of blood from the tail

vein and monitoring of blood oxygen saturation and heart rate. These effects will typically be in the form of soreness and swelling at the site of needle insertion, or short-term stress from the restraint. These are likely to occur in all animals but are not anticipated to have lasting harm.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of the work is to determine the effects of a cigarette smoke extract on the development of COPD and its progression. Such studies, while of significant benefit to human health, would be considered un-ethical in humans. Therefore, to achieve the aims of this project, the use of animals is necessary to cover the complex, inter-related, whole body nature of the study.

Which non-animal alternatives did you consider for use in this project?

As COPD is a systemic disorder, appropriate models are needed which permit the analysis on a whole body basis. Therefore, in vitro or isolated organ systems do not provide sufficient interrogation with which to determine whole body effects of cigarette smoke exposure on COPD development.

Why were they not suitable?

The central aim of this project is to examine the effects of a cigarette smoke extract on whole body physiology and disease progression in a clinically relevant model. While complex in vitro systems have been developed to study central biological processes e.g organ on a chip, organoids, 3D-scaffolds for cell culture, these models represent isolated systems in vitro. Therefore, in order to understand how a cigarette smoke extract affects lung function and physiology, inflammatory status and peripheral organ structures (all interconnected) in an undisturbed system, live animal research is necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The appropriate number of mice to be used has been determined through the use of the NC3R's online Experimental Design Assistant and existing published literature of mouse models of cigarette smoke extract. Pathophysiological data on lung morphology, circulating inflammatory markers and immune cell populations (all parameters that will be assessed under this Licence) have been taken from relevant publications (He et al, 2015, Tob Induc Dis. 13(1):6; Tabata et al. 2015. Int Immunopharmacol. 25(2):511-7; Braber et al. 2011. Am J Respir Crit Care Med. 185(8):817-24).

Using these resources, we have calculated that an n of 10 animals per group would be required to observe significant differences within any single treatment or control group. As the majority of existing studies only assess the pathophysiological impacts of COPD in a single sex, and sex-specific differences in the responses to the cigarette smoke extract are anticipated, an n of 20 animals (10 males and 10 females) per group (either treatment or control) would be assessed for each individual experiment.

Based on these factors, it is anticipated that under Protocol 1, a maximum of 200 mice will be required, while under Protocol 2, a maximum of 310 mice will be required

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical advice was sought to devise an analytical approach which allowing us to take into account the multiple levels of interaction within our data and other potential confounding variables (e.g. sex, body weight, age, dosing regimen). Using this approach we are able to factor into our statistical analyses the multiple measurements from individual animals and any potential extract 'batch' effects. Such analyses allow us to maximise the information gained from any one individual animal and so reduce the number of mice required.

In addition, we have used the NC3Rs experimental Design Assistant to confirm that an n of 10 males and females per treatment group are necessary to observe significant changes in lung function and morphology, circulating inflammatory mediators and altered immune cell populations based on existing published data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, multiple measurements will be taken from any one individual animal prior to culling for the collection of tissues for subsequent molecular and biochemical analyses. This will ensure maximal data is obtained from mouse and will minimise unnecessary repetition of experiments.

From all animals used within this project, a range of tissues will be collected and stored for later analysis. These will be used for under-and post-graduate studies within our

laboratory, for the generation of preliminary data for further grants and will also be made available to collaborators where appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The aim of this project is to use a cigarette smoke extract for the induction and study of COPD progression in mice. Many of the hallmark features of human COPD, namely (i) lung inflammation, (ii) impaired lung function; (iii) emphysema; (iv) mucus hypersecretion and (v) airway and vascular remodelling, can be induced in response to cigarette smoke. However, the animal welfare issues and modest scientific benefits associated with rodent chronic cigarette smoke aerosol exposure means alternative models are needed. Exposure of mice to a cigarette smoke extract (via an intra nasal route) have been shown to result in the same pathophysiological changes as those observed in restrained animals exposed chronically to cigarette smoke aerosol. Therefore, the use of such extracts represents a significant refinement (reduced handling, minimal number of exposures) over older, whole body- exposure methods which required long-durations of restraint.

Mice represent the most appropriate model for use in these studies as they represent the lowest vertebrate species that develops lung injury, lung inflammation and pulmonary fibrosis in response to various challenges. As such, the use of non-mammalian species, such as insects or fish, would be inappropriate for the proposed series of studies. Additionally, aspects of mouse physiology, central to understanding the whole body disease progression, share significant similarity with humans.

Mice provide a further experimental benefit through their unparalleled genomic annotation. After cull, numerous tissues will be collected and stored for down-stream detailed investigations into the genomic and epigenomic mechanisms underlying the development of COPD. The detailed annotation of the C56BL/6 genome, transcriptome, proteome and epigenome will allow for maximal levels of data to be retried from each animal. For these reasons, rodents provide the most appropriate non-human model for such studies.

Why can’t you use animals that are less sentient?

COPD is a complex whole body condition that develops over time and typically within adults. In order to better define and understand the development and aetiology of this disease, complex whole body models are needed. As mice are the lowest mammalian

species to develop the pathohysiological symptoms of COPD, then the use of less sentient animals would be of lower disease relevance to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals studied under this protocol will be monitored weekly for weight gain/loss, general condition, demeanour and behaviour. Any significant deviations from normal will be recorded and, where appropriate, result in discussions with staff withing the facility, the NVS or their deputy and appropriate action enacted.

In all protocol steps where dosing/substance administration is required, maximum volumes will not exceed LASA guidelines.

Animals will be humanely killed via a scheduled one method if they show other than transient signs of ill health such as pronounced piloerection and hunched posture (score of 3/3 on health monitoring record), inactivity, or inappetance for a period greater than 24 hours. Any animal with a cumulative health score of 12 or above will also be humanely killed. Any animal that loses 20% of its body weight, records a body condition score of 2 or shows serious clinical signs such as diarrhoea will also be killed. Any animal making significant respiratory effort such as breathlessness or increased respiration rate (respiratory score of 3/3) and/or laboured breathing (laboured breathing score of 2/3) for a period of up to 4 hours with no improvement in symptoms will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Throughout the course of this project we will make reference to multiple sources for best practice guidance. these will include:-

Fund for Replacement of Animals in Medical Experiments: www.frame.org.uk

NC3R’s website for details on experimental design: https://nc3rs.org.uk/experimental-design NC3R's ARRIVE guidelines: https://www.nc3rs.org.uk/arrive-guidelines

Laboratory Animal Science Association (LASA) publications: https://www.lasa.co.uk/current_publications/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I currently subscribe to the NC3Rs monthly e mail alerts which keep me updated to the most recent developments in NC3Rs publications, guidance and information.

We also receive regular updates and latest animal welfare guidance information via bulletins disseminated from our Biomedical Research.

Finally, information is disseminated and methods of best practice are discussed via our establishment users meetings of which my research group are involved with.

58. Improving our understanding of the bovine immune system

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Immunology, Bovine immune response, Pathogenesis of disease, Mastitis

Animal types	Life stages
Cattle	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to take a multifaceted approach to improve our understanding of the bovine immune system (the tool kit to fight infection), both in the 'healthy' animal and when faced with 'insults', such as infection with a microorganism. It will consider the development of the immune system, from a neonatal calf through to a lactating (in milk) cow; from the start of an animal's life through to adulthood.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit – these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The current Dairy Cattle Welfare Strategy lists priority areas, including lameness, calves/youngstock, promoting higher welfare, mastitis, fertility and breeding, as issues that are challenging the dairy industry. With global demand for dairy products expected to grow by ~2%/annum over the next 10 years and a potential for UK growth post-Brexit, it is key that research gaps around these major challenges are addressed.

This research will advance our understanding of basic bioscience underpinning health, the stages of development of key diseases, including mastitis, and how immune system development impacts on healthy ageing, potentially maximising the health, welfare and productivity of the dairy cow and the sustainability of dairy farming, benefitting animals, dairy farmers and consumers. The UK has ~1.8 million dairy cows that could benefit.

This research will identify key roles of the immune system across the ages, from early life 'insults' into their productive adult life, and a deeper understanding of the key issues that impact the industry and cattle health welfare. It will advance the science of both the fundamental biology of the immune system as well as provide potential targets for intervention or vaccine candidates.

What outputs do you think you will see at the end of this project?

This research will advance our understanding of basic bioscience underpinning health, the progression/development or pathogenesis of key diseases and how immune system development impacts on healthy ageing, potentially maximising the health, welfare and productivity of the dairy cow and the sustainability of dairy farming, benefitting animals, dairy farmers and consumers. The UK has ~1.8 million dairy cows that could benefit.

Intended outputs

This research will identify key roles of the immune system across the ages, from responding to early life 'insults' into their productive life, and a deeper understanding of the key issues that impact the industry and cattle health/welfare. It will advance the science of both the fundamental biology of the immune system as well as provide potential targets for intervention or vaccine candidates. The research will provide a wide array of data including whole genome sequencing, correlations between an animal's genetic make-up (genotype) and an observable trait (phenotype) and immunological/gene expression data. All of these will results in publications in peer-reviewed journals, as well as dissemination at conferences and stakeholder events.

Who or what will benefit from these outputs, and how?

Who?

The outputs will be used by researchers investigating the bovine immune system, bovine diseases and others interested in the age-specific response. The research could directly inform the optimal management of dairy calves in order to minimise exposure to early life challenges (these can be infections or stressors) and may inform age-specific vaccine

design. Results will be presented directly to AHDB Dairy (levy board) for use in knowledge exchange activities, farmers and the research community/policy makers via peer reviewed publications and conference presentations.

How?

The outputs would provide a scientific understanding of the differences in the immune system through the key life stages of the dairy cow, a current research gap, which could be harnessed for therapeutic/vaccination regimes as well as management strategies. A greater understanding of disease pathogenesis will provide avenues to investigate for diagnostics, vaccine/vaccine adjuvant candidates and in breeding for greater resistance to the development of a disease.

Short-term benefits

Researchers will benefit from a better understanding of the immune response, particularly through the key life stages. Findings will be made available to scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings.

Pharmaceutical industries/farmers may benefit through improved vaccination regimes, particularly with regards to neonates. In addition, this research will lead to investigations into therapeutic targets, vaccine adjuvants and candidate vaccines. Identifying correlates of disease (essentially the fingerprint of a disease and how that changes as a disease progress) may lead to the development of novel diagnostic tests, enabling the potential for an infection to progress to disease much earlier. We will work with farm vets/farmers on the impact of early life insults on the long term health of the dairy cow. There is the potential to improve cow welfare (and therefore enhanced consumer confidence) and improved sustainability through improved long-term cow health and productivity.

Medium and long-term benefits

In terms of sustainability, benefits of the research would include a reduction in greenhouse gas emissions, carbon and non-renewable energy consumption, through improved health and reproductive performance during the life of a dairy cow, with potential to improve their life span. In terms of financial return to farmers, small improvements in calf survival, health and fertility would lead to large increases in efficiency and profitability. The potential financial benefits extend beyond those associated with health and production, as the image of dairy farming is critical to consumer confidence and the long- term sustainability of the industry.

How will you look to maximise the outputs of this work?

All work covered by this application will be funded by funding bodies who will expect all new knowledge to be disseminated as detailed in the Impact part of any grant application; whilst UKRI have recently removed the standalone Pathways to Impact document this will

still form a key part of any funding application. Dissemination will be through publications, conferences and workshops ensuring to involve all stakeholders, with data made freely available on appropriate platforms. The in vivo studies, funded through a BBSRC grant, will all be using well established protocols for the infection studies, therefore we do not anticipate any unsuccessful approaches. The remainder of the work is primarily of a fundamental nature, providing new knowledge and again we would not expect any unsuccessful approaches. Should this occur we would ensure that that approach is part of a bigger publication.

Species and numbers of animals expected to be used

- Cattle: 190

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In humans, several differences between lymphocyte (white blood cell) subpopulations obtained by immunophenotyping (determining the immune cell profile) in healthy neonates, infants and adults have been reported. In neonates and infants, lower levels of lymphocyte function, compared to adults have been described. Healthy neonates/infants react differently to antigens and are less efficient in coping with some microorganisms. Their lymphocytes undergo maturational changes that are essential for normal development.

Previous studies in cattle are now out dated, with the discovery of novel cells and immune markers (parts of the cell that enable them to be identified, such as T-helper/Th17 cells and interleukin (IL) -17 protein family, the need for an updated and thorough comparison across the key life stages is essential. This combined with an understanding of their comparative response to key microorganisms has the potential to improve animal health and productivity.

With UK farmers experiencing continual losses of potential replacement adult cows throughout their rearing period with ~8% calf mortality, 14% of calves failing to reach first calving, and a further 15% of cows culled in their first lactation (milking period), a better understanding of how early life insults impact on animal health aims to reduce these losses. The project will generate evidence to support the age-specific immune phenotype of the dairy cow from birth through to adult life, demonstrating how key immune cells respond to stimulation with key microorganisms.

Specifically the project will address two key areas:

1. How does the type, proportion and functionality of key immune cells differ with age and how do they respond to key microorganisms?

2. Greater understanding of disease pathogenesis, particularly with regards to mastitis.

Typically, what will be done to an animal used in your project?

The project involves simple protocols unlikely to cause any harm or distress to an animal, these include the use of a blunt cannula (very similar to a syringe without the needle) to remove milk aseptically from the udder and the use of a swab to sample faeces. Both of these protocols would involve the reuse of animals to allow the monitoring of milk immune cells and bacterial carriage (present but causing no adverse effects) over time.

Obtaining blood by venipuncture (removal from a vein) is unlikely to cause more than transient discomfort. Animals may however be re-sampled (continuous use) for analyses studying immune responses through the life stages, and the risk of haematoma formation or infection will be minimised.

Infection studies involve the experimental infection, through the use of a blunt canula directly into one/two quarters, of lactating heifers (first milking) in order to investigate the pathogenesis of mastitis. This may involve taking blood during twice daily milking. Infection studies will last no more than four days (excluding acclimatisation and monitoring pre- and post-study respectively), with animals treated, monitored prior to release from the study; typically two weeks in complete duration.

What are the expected impacts and/or adverse effects for the animals during your project?

The protocol with the highest severity (moderate) is the infection studies, with ~10% of animals expected to be part of studies where this level of severity may be expected. Pain, from the onset of clinical mastitis, is likely to coincide with the study end point, with animals then receiving antibiotic treatment, in addition to pain relief where necessary. Typically animals will be very responsive to treatment, resulting in a very short period (one/two days) before they start to improve.

The majority of animals to be used in these studies will see the animals released back into the herd.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The infection studies uses adult cows only, and is the only protocol with a moderate severity. Of those animals used for infection studies, <15% are likely to experience moderate severity.

All other protocols have a mild severity rating.

Collection of milk aseptically uses adult lactating animals, and when performed competently is a painless procedure that is very similar to the administration of intramammary antibiotics; as such <5% of animals will experience mild severity.

The remaining two protocols (both mild) will use animals across all life stages.

What will happen to animals at the end of this project?

Killed
Kept alive
Used in other projects
Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work aims to investigate the

(i) Immune phenotype of the dairy cow from birth through to adult life

(ii) Age-specific response of key immune cells from dairy calves/cows at key life stages

(iii) Health and physiological responses of lactating dairy cows kept under experimental conditions and infected with microorganisms that cause mastitis.

Immune phenotyping and the comparative immune response of immune cells must be done from the target species. Dairy cows are the subject of, and direct beneficiaries of the research; as such it is not possible to conduct this work without using animals and no other alternatives are suitable. The project aims to further investigate the bovine immune response providing data that will benefit the health and welfare of this key livestock species.

In vitro studies (performed in a lab with no animals) will integrate with the data from in vivo studies; looking at both the individual role of immune cells in the milk and the pathogenesis of the disease in vivo to get an understanding of how the cells interact and the cross talk between them. The work will investigate the healthy immune system and how it correlates with other body systems and immune responses of dairy cows in response to infection in order to optimise the health and welfare of farmed dairy cattle.

Which non-animal alternatives did you consider for use in this project?

None are suitable

Why were they not suitable?

The immune system of a cow is multifactorial in nature, involving communication between various cell types plus the recruitment of other cells to the site of infection, e.g. neutrophils (a specific white blood cell) crossing from the blood stream into the mammary gland/udder. Understanding the role of key cells and their part in the immune response is essential if we are to improve the health of the dairy cow; this cannot be recreated in a non-animal alternative.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each protocol has a proposed number of animals associated with this. Protocol 1 - 60 animals

Protocol 2 - 20 animals

Protocol 3 - 50 animals

Protocol 4 - 60 animals

This estimate assumes that some of the animals used for one protocol (e.g. blood sampling 1 and faecal collection 4) may or will be used in another (e.g. milk sampling 2) as part of the same experiment; this is particularly true of animals that form part of the immune system through the life stages. Equally if correlating microbial carriage (in faeces 4) with response to different microorganisms (through the stimulation of blood cells, 1).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use the NCRs Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design- assistant-eda), thereby improving transparency of our experimental design, and allowing us to share/discuss plans with colleagues and collaborators. This will provide support for randomisation, blinding and sample size calculation, and ensure that confounding variables, such as age and days in milk, are accounted for, and that each experiment will yield robust and reproducible data, ensuring that the data from every animal is utilised to its full potential. Thereby reducing the number of animals required and maximising the information obtained.

In addition:

Protocols 1 and 2: Within animal controls can be used for in vitro cell assays and stimulations, such that a proportion of each cell type from each animal being analysed is always used a control; for example a media-alone control if comparing their response to a particular microorganism grown in that media.

Protocol 3: Once data from a representative control group has been determined for a series of infection studies following strict protocols, this will eliminate the need for additional control groups, thereby reducing animal use. Animals will be randomly assigned to groups where possible/relevant.

Protocol 4: This protocol is around analysing the carriage of microorganisms that cause mastitis with the GI tract, with sampling numbers determined by the exact question being addressed alongside experimental design.

Data will be analysed using appropriate multilevel statistical techniques. For every experiment, we will write an experimental protocol which will include a statement of objective(s), a description of the experiment, covering such matters as experimental procedures, size of experiment (number of groups, number of animals/group, power calculations), how animals were allocated, and experimental material and an outline of the method of analysis of results, statistical tests, significance level and confidence limits plus treatment differences to be estimated.

I confirm that the experiments will be conducted and reported in a manner that will allow publication according to the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The project will ensure that the number of animals used is both minimal and appropriate. Confounding variables will be minimised, for example the use of age-matched, parity (how many times an animal has been in milk)-matched, stage of lactation (lactation is on average 305 days) matched animals where appropriate.

For work requiring blood or milk, any optimisation of laboratory work or pilot studies can utilise cells obtained through a non-ASPA method; e.g. direct from the abattoir and bulk tank milk/milk from the robot sampler.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Dairy cows are the subject of, and direct beneficiaries of the research proposed herein. The effect that a deeper understanding of age-specific immune responses, pathogenesis of key diseases including mastitis and immune phenotypes of dairy cows across the key life stages cannot be assessed in another species. Holstein Friesian cows have been chosen as this breed makes up the majority of the UK dairy herd, meaning the results of this study will be applicable to most animals in the UK.

Throughout the experimental work, many of the animals will not be removed from their normal living environment, with no change to management or social grouping (those used for protocols 1, 2 and 4). Those that are used for infection studies (protocol 3) will be taken from the same social grouping where possible to minimise stress on moving to the containment area - Barn 2, and will undergo a period of acclimatisation to the new environment before the work commences; investigating mastitis in the target species is essential for a further understanding of the pathogenesis of disease.

The experimental work in cattle will involve the predominant microorganism that causes mastitis here in the UK, namely Streptococcus uberis, and this work will use a long established experimental model of infection where the infectious dose using a virulent strain results in reliably repeatable outcomes, including detectable increases in the numbers of cells (cell counts) in the milk by 24hr post-infection. This ‘tried and tested’ approach represents the most refined model to obtain the required scientific data needed to meet the objective. As such, our choice of animals (the breed representative of the UK dairy herd), the use of first time mums/heifers (ensuring no previous cases of disease) and approach (using a well-established model) is the most refined for the intended purpose.

The methods have been refined using the following approaches:

1. To limit disturbance to the animal’s normal regime, many of the animals will not be moved from their normal environment, with blood sampling when animals are temporarily restrained for bleeding, faecal collection or sterile milk collection. Pain relief is not considered necessary for these procedures to be undertaken as it is not required for routine blood sampling, a rectal examination or the removal of milk or infection via a cannula, which is comparable to the application of intramammary antibiotics.

2. The duration of experiments and the number of procedural steps will be limited to the minimum necessary to collect robust data. Bleeding will be no more than twice a week except in the infection studies where blood may be taken at milking, with the smallest gauge needle used to minimise potential for the development of a haematoma (bruising).

3. Where ever possible individual procedural steps will be combined (e.g. blood sampling and infection), to minimise extra stress through handling.We consider three of the four procedures in our protocols to be of mild severity. Bleeding is considered to cause only

mild transient discomfort to the cattle. To minimise any discomfort all staff will be trained and experienced in handling and blood sampling cattle, and the smallest size needle appropriate will be used. Insertion of a cannula to remove milk, when performed by trained and experienced staff, should cause no discomfort as it is directly comparable to the application of intramammary (into the mammary gland) antibiotics. Collection of faecal samples should also cause no discomfort as it is comparable, but far less intrusive, than a rectal examination.

The third protocol, involving the experimental infection or one/two mammary quarters per cow is considered to be moderate in severity because for some of the work will be treating as the signs of clinical mastitis become evident. The model of infection used is very well established, and the timing and nature of clinical signs well documented. Together with the monitoring of somatic cell count (cells in the milk) at each milking (results will be generated almost immediately), we will end experiments and begin treatment based on a wide array of information; more than that available in a typical dairy environment. We may see some hardening and inflammation of the infected part(s) of the udder, but these will be humane end points. Animals will be monitored through scoring of the four quarters that make up the udder, their milk and animal demeanour/behaviour.

In addition, current funding is around the early stages post-infection, therefore these animals will be treated with few if any signs of clinical mastitis.

Why can't you use animals that are less sentient?

Our choice of animals is the breed representative of the UK dairy herd. Some of the proposed work will be looking at the development of their immune system through the life stages with the overall aim of improving their health and welfare through a better understanding of their immune system, pathogenesis of diseases which are relevant from an animal health and welfare perspective. This has the potential to ensure each cow is as healthy as she can be, extending her productive life and therefore reducing the need for increases in cow numbers when increases in productivity can meet demand.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

While three of the four protocols are considered 'mild', each animal will be monitored after a procedure to ensure they are not suffering any adverse effects. To minimise any stress from handling, food 'rewards' may be offered during, for example when using a head yoke to facilitate faecal sampling, or after a procedure, for example following venepuncture. The latter would also allow for monitoring of the site to ensure blood flow had stopped.

For those animals used in protocol 3 (infection studies), allowing for the animals to get used to their new surroundings prior to the study starting is essential to minimise their stress. Typically the animals will be monitored twice a day at time of milking, but as a complete infection (through to humane end point) study end point nears a third monitoring time will be added. Most of the studies planned are around the early stages of disease

and, as such, studies will be ended before this extra monitoring is needed and before many if not all signs of clinical mastitis are observed.

Post-procedure, analgesia/pain relief (in addition to local intramammary therapy used at the study end point plus systemic antibiotics were needed) will be administered if the animal is thought to be showing any signs of pain.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

3Rs resources available at https://www.nc3rs.org.uk/3rs-resources.

Animal Research: Reporting of In Vivo Experiments guidelines available at https://www.nc3rs.org.uk/arrive-guidelines.

The general principles for blood sampling are available, including the safe volumes for a single bleed for cattle - this resource will be regularly reviewed for updates to the guidance.

https://www.nc3rs.org.uk/blood-sampling-general-principles

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I subscribe to monthly updates from the NC3Rs on funding opportunities, events and publications, and have utilised and will continue to utilise the many resources made available by them. Before work commences I will ensure that new advances or recommendations are incorporated into the planning thereby ensuring their timely and effective implementation.

59. Defining osteoarthritis mechanisms

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

osteoarthritis, musculoskeletal health, trauma, ageing

Animal types	Life stages
Mice	embryo, adult, juvenile, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to define novel mechanisms implicated in osteoarthritis (OA) development, as potential targets for therapy.

This will include answering the following questions:

1. How does abnormal extracellular matrix components, such as Fibrillin-1, contribute to OA development?

2. How does growth factor signalling modulate OA progression? (how are growth factors expression regulated in musculoskeletal tissues during development, growth and ageing, and with OA development? How does the extracellular matrix further regulates growth factor activity? (growth factors include TGFβ, CCN family members, BMPs)

3. Which cell subtype contribute to joint health and OA development?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Osteoarthritis (OA) is the commonest chronic disease, affecting almost 9 million people in the UK. The World Health Organisation estimates that 9.6% of men and 18.0% of women aged over 60 already have symptomatic OA, making this disease one of the ten most disabling disease in humans. OA affects joints and include pathological changes and degeneration of articular cartilage, synovial membrane hyperplasia and fibrosis, sclerosis of subchondral bone, osteophyte formation, meniscal and ligament pathologies. These all contribute to pain and restriction in range of movements of the joints. Despite the prevalence of OA, there is currently no disease modifying treatment to slow the progress of the disease. As the aged population is increasing, new treatments for OA will only become more needed.

What outputs do you think you will see at the end of this project?

Outputs will include the generation of new understanding of how the musculoskeletal system forms and functions to allow for healthy joint ageing, and to define mechanisms by which osteoarthritis develops. This new understanding will lead to potential new therapeutic targets to prevent or reduce OA development.

All of these data will also be published in open access journals to ensure these new information are shared equally to other scientists, clinicians and the public.

Who or what will benefit from these outputs, and how?

The main beneficiaries of this applications are the human and animals that develop OA, either due to genetic predisposition to joint degeneration, or following ageing, joint injury or altered mechanical environment.

They will benefit from advances in our knowledge of how to combat this disease and will be the beneficiaries from drugs that are developed to target molecules that we have shown to be critical to the development of the disease.

The other beneficiaries are scientists around the world who are working on this and related diseases, including pharma companies developing drugs that can manipulate some of the molecules that are highlighted in this programme of work

How will you look to maximise the outputs of this work?

We will disseminate our results periodically through presentation and discussion at national and international conferences, as well as by open access publication. In addition, collaborations across the world with expertise in complementary areas of research, or with

specific skills, methods or material of interest will be sought out to complement our work. Conversely, our data and biological material created through this project (such as new transgenic mouse lines) will be shared openly.

Species and numbers of animals expected to be used

- Mice: 9,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in this project are mainly transgenic mice. Mice are genetically tractable mammalian system. We will be using all stages of a mouse lifecourse to be able to answer our questions relating to joint health and osteoarthritis development (a chronic age-related disease).

Throughout the different aims of our project, we will:

1. Define how our cell or molecular target of interest contributes to normal limb development and growth. These events are shown to contribute to OA susceptibility and development.

2. Understand the mechanisms involved in ageing- and trauma-induced OA. For these adult and aged mice will be used.

3. Develop new transgenic lines in order to assess the origin and function of cell subtypes in musculoskeletal tissues across the lifecourse and in response to joint trauma. Development of new transgenic lines involves genetic manipulation in early embryogenesis (either via CRISPR-Cas9 systems or via transgene expression).

Typically, what will be done to an animal used in your project?

Various manipulations will be used depending on the specific question and experimental set up. A few examples as described as follow:

- Creation of new transgenic line. Targeted deletion of a specific genetic segment will first be identified in silico and tested in vitro. New mouse lines for targeted gene manipulation will be created using one-cell stage embryos microinjection of the required components and their transplantation into pseudo-pregnant female mice. A similar method is also used for expression of a specific transgene (for example to follow a cell that may be expressing a specific gene). Pups born will be genotyped and selected as founders for new transgenic lines to be bred. Following appropriate breeding regimes, homozygote KO (both alleles

deleted) lines will generally be used, with a separate WT line (to reduce waste of Heterozygote animals that will not be used).

- Induction of post-traumatic OA (PTOA). Adult mice (usually from 10wks of age) are used. The right knee and ankle are mechanically loaded at specific magnitudes (40 cycles of 9N is sufficient to induce PTOA without ligament rupture) 3 times per week for 2 weeks, under Isoflurane anaesthesia. After a specific period of time, mice are killed via an accepted schedule 1 method and tissues processed for analysis. Non-invasive gait monitoring may be used throughout the experiment, starting 1 week before the first loading episode, followed by weekly measures for a month, and bi-monthly after that. Treatment with either Tamoxifen (for induction of the Cre-recombinase activity in specific transgenic mice) or with a drug of interest will be used when appropriate. Some mice may also be kept in specific cages allowing for voluntary exercise: mice will be individually housed in cages containing wheels; full information including time used on the wheels and distance run are automatically recorded in this system. Control animals in identical cages, but without the wheels, will also be used in parallel.

- Ageing-induced OA. Mice will be left to age up to 72weeks of age. During this time, gait may be assessed on a monthly basis. As above, treatment and voluntary exercise set up may be used.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the transgenic mice that we use and will be generating fall under mild category, because we express a transgene that does not cause harm (for cell tracing). The transgenics in which we will be deleting a gene, such as Fibrillin-1, do show spontaneous limb weakness and increased OA development. These are therefore classified as “moderate". In addition, mouse ageing to 72wks and induction of post-traumatic OA will also be classified as “moderate” due to the development of joint disease. For the joint loading model (used for induction of post-traumatic OA), some possible redness and swelling of their loaded limb is possible in a small proportion of mice, but are generally only seen during the loading period.

These models have now been used extensively and we know they do not affect the ability of the mice to freely move in their cages and access food or water.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: majority of mice being bred.

Moderate: all mice following post-traumatic OA induction; a majority of mice aged over 52wks of age.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to define mechanisms that control joint degeneration in osteoarthritis, which is a slow degenerative disease, that affects various tissues within a joint and is often dependent on the physiological setting of the individual (such as diet, genetic background, lifestyle, etc).

here are 3 main reasons why this cannot be achieved without the use of animals:

- The time needed for the disease and the mechanisms to take place, mean that it is not possible to achieve in vitro (in humans, disease can take place over decades)

- The joint is a 3D system, with important interactions between cells and extracellular matrix, with strong cross talk between tissues that comprise this organ, all of which are highly mechanosensitive. There are currently no in vitro systems that can recapitulate all of these aspects together.

- It is becoming also clearer that other organs may influence disease progression (e.g. immunity, metabolic events, gut flora).

Which non-animal alternatives did you consider for use in this project?

When possible and relevant to the research question, we will use already published datasets to investigate initial results: this may include publicly available multi-OMICS datasets, and in silico models used for promoter-enhancer activities. In addition, when human samples are available, these will be used before investigating the mouse model. This ensures the specific mechanism is a likely target, that can then be confirmed in mouse models.

Before generating any new transgenic mice, we will be searching KOMP and IMPC and any cryo banks of frozen embryos in order not to duplicate the creation of mouse transgenic lines. In addition, we are freezing down our own lines and making them available to the community at large.

Why were they not suitable?

It is well accepted now that multiple cells and organs are involved in OA and studying each separately is not sufficient to replicate the in vivo situation. In addition, each tissue in the joint is rich in a complex extracellular matrix that we have yet to be able to replicate in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in these studies is calculated from power analysis based on similar previous studies. Indeed, taking into account the standard deviations in previous studies and the primary outcome expected in order to reach clinical significance, it has been estimated that n=15 animals per group must be used in OA models.

In addition, we account for breeding issues and the rate of mice of the right genotype being born.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Careful design of the experiments must be implemented to avoid unnecessary use of animals. The use of software such as the NC3Rs Experimental Assistant Design will ensure adequate planning before the start of experiments (including randomisation and blinding when possible).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Appropriate controls are also used: all studies use aged and gender matched WT controls; control for treatment such as loading include sham mice. The contralateral leg is not used as a control as we have shown significant changes in this limb.

Re-use of ex-breeders to the ageing protocol also serves to reduce the number of animals used. These have already been kept for 6 months.

We have extensive experience in the use of mouse models to study our questions, with appropriate skills necessary for the best tissue preparation and analysis. When a method is new and requires practice or refinement, mice that are not used for any experiment (such as mice not needed for experiments from breeding, having the wrong genotype) or tissues not needed from collaborators experiments, will be used for practice.

Finally, we always endeavour to collect and share tissues that are not needed with collaborators or for future potential analysis (for example, collecting spine from transgenic mice that only hind limbs might be initially needed, providing tissues for undergraduate students and providing preliminary data for future grants).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the most appropriate species due to techniques available to modify their genome. In addition, osteoarthritis development in our models is well described and resembles closely human pathology.

Tail tipping for genotyping has long been overtaken by ear clip just after weaning.

The models of OA used in this project are all non-invasive; this in itself is an important refinement for the animal, and also scientifically (limiting confounding factors such as wound healing, infection due to surgery, no micro-surgical skills required). The loading regimen used in this programme was devised to limit severe injuries that have been described and used by other groups (including joint dislocations, bone fractures).

For ageing animals, we have in place a scoring system for welfare assessment and determination of humane end-points for ageing animals.

The use of inducible Cre systems allows to “activate” gene deletion or overexpression to specific ages; thus to avoid any possible effects of developmental issues, activation will be induced after weaning (Fibrillin-1 deletion is embryonic lethal, but animals remain healthy if deletion is achieved after weaning). In addition, targeting to specific tissues can also limit severe detrimental effects on the animals health. For example, fibrillin-1 deletion from the cardiovascular system leads to early death, we therefore use musculoskeletal-specific Cre.

When possible, WT females are used for breeding: this ensures that the females are less likely to encounter issues during pregnancy that may be linked with gene mutation.

Why can’t you use animals that are less sentient?

OA is a slow progressive disease taking months to develop, and seen in adult and old individuals. Therefore adult and aged mice are necessary for some of our aims.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We always try to provide alternatives in route of administration of substances: for example through food or drinking water rather than injection. We provide analgesic following surgery and increased monitoring and weight measurement to ensure animals are recovering following procedures.

Experiments are terminated when new unexpected phenotype occurs and are affecting the animals' welfare, always in consultation with our local vet

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In the scientific community that work on animals , we all follow as the Animals (Scientific Procedures) Act 1986 (ASPA) and guidance. New development that focus on " lessons learnt" disseminated by the NC3R website, LASA recommended maximum volume of administered substances and guidelines for blood removal as well as intervals between imaging sessions (LASA appendices A-C).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As an animal user and a BSU user representative, I receive regular updates from the NC3R through emails and through meetings held locally by the NC3R regional programme manager. In addition, the BSU is very informed and willing to improve animal welfare whenever possible and regularly discusses possible adjustments.

60. Understanding genetic and diet effects on the productivity and environmental footprint of dairy cattle.

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Genetic selection, Feeding systems, Environmental footprint, Microbiomes, Animal health and welfare

Animal types	Life stages
Cattle	juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims are: to identify effects of long-term selection for yields of milk fat and protein on a series of measures of production and technical efficiency of dairy cows; to identify interactions with different feeding/management systems; and describe mechanisms explaining these effects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The study will be an important data resource for development of many components of new breeding indices, underpinning national and international dairy breeding programmes. Genetic selection and altered feeding have both been used to increase the productivity of Holstein cows. These tools will continue to be used as farmers seek to improve health and welfare of cows, as well as reduce the environmental footprint of milk production. This work meets the need to monitor a broad range of effects of genetic selection for milk output (milk production and composition; cow health and welfare; carbon footprint and other environmental consequences). We also need to understand how genetic selection interacts with cow management and feeding, as well as the mechanisms underpinning these effects and interactions.

What outputs do you think you will see at the end of this project?

Database information for use by the animal breeding community to develop new selection indices. The project will provide data from controlled systems which will be used to improve selection in the national herd.

More efficient, resilient and profitable dairy cows. Improved selection will be combined with refinement of systems to improve the sustainability of dairy farming systems with improved animal health and reduced environmental impact.

Publications about the interactions between genetic selection lines and feeding systems.

Publications about the role of microbiomes in mediating the effects and interactions of animal genetics on performance and health of dairy cattle.

Who or what will benefit from these outputs, and how?

All recording from the study will go into a database, which has comprehensive records dating back to the initiation of selection lines. This is an invaluable resource for animal breeders developing new selection lines and needing to understand interactions between different traits. By this means the work contributes directly to genetic advances in the national and international herd, with dissemination through genetic material (semen and embryos). Genetic effects are by nature permanent and additive, so guaranteed in both the short- and longer-terms.

The work also contributes to the design of new dairy production systems to improve the environmental footprint of dairying, as well as the health and welfare of cows. The work to understand these effects through measuring interactions between genetic selection lines and feeding systems, as well as understanding mechanisms behind these effects will mostly be disseminated to the global scientific community through scientific publications. The study also provides an excellent platform for dissemination of new concepts and practices to farmers. Previous examples include dissemination of the use of multi-trait selection indices (PLI), adoption of genomic breeding values, as well as work on body reserves and cow fertility.

How will you look to maximise the outputs of this work?

This work will inform the national breeding programme for Holstein cattle. We are continually looking for collaborations and partners to draw on the study resource for other purposes – utilising other techniques and expertise in the UK and globally to make use of data/samples collected in the study. In a recent example, work looking at lameness by scanning feet of culled cows benefitted from our extensive records of locomotion scores and hoof trimming across the lifetime of the cows.

Species and numbers of animals expected to be used

- Cattle: 600 – animals enter the study as young calves and remain under recording until 3 lactations are complete or they leave the herd for other reasons.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have monitored animals from birth up to the end of the third lactation for many years, providing a unique catalogue of genetic progress. Recording has been focused on the first three lactations, with some monitoring of growth of calves and youngstock. We must continue the recording during lactations 1 to 3 and plan to increase the amount of recording from calves and youngstock, which is a major information gap. This has become possible because of (1) the availability of non-intrusive systems for recording the intakes and weights of calves, and (2) funding to study the establishment and effects of microbiomes at various critical sites of the ruminant body (upper respiratory tract; digestive tract; skin).

Typically, what will be done to an animal used in your project?

We will continue to maintain the study herd with approx. 200 milking cows plus the calves and youngstock replacements required to maintain the herd. We will continue the two selection lines (selected for either national average or highest possible fat + protein yield). These cows will be managed on one of two feeding systems in a 2 x 2 factorial arrangement of genetic lines and diets. One feeding management will be close to typical moderate energy feeding levels achieved on many commercial farms, whilst the other will feed higher levels of concentrates typical of the most intensive commercial systems. We will incorporate consideration of the embedded carbon footprint of diets into this design.

Ongoing recording for milking cows will include: feed intakes, water consumption, milk yield and composition, weight and body condition score, locomotion scores, oestrus and fertility records, activity monitored using commercial animal-mounted sensors, health events and veterinary treatments.

To avoid compromising the genetic experiment by treating different genetic lines differently, we will ensure that any procedures that involve handling/sampling animals, as opposed to non-intrusive monitoring, will be conducted on all animals within a cohort:

- For all animals - blood samples will be taken from a superficial vein, according to Home Office guidance on volumes – aliquots will be used for genotyping and others archived.

- For one cohort of heifer calves (100 calves over a 12-month period) we will also collect samples (faeces; swabbing of upper respiratory tract; naso-gastric or oro-gastric sampling of rumen contents; swabbing of inguinal skin) for microbiome and 'omics' analysis according to the following plan:

- At birth, 1 week and 3 weeks (upper respiratory tract and faeces)

- 2 months and 8 months (all sites)

- At mating, before calving and 30 and 100 days in milk (rumen and skin sites).

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are managed under normal farm conditions with no planned restriction on availability of feed or water. We will monitor the natural incidence of disease under normal farm conditions, but nothing in the study is designed to cause disease.

Animals may experience some mild transient pain during blood sampling.

Microbiome sampling procedures and associated handling may cause minor discomfort and short-lived anxiety. Our animal handling facilities and staff training in handling and sampling of animals is designed to minimise distress. We will continually investigate and utilise best practice in the collection of samples in the least intrusive way. Naso-gastric or oro-gastric sampling from young cattle is a new technique for us and we will seek advice from project partners who have previous experience. Animals which show adverse reactions to sampling procedures will be withdrawn from the study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not expect severity to exceed 'mild' for any animal.

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The basis of this research is to collect and analyse data from actual dairy farming systems, these data cannot be obtained without animals in the different systems to provide the background data. These data will then be used to develop and improve existing models to obtain modelled outputs from a range of similar systems with different milk production levels. Animals are also required to link the genomic information with phenotypic information on animal performance, intake and health, as well as with the development and maintenance of microbiomes in the digestive tract, respiratory tract and skin surfaces. Alternatives to blood sampling to obtain genetic information are continually reviewed but to date no suitable alternative has been found to provide accurate longitudinal data.

Which non-animal alternatives did you consider for use in this project?

Modelling

Why were they not suitable?

Cow genotypes continue to change and so we need to maintain this monitoring of genetic lines to keep information relevant.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

With approximately 200 milking cows on the study, we expect around 100 heifer calves each year (5 years) and have previously reared all as potential replacements. With the availability of sexed semen, this calculation will be reviewed – we may have many more heifer calves born than are needed to provide enough replacements and, in that situation, will select a proportion for the study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Each lactating group (system x genetic merit) will consist of 50 cows, the group size will be kept at approximately 50 by replacing animals which are either culled, in normal farm practice or are replaced at the end of 3rd lactation. At the end of the third lactation the cows are returned to the main herd.

Keeping cows on the study for 3 lactations is a balance to provide enough data for the systems component of the study and allow for a controlled entry of animals with improved genetic merit. Previous systems work has shown that 50 animals is the minimum to represent a farm system, current average herd size is 180 cows. During the 3rd lactation there is an average of 10 animals / system which in discussion with a statistician was considered to be the minimum number to obtain reliable data, especially on health and fertility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. Our database contains comprehensive data from many years of work with these selection lines. It ensures that the animal breeding community can make use of these data.

2. We endeavour to share samples from these animals for use in projects designed by others – recent examples include lameness work using feet from cull cows; provision of milk samples for work on immune function and micronutrients; provision of milk samples for commercial development of calibrations for productivity and health traits using infra-red milk analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Sampling from the digestive tract involves per rectum sampling of faeces – we need to be confident that faeces were from a particular animal and not contaminated so cannot collect from the pen floor.

Sampling of rumen contents will use a naso-gastric or oro-gastric sampling tube method, which avoids the need for rumen fistulation. We cannot collect these samples after slaughter because we need sequential samples from the same animal, and also need subsequent health and performance records in order to explore relationships.

Why can’t you use animals that are less sentient?

Our research questions are specific to dairy cattle of specific ages – establishment and maintenance of microbiomes in calves; effects of genetic and diet on production and health during the transition period and established lactation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Having a dairy systems approach is integral to the study as the scientific questions relate to dairy production. All animals will be kept in designated Home Office compliant buildings with individual feeding, however the day-to-day management routines are similar to normal farm practice and veterinary attention will be sought for any animals which are ill.

If veterinary advice is that the animals need individual attention, they will be moved to a suitable area away from the main study group. If only for a short time (<4 weeks) then they will return to the study group. If removed for more than 4 weeks, or veterinary surgeon advises that they should not return to the study group then the animal will be permanently taken off the study. If >10% of the animals are removed from the study at any one time, the whole system will be reviewed and amendments made.

Animals which become distressed during any sampling procedures will be taken off study, under the guidance of the NACWO.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Home Office Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes.

Published guidance on blood sampling volumes, such as: Wolfensohn, S. and Lloyd, M. (2003). Handbook of Laboratory Animal Management and Welfare, 3rd Edition.

ARRIVE Guidelines (Animal Research: Reporting of In Vivo Experiments).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through ongoing literature review, we will maintain awareness of less-invasive techniques to study rumen function (such as analysis of urine, milk or breath)..

61. Investigation of drug resistance mechanisms in haematological malignancies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Leukaemic stem cells, Therapy resistance, Autophagy, Metabolism

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall purpose of this project is to gain a greater knowledge of drug resistance mechanisms that occur in the different types of leukaemia. We will investigate this using cell culture and animal experiments. Leukaemia describes four main subtypes, acute lymphoblastic leukaemia (ALL), chronic lymphoblastic leukaemia (CLL), acute myeloid leukaemia (AML) and chronic myeloid leukaemia (CML), as well as a number of less common types. Although we focus on targeting stem cells in CML, we have crossover projects in other leukaemia types, such as Philadelphia chromosome (Ph)-negative myeloproliferative neoplasm (MPN), AML and ALL. Some leukaemia subtypes behave similarly and research in one subtype naturally crosses over into the other subtypes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite decades of research and increased knowledge about how blood is made, blood cancers remain generally incurable. Between 2015 and 2017 there were 10,084 recorded new cases of leukaemia in the UK, and there has been a 17% increase in all types of leukaemia (AML, ALL, CML, CLL) since the early 1990s (CRUK statistics). Leukaemias are organised in a hierarchy (a pyramid- structure) with leukaemic stem cells (LSCs) at its top. These "originator" cells, called stem cells, are both in healthy individuals and in people with leukaemia responsible for the production of blood cells. However, only in people with leukaemia do the blood stem cells have defects. The LSCs are of interest since current drugs do not target them. New ways to study LSC biology are urgently needed which will help develop improved treatments.

What outputs do you think you will see at the end of this project?

Throughout these studies we will use animal experiments in combination with computer modelling and computer assisted drug discovery to create information libraries from leukaemia stem cells that are resistant to drug treatment. We will work closely with the pharmaceutical industry with the aim of:

Generating data leading to a better understanding of drug mechanisms in leukaemia cells to aid in the discovery of new drug targets.

Discovering new drug targets and/or novel drug combinations with existing therapies, which will assist doctors in the delivery of rationally designed clinical trials.

We aim to publish a number of scientific papers in open-access, high impact journals and present our findings at key conferences and workshops which will allow us to communicate our findings to the wider community.

Who or what will benefit from these outputs, and how?

Prior to this project we performed a drug discovery project on leukaemia cells in the lab looking for new drugs against both AML and CML cell lines. This project gave us a hit list of potential new drug candidates to explore more. The follow-up of some of these potential candidates, will be a large part of this project.

Short term benefits

A better understanding of leukaemia and the related diseases in this study. This will help both scientists in academia as well as in the pharmaceutical industry. Our research will be

shared globally in publications, conferences, seminars, the press, and social media that attract clinicians, scientists, nurses, allied health professionals.

Medium term benefits

Understanding the inner workings in leukaemia disease in its cell environment as well as in the whole animal will give us a more complete view of the disease. This will allow the creation of drugs that have a greater effect on diseased cells while having less impact on normal blood cells than current drugs.

Long Term Benefits

This project is using mouse models, human cell lines and primary patient samples, therefore the results will be of clinical relevance, so clinical trial organisations will benefit from the findings in our study.

Patients may benefit from appropriately tailored clinical trial design and drugs which are explored and suggested from our studies. Health organisations such as NHS and National Institute for Clinical Excellence may benefit from saving in the costs of cancer treatments

How will you look to maximise the outputs of this work?

The aim is to make all our information available to the wider community, both scientific and non- scientific via relevant publications. We also have ongoing collaborations with industry.

Species and numbers of animals expected to be used

- Mice: 32,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All the various mouse models were developed to allow investigation of the blood system in the animal, in disease, as well as the normal state. Blood cancers, such as leukaemia, are so complex that mimicking this in cells in the lab alone is unfortunately not sufficient. Most of these experiments will be done on adult mice, as they have a more fully developed blood system. AML and CML generally happen in adults, and therefore adult mice will be more appropriate.

Typically, what will be done to an animal used in your project?

The project covers a broad range of techniques, but for 80% of the mice the process will be to irradiate them, inoculate (inject) them with either human or mouse leukaemic blood (stem) cells and follow how the disease gets worse over time by e.g., microscopy. Animals

will be routinely monitored to assess disease worsening, and 50% of the mice will receive drug treatment to assess the drug effects on the disease. Drug treatment will be administered by a combination of oral gavage, injection or by surgical implantation of a minipump for up to 4 weeks. Animals will be on study for up to 20 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

The health of animals will be routinely checked using a health scoring chart to make sure they do not get too ill and also for robust analysis of the mice across different cohorts (mouse groups).

Irradiation (adult mice only):

Irradiated mice will be more likely to get an infection after irradiation, because of their compromised immune system. They will be kept in special (barrier) caging and handled with clean (sterile) precautions to reduce the risk of infection. Advice will also be sought from the Named Veterinary Surgeon regarding any treatment required.

Irradiated mice will likely show weight loss and they will get soft foods to stop weight loss, as well as antibiotics to pre-empt infections.

Administration of cells or media:

The procedure will conform to current guidelines when administering substances (e.g. www.nc3rs.org.uk).

There is a risk that the mouse may develop an infection because of being inoculated (injected) with cells, particularly if the mouse has less ability to fight infections. This risk will be reduced by the clean (sterile) preparation of the cells and media and by regular, close monitoring of animals after injection. If animals show signs of ill health or distress more frequent monitoring will be introduced, advice will be sought from the Named Veterinary Surgeon if necessary, or the mouse will be humanely killed.

Injections carry a small risk of organ damage and peritonitis, and can also carry the risk of thrombosis and phlebitis. These risks can be minimised by using experienced licensees to perform these tasks. Mice observed to be experiencing discomfort as outlined will be humanely killed.

Surgery and Anaesthesia (General adverse effects):

Surgical procedures will be carried out aseptically. In the uncommon event of post-operative complications, animals will be killed unless, in the opinion of the Named Veterinary Surgeon, such complications can be treated.

All animals are expected to make a rapid recovery from the anaesthetic within two hours. Uncommonly animals that do not recover or show signs of pain, distress or obvious ill

health will be humanely killed unless a programme of enhanced monitoring and care is instituted, and the animal fully recovers.

Any animal not fully recovered from the surgery within 24 hours (eating, drinking and return to normal behaviour) will be humanely killed.

In each experiment, it is always our aim to cause the least severity and stress possible for the animals while still gathering meaningful data.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity (causing no more than momentary discomfort) - 60%

Moderate severity (discomfort lasting no longer than 72 hours on any occasion) - 40%

What will happen to animals at the end of this project?

Killed

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although our initial work will always be done using cell lines in the lab (cell-based experiments), there is a limit to how well you can replicate the cell and disease response to e.g., chemotherapy, in a petri dish. This is particularly true for something as complex as the bone marrow (the home of leukaemia cells), where many different cells interact and work together. You cannot mimic this completely outside a living organism.

Which non-animal alternatives did you consider for use in this project?

There will always be a great number of e.g., toxicity studies and other drug treatment studies done in the lab with cells grown in culture, before moving on to animal experiments. If possible, we will use cell line and primary cell-based alternatives to animal testing. Our lab works with human patient cells from consenting donors to further test our research questions and drugs. This also reduces the number of mice experiments needed. As paraphrased from Duarte et al. 2018* “The precise composition and function of the bone marrow niche is still under intense investigation. It is thought to be regulated by a complex array of cell populations, including arteriolar and sinusoidal endothelial cells,

mesenchymal stem cells, perivascular stromal cells, osteoblasts, sympathetic neurons, non-myelinating Schwann cells, adipocytes, megakaryocytes and regulatory T cells".

This gives a good idea just how challenging it is to replicate this cell interplay in a lab system. People have attempted it with some measure of success (see e.g., Munaka et al. (2011) "A MICROFLUIDIC DEVICE TO MIMIC THE BONE MARROW MICROENVIRONMENT: REAL-TIME OBSERVATION OF

THE LEUKEMIC CELL BEHAVIOR" (conference abstract)). However, this is very challenging to reproduce, and even lower throughput than mouse experiments. In future even at its most advanced microfluidic devices are still highly unlikely to encompass every single cell type found in the actual leukaemic environment in the living organism. Nevertheless, we are continuously searching for viable lab-based alternatives that could approximate the in vivo situation sufficiently for our experiments.

*(The interplay of leukemia cells and the bone marrow microenvironment; Blood 131(14) Duarte, Hawkins and Lo Celso (2018))

Why were they not suitable?

Growth conditions in the body play a critical role in disease in both leukaemia and solid tumours. With the technology currently available to us we cannot duplicate these growth conditions in a petri dish in the lab.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is the estimated total use for the 5 years that the project will run. Many animals are born with the incorrect genetic make-up for our research. This is one of the reasons for the large number of animals estimated, many of the animals will not undergo any procedures other than testing their suitability for our research. Our breeding colonies are monitored constantly and tailored to meet our experimental needs. Where possible we will have colonies that are homozygous for the alleles required for our research, thus minimising excess animals. We also try to minimise an excess of animals minimising numbers of controls. As not all mice in our experiments will develop disease, we may need to repeat some procedures and for this reason we estimate larger animal numbers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We discussed our experimental design with bio-informaticians, including the AWERB committee bio- statistician. Using specific software to assess mouse number requirements for our experiments. We are confident we are using an appropriate number of animals in each experiment. Blood sampling and non- invasive imaging techniques (for example MRI) will be carried out for studies to obtain as much data from a smaller number of animals. Sperm/embryos will be frozen from lines not immediately required for scientific studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Ongoing monitoring of a given cohort (mouse group) allows experiments to be stopped as soon as there is enough data (information), thus minimising suffering whilst obtaining meaningful and publishable results. When possible, control mouse cohorts can be shared across studies, to reduce mouse numbers required for individual studies. Blood sampling and non-invasive imaging techniques will be carried out for studies to obtain as much data smaller number of animals. Pilot experiments will be used to e.g., assess maximum tolerance and guide further experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a variety of mouse models in this project (mentioned in detail in protocol 3), all of which are specifically developed to allow better investigation of the disease, by being e.g., more susceptible to the human disease or have fluorescent markers that allow more straightforward investigation of processes within the organ(s) of interest. For example, NRGW-41 which has been reported to significantly enhance the percentage engraftment of human HSCs in the absence of irradiation. GFP-LC3 mice have fluorescent markers, which removes the need for administration of fluorescent tracers. The strains we will use allow more straightforward investigation of processes within the organ(s) of interest without the need for additional procedures. All these models were developed to cause the least pain, suffering or distress possible while providing us with valuable data on the disease of interest.

Why can’t you use animals that are less sentient?

Mice are still sufficiently closely related to human beings to adequately represent the human condition, whereas other model organisms more distantly related would not duplicate the disease sufficiently (on a genetic and phenotypic level). Most of these experiments will be done on adult mice, as they have a more fully developed blood system. AML and CML generally happen in adults, and therefore adult mice will be more appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We always refer to the literature for adverse effects of a new chemical or drug and when a cohort (mouse group) is given a treatment for the first time, studies with a pilot-sized group (n=3-6) are carried out and closely monitored before extending to a larger cohort.

Animal monitoring, post-operative care, and pain management are an important part of all the procedures within the project. We use genetically engineered mice which exhibit the same genetic mutations in human cancer. None of our protocols exceed a moderate severity level. To minimise suffering all mice on procedure will be frequently monitored and humanely culled when showing signs of worsened health or other specified end-point is reached. All researchers working on this project will have specific training for each of our models used. All animals are housed in a dedicated facility proactive with environmental enrichment and the use of anaesthesia and analgesia under guidance from the vet is routine practice. Post-mortems are carried out to investigate any unexpected deaths.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all studies we will refer to the Guidelines for the welfare and use of animals in cancer research (Workman et al, 2010) and ensure best working practice. We consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All our work is in observance to governmental guidelines and the facility we perform our experiments at is under constant scrutiny (by e.g., Named Veterinary Surgeons etc.) with the intent to adhere to newer guidance when these are published. We are also actively involved in the university's 3Rs Day, and there are a number of Culture of Care events organized throughout the year to ensure everyone stays up to date with current guidelines.

62. Imaging and treating tumours

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Detection, Hyperthermia, Imaging, Therapy

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to develop safer, more effective, solutions for the early detection and treatment of cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are several cancer types where existing medical treatments are not very effective. This may be due to inability to detect them early enough, surgical interventions having low success rates, or drug safety concerns limiting the dose that can be administered. Improvements in these areas have the potential to significantly increase patient survival and quality of life.

Nanoparticles are tiny spheres (~50-300 nm in diameter) made of an inert or biocompatible material. Being significantly larger than most drug molecules, their circulation and distribution behaviour in the body is very different. In particular they tend to be taken up and then retained by tumours. If an anti- cancer drug is attached to a nanoparticle it can be delivered to tumours far more effectively and specifically than otherwise. This useful property can be enhanced by engineering the nanoparticles' chemistry or by the application of external 'triggers' that change nanoparticle or tumour behaviour.

Various forms of clinical imaging are commonly used to diagnose cancer and examples include CT and MRI. It is possible to attach imaging 'labels' to nanoparticles, which enhance their contrast against normal tissues. This allows the tracking of nanoparticles in the body, gives information on where they go and when.

If nanoparticles carry both a drug and an imaging label, they are described as theranostic (therapeutic + diagnostic). This idea has already demonstrated huge potential to enhance the effectiveness of existing drug treatments. But to be of value to patients, these 'proof-of-principle' findings (often discovered in vitro) need to be developed and translated to the clinic. This includes testing against difficult to detect and treat cancer types, optimisation of methods and technologies, and assessing the safety, efficacy, and cost of the new approach.

These technologies promise to detect then treat cancers early in their development and hold the potential to save millions of lives. In our project we will development, test, and assess the efficacy of some of the best of these novel approaches.

What outputs do you think you will see at the end of this project?

In this project the team will develop novel healthcare technologies that will benefit humanity. Our aim is to develop and promote safe nanotechnologies that allow for early cancer detection, and then combine them with sonic or microwave activation technologies that are non-invasive, applied externally, and highly controllable. This allows for specifically tumour targeted drug delivery, reducing the amount of (often highly toxic) anti-cancer drug in blood circulation. Our studies are designed to collect new information and explore new materials that respond to ultrasound and to microwave energies, allowing the design of novel protocols to introduce these technologies to the clinic. The project will dissipate this new knowledge in the form of publications, communications in meetings, and collaboration with other researchers, as well as in the development of products that can be tested and used in humans.

Who or what will benefit from these outputs, and how?

The long-term beneficiary of this project are human patients with difficult-to-detect or difficult-to-treat cancers (for example, pancreas, intestine/colon, or brain. The team has developed technologies that have the potential to be rapidly translated and become products. During the last years, the team has demonstrated combinations of materials and

imaging/intervention technologies that have shown proof of therapeutic efficiency in xenograft models. In this project the team will focus to translate these findings to the clinic. The team collaborates with oncologists, radiologists, and equipment providers to rapidly bring these safe and efficient treatments to human use.

How will you look to maximise the outputs of this work?

The team is collaborating with radiologists, clinical oncologists, specialists in pancreatic cancer, brain oncologists, as well as paediatric brain tumour specialists. These clinicians have approached the team to collaborate and provide advice for the translation to the clinical phase. The team has published a book and will progress to organising meetings about these non-invasive treatments to communicate the findings to oncologists and publish in high impact factor journals. The team will make all findings from this project available to the scientific community and to patients' groups.

Species and numbers of animals expected to be used

- Mice: 2200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project will use adult mice for the tumour models. These mice will be either genetically altered to develop cancer or will be inoculated with cancerous material which develops into tumours in the subcutaneous fat. This is the only experimental approach that can realistically mimic tumours and their vasculature biology. The developed nanoparticles are generally administered into the blood stream and require a fully functional tumour blood vasculature in order to reach the cancer cells. Assessing the effect of applied interventions also requires an experimental model that is as close as possible to human cancers. No other models are currently available to perform this analysis and lower species (such as fish) are inappropriate for modelling a human disease.

The adult mice are used as they can develop tumours that reach a minimum size that can be used to assess therapeutic effect. Younger animals would have to carry a disproportional to their size tumour affecting their wellbeing

Typically, what will be done to an animal used in your project?

The animals used in this project are either: i) unmodified for use as reference/controls; ii) genetically altered to develop precancerous lesions; or iii) injected with cells that develop tumours subcutaneously. The animals will undergo a series of treatments which may include one or more repeats of: injection or oral administration of drugs or labelling materials, blood sampling, bioimaging using a variety of approaches (e.g., near infrared

florescence or MRI), and the case of subcutaneous tumour models, the application of non-ionising, non-invasive radiation provided by focused ultrasound or microwave antennas to affect the tumour response to the injected drugs. The mice will be carefully monitored to track their health, body weight, and (where possible) the size and conditions of tumours. The studies would normally continue until either a series of images/samples was complete, or a tumour has reached a pre-determined maximum size. The time frames of this are dependent on the aggressiveness of the tumour model but we have previously noted that treated animals can show inhibition of the tumour growth for 2 months (compared to 14 days of untreated animals).

What are the expected impacts and/or adverse effects for the animals during your project?

i) Genetically altered mice. These have been genetically modified to develop intestinal polyps. These need to develop to stage where the models are a reasonable mimic of the human lesion stage and so some animals may develop pain, weight loss, anaemia, or other clinical signs over a period of up to 5 days. These mice will be closely monitored and would be humanely killed they start to show signs beyond defined humane endpoints.

ii) Subcutaneously induced tumours and administration of anticancer agents or other therapeutics. The treatments may cause some weight loss (about 10-15%) for about 3 days post-treatment. Inoculated tumours will grow to certain maximum size (12 mm diameter over about 2-8 weeks) before termination and are not expected to cause any significant behaviour disruption or pain.

iii) Application of ultrasound or microwaves. A small percentage (5%) of animals may show localised swelling/inflammation, or mild pain for about 3 days after intervention. This will be controlled by the administration of analgesics.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

i) Mice that develop polyps will undergo protocols of breeding, induction with tamoxifen, and injection of substances. Protocols are of mild to moderate severity (50% of animals). From these 80% will experience mild and 20% moderate.

ii) Mice that will be inoculated with tumours subcutaneously will undergo protocols of treatment with substances and intervention. This is of moderate severity (75% of animals).

iii) Control mice will undergo protocols of mild severity, generally injection with substances and imaging.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To achieve the aim of the project, animals that develop tumours are required. Much of the mechanism of action is based on biology of tumour vascularity and how it influences nanomaterial distribution and responds to external interventions. It is not possible to effectively study tumour growth rate inhibitions, the uptake and display of labelled materials by intestinal polyps, or the effects of hyperthermia or cavitation on tumour uptake, outside of a living animal and there is no experimental model now that accurately mimics the tumour and vasculature.

Which non-animal alternatives did you consider for use in this project?

The team has developed an in vitro blood brain barrier glioma model and are currently investigating pancreatic tumour organoids to test some of the parameters (e.g., efficacy of drug when it is released from the nanocarriers). The team is also exploring in silico computational methods to estimate the nanoparticle concentration in the tumour vasculature.

Why were they not suitable?

In vitro methods currently lack formed blood vessels and hence the element of nanoparticle extravasation to the tumour, and its modification due to external intervention (such as hyperthermia or cavitation). This is a key mechanism we explore.

In silico methods are still very early stage. Since the interactions between tumour vasculature and applied interventions are not yet well understood, they cannot yet be realistically modelled.

These alternatives provide useful pilot or supporting information but are not yet a replacement for animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The team has worked for more than 10 years with similar projects using the subcutaneous tumour model with techniques like ultrasound and microwave, as well as imaging and labelling of tumours.

We have extensive experience using these subcutaneous tumours and we estimate this number based on previous experience.

We are going to experiment with a GA mouse and for this we liaised with experts holding project licenses using this model and we assessed the breeding and the genotyped animals that will enter the protocols.

We have estimated the experimental groups that we will investigate in the next few years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the Experimental Design Assistant based on data we collect using similar experimental models or from published literature results.

We have discussed the hypotheses and the aims of the experiments and we introduced designs that are well aligned with the experiments we will perform.

Imaging is used for all mice bearing subcutaneous tumours so each animal is used for multiple time points and used as its own negative control (imaging with no treatment).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding of genetically altered strains will be carefully managed to ensure sufficient but not excessive numbers of animals are bred for use on subsequent protocols, whilst ensuring no genetic drift within the colonies.

Where possible, we will use the same animal to assess multiple scientific endpoints where it is compatible with good animal welfare in the context of the overall animal experience (e.g. use same animal for longitudinal assessment of tumour growth).

Pilot studies using limited number of mice to determine feasibility of new experiments will be carefully planned and performed.

We will have detailed consultation with others who have used the relevant protocols.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

1. Genetically altered mice that develop polyps. These models have been selected as sufficiently accurate mimics of human disease and there are no good alternatives to their use. Close monitoring of tumour development will ensure animal suffering is kept to a minimum.

ii) Mice that bear tumours subcutaneously. These models are a widely accepted approach for assessing and comparing the anti-tumour activity of different treatment protocols while balancing good mimicry of human disease with minimised animal suffering. The predetermined endpoints (20 % weight loss; 12 mm maximum tumour size) have been selected from experience and consultation points at which few animals can be expected to show significant adverse effects.

iii) Unmodified mice as controls. These are likely to show little adverse effects but are essential to allow proper comparison of the treated tumour groups.

Why can't you use animals that are less sentient?

The team focuses on the development of future products that can translated to the clinic. This requires study using models that are an acceptably realistic mimic of human disease, including the interaction of tumour biology with externally applied interventions. Less sentient species are not suitable models, and we require the use of mammals of a size compatible with pre-clinical imaging and intervention equipment. Adult mice are the best alignment with these requirements. Terminally anesthetised animals cannot be used in this project as the effects of the treatment will occur some days afterwards.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The team is closely monitoring animals post treatment - normally monitored once per day by the team and once per day by the staff at the facility. This intense monitoring allows noting down any adverse effect and these will be tracked using scoring sheets.

We follow the NC3R instructions and training for recognition and prevention of pain suffering and distress and will introduce a score sheet to monitor their wellbeing.

Non-aversive handling methods using tubes e.g. plexiglass will be used .

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow advice from the Br J Cancer Guidelines for the welfare and use of animals in cancer research. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.

The NC3R welfare assessment EU5 will be followed by all members of the team and refreshers will be compulsory before experiments.

The website on mouse welfare will be used throughout the experiments http://www.mousewelfareterms.org/doku.php

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The team is following the NC3R webpage routinely and they receive notifications from the related social media. The team is regularly consulting with the experts in the College AWERB and NC3R. The team is also following news on organoids (and similar models) and is in close collaboration with experts that use in silico experimental design.

63. Novel nanomaterials as delivery vehicles for drug and cellular therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

grafting, nanomaterials, biodistribution, anti-microbials, cancer

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult
Chicken	embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Nanomaterials have been recognised as superior vehicles for small molecule drug delivery and ideal matrices for cell transplantation. They open up optimal temporal and positional control of drug or cell therapy application and, thus, improve patient treatment. Here, we aim to understand the basic properties of novel nanomaterials in animal models heavily utilised in biomedical drug discovery to help their development and demonstrate their potential for translation in clinical development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Virtually all drugs have not only desired therapeutic effects, but also unwanted side-effects that are due to their off-target activity or toxicity, e.g., through metabolites. This makes it essential to keep their levels in the body within a defined therapeutic window, which might be larger or smaller depending on the specific drug's properties. Especially for drugs with a small therapeutic window or the need for very long treatment periods this might present a significant challenge to treatment success; may that be via reducing toxicity or improving pharmacokinetics as well as enhancing ease of application for the patient. Thus, finding better ways to apply current and future treatments is of high medical importance and has the potential to generate more effective and less toxic treatments, which will ultimately benefit human health.

Moreover, other therapeutics, such as biologics or cellular (auto) transplantation, might necessitate "packaging" solutions that allow delivery to the body in the first place. Recently, this has been demonstrated for the delivery of an RNA vaccine by others, but is also applicable for providing a cellular matrix for transplanting cells such as fat cells for restorative surgery.

Of note, such improved delivery forms can also benefit basic research and animal welfare, for example, through improving experimental drug delivery schedules to refine the routes or frequency of application. This approach can be utilised in various contexts, e.g., when delivering tamoxifen to induce transgene expression in mouse lines, a widely used method, or substrates for bio-imaging. A thorough understanding of less invasive methods compared to repeated oral gavage or injections has the potential to not only change the animals' experience but also make experiments more reliable and less variable.

In summary, it is important to characterise, understand and then expand the current toolset of nanomaterials. This application aims to address the current gap in knowledge and systematically improve our understanding.

What outputs do you think you will see at the end of this project?

A primary output of this project will be an increased understanding of the "structure activity relationship" of novel nanomaterials with their function but also with their behaviour in vivo. This will be disseminated in to the various academic and medical communities in form of publications and conference presentations of the groups involved in this project. Further outputs might include patentable nanomaterials for various purposes. Specifically, we expect to have screened and developed a number of novel nanoparticle entities to deliver drugs, e.g., for cancer chemotherapy or antibiotics, and have secured follow on funding to develop these towards clinical applications.

Furthermore, a number of Hydrogels will be tested with the expectation to be able to move effective formulations towards clinical development. Lastly, we expect to be able to deliver proof-of-concept evidence for transdermal delivery patches for 1-2 chemicals often used in experimental animal studies, e.g., to trigger transgene expression or for imaging purposes.

In addition to developing new health-care technology, we will endeavour to publish the novel materials and their properties in appropriate biomedical and chemistry focussed peer-reviewed journals. We expect that multiple publications will arise from each part of the project, not only reporting on the materials themselves, but also on the underlying, fundamental effects and interactions with physiological processes. Lastly, we expect to report on novel methodology enabled by transdermal delivery of compound to experimental animal models.

Who or what will benefit from these outputs, and how?

In the short-term (before project end or shortly thereafter), we hope to have established a pool of candidates that can be taken forward for further efficacy testing in disease models of cancer and bacterial infections, which we need to establish the pharmacology and toxicology parameters for in the first place.

In the long-term, we expect a real health benefit for the human population from the ability to deliver drugs and embed transplantation material in nanostructured materials. Our project would have at least delivered some of the vital information on how these materials behave in a biological context and at best pushed one or a number of them to the clinic for a direct patient benefit. In addition, we feel there is a good possibility that animal welfare could also benefit from our research into transdermal drug delivery patches for experimental animals.

How will you look to maximise the outputs of this work?

We have an extensive network of collaborators inside the UK and beyond that will benefit from the gain in knowledge in general and by sharing reagents and results. However, a number of current and future collaborators in the research organisation will also be benefiting from the knowledge and methodology base build in this project and will further develop. A number of proposals are under development that would further benefit from the knowledge we will acquire.

Part of the project is to develop further the transdermal delivery of substances in rodent and chick chorio-allantoic membrane (CAM) experimental models, which will also be disseminated through contacts we have established, for example, with another large contract research animal facility in the UK. Such largely non-invasive methods might hold a great advantage for recurrent doing of chemicals via oral gavage or other injection routes.

Species and numbers of animals expected to be used

- Mice: 3600
- Rats: 240
- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents (Mice and Rats)

In line with current practice, this project will use adult mice for the majority of the in vivo characterisation work and only choose rats where prior models have established an overwhelming consensus to do so, or so far unforeseen experimental difficulties necessitate this. Both species have been extensively studied in their physiological parameters and reactions to xenobiotics in general as well as nanomaterial in particular. In addition, these rodents have been well established as models which lead to conclusions relevant to humans, and there are a number of transgenic animals available that will enable a more detailed refined experimental approach.

Chicken (Embryos)

The chick chorio-allantoic membrane (CAM) model is well established model for tumour angiogenesis that has received renewed attention more recently as an ethically advantageous alternative to rodent tumour models. We are using it here to pre-screen compounds and nanomaterials, which will reduce the number of more sentient rodents to be used. It is thought that the chick CAM assay is painless, as the CAM is not innervated by the embryo and the early developmental stage.

Typically, what will be done to an animal used in your project?

Rodents (Mice and Rats)

A subgroup of transgenic animals will be used for breeding purposes or humanely killed only to supply cells or organs for analysis and transplant material.

A further subgroup of animals will be used for subcutaneous implantation of cells with or without a nanomaterial as extracellular matrix, and the growth of such cells will be monitored over time using imaging and/or callipers. The animals will then be killed, and tissues are taken for further analysis. We might use syngenic wild-type lines or immunocompromised animals for transplantation of human cells.

The majority of animals will be used for administration once or multiple times of nanomaterial and then imaged and/or sacrificed for further quantitation of the nanomaterials or their effects on the rodent.

Administration routes can be nasal, intraperitoneal, intravenous, oral or transcutaneous. A small portion of these animals will be grafted with subcutaneous tumours before the nanomaterials will be injected to study the uptake of these materials in tumour tissue.

Chicken (Embryos)

The fertilised chicken eggs will be allowed to develop for a maximum of 18 days (3 days before hatching), at which point the embryos will be euthanised using a Schedule 1 method. At specific points during the development, we will open the egg shell or completely remove the egg shell to graft tumour material or cells with or without a matrix. The resulting tumours will be imaged and or treated with formulations of drugs to study their efficacy on limiting tumour growth or metastasis.

What are the expected impacts and/or adverse effects for the animals during your project?

Rodents (Mice and Rats)

Most common will be transient adverse effects from injections or inoculation with tumour cells or other graft material. These might lead to pain at the injection site or some skin irritation but will only be of short duration. Further, only short-lasting effects on the general wellbeing might stem from general anaesthesia used for tumour inoculations, grafting and imaging. Orthotopic tumour inoculation requires a small (<1cm) incision that is associated with pain during the recovery period, and a small chance of wound breakdown or infection.

Moreover, there might be direct and unexpected toxic effects of the tested nanomaterials that impact on the well-being of the animal and would lead to Schedule 1 killing.

Chicken (Embryos)

Based on published data as well as our own experience with this model, up to 50% of embryos will not start or stop development before the end of the experiment. Some of these might be adverse effects due to procedures that were carried out but might also be related to a number of other factors starting with the genetic makeup and transport of the eggs before inclusion in the experiment. It is assumed that there is no pain reception in the developing embryo up to 15 days of development. We do not plan procedures on the eggs after day 15 of development apart from imaging, but critically need those additional days to, e.g., monitor growth of grafts or tumours to establish the effects of pharmacological interventions. Thus, we do not expect to induce significant pain or suffering during those 3 days, but gain important additional information. All embryos will be euthanised latest on day 18 days of development.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rodents (Mice and Rats)

Breeding animals: Most animals will have at most mild severity as we will not use mice with harmful transgenes. However, few (<5%) may suffer complications during birth, which would be mitigated by Schedule 1.

Administration of substances: There might be up to moderate pain in <10% of animals that will be injected because animals will be injected with compounds below their known level of toxicity.

Grafting of transplants and turmour inoculation: There might be up to moderate pain in <10% of animals in the animals grafted with cells.

Chicken (Embryos)

The chick CAM is not innervated, and it is considered that the embryo has no capacity for nociception to day 14 (e.g., Eckrich et al. doi: 10.1038/s41598-020-75660-y), which means that the majority of all procedures will have minimal impact on the animals as they happen before day 14, i.e., the severity is at most mild for the procedures. However, those embryos that will be monitored up to day 18 of development before Schedule 1 might experience discomfort from the previous treatment or growth of tumour material on their CAM.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The human body is a complex environment and we are aiming to model the interactions of novel materials with this complex and dynamic environment. Drug behaviour in the body is dependent on how the drug is absorbed into the body by, for example the gut in oral drugs, how it is distributed throughout the tissues and blood, and then metabolised and excreted via the kidney or in faeces (ADME). Processes that are being shaped by multiple organ systems. Toxicity of drugs to the body introduces yet further parameters at multiple levels and distributed throughout the body that need to be considered. As such, no alternative to animal models is available at this point.

Which non-animal alternatives did you consider for use in this project?

We have considered and are actively using in vitro methods (2D/3D cell culture) as well as replacing the use of rodents with less sentient chicken embryos.

Why were they not suitable?

The in vitro models are not yet fully recapitulating the complex environment generated by mammalian biology, but only aspects thereof that might be misleading on their own.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Where known, we will use the expected effect sizes of quantitative parameters to estimate group size, and consult with the relevant literature for appropriate experimental designs as well as take expert advice on trial design to optimize our experimental program. A general rational for our estimated overall animal numbers, divided by animal species, for the project over the next 5 years are as follows.

Mice

The number of mice includes those used for breeding (protocol 4), which will be mostly transgenic and those from commercial breeders where no transgenic animals are needed. While we do want to minimise this, we expect that a portion of animals will not be used in this programme due to wrong genotype and/or sex. We estimate a colony size of an average of 2 breeding pairs over 5 years. (1000 Mice)

Furthermore, we to test at least 50 nanomaterials in pharmacokinetic and biodistribution experiments with or without payload delivery (Protocol 1, 2000), as well as grafting studies including 20 novel matrix materials (Protocols 2, 600 mice).

Rats

The number of rats is based on testing nanoparticle distribution parameters and propterties of 2-3 selected formulations (Protocol 1). Futhermore, it is based on the assumption that we will test up to 2 different gels in addition to the current Matrigel control and a further no-matrix control with up to 3 different kinds of grafted cells in groups of up 10 animals (Protocol 2).

Chicken (embryos)

We assume that we conduct experiments with up to 40 eggs per experiment, for 20 weeks per year for 5 years. Based on our experience with the model, there is a high attrition rate of infertile, non-developing eggs that we account for by overestimating the needed eggs by 25%, which bring the total number to 5000.

Biodistribution and pharmacokinetics

The relative and/or absolute amount of nanomaterial will be assessed at multiple time-points after single or multiple application.

To achieve sufficiently rigorous results, we anticipate using around 100 mice.

Novel materials for grafting

Group size will be determined for growth of transplanted cells will be compared between novel matrices vs. "state of the art" matrigel over time. Using longitudinal designs with imaging will enable to improve data quality and reduce the number of animals needed to reach meaningful statistical comparison.

Chicken CAM

Based on previous experiments we estimate to require around 100 eggs per experimental group. This is determined not only by the effect size that are expected, but also by the significant drop-out rates.

While we have achieved comparable survival rates to day 14 compared to the literature, this might still be somewhat variable due to variables beyond our control (transport of eggs, seasonal variability, etc.), which means we have to plan with a certain contingency number in every experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will be guided by the PREPARE guidelines (Smith et al. doi: 10.1136/bmj.k760) to plan our experiments. Moreover, we took statistical advice on the design of the experiments by local statistician colleagues as well as an external company specialised in the chick CAM model. We used the best estimate of effect size based on previous experience with nanomaterials in our group or published literature to inform our group size calculations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Firstly, we will monitor all transgenic breeding closely to prevent producing to many experimental animals. Regular project meetings of PILs involved in the research programme will guarantee the adequate breeding colony size, as well as appropriate planning of experiments to use the bred animals most efficiently.

Pilot studies will be performed to get good estimates of effect size and optimal dosing regimen. Should our program demonstrate that our estimates of effect size are wrong (either too big or too small) we shall re-perform the power calculations to ensure we arrive at a rigorous outcome. If it appears that the effect size is much smaller than anticipated for a particular experiment, we shall consider abandoning that part of the program.

We shall routinely harvest tissue to enable biochemical, genetic, cellular and histological/immunochemical analyses and share this tissue with our collaborators.

The in vivo imaging approach permits longitudinal data collection from the same animal/embryo and this reduces the number of animals/embryos required in the study as the repeated measurements will give greater statistical certainty and will allow study of various quantitative and qualitative parameters in one animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents are a well-established model for studying the effects of novel chemical entities on the mammalian body and characterise their behaviour. There is a robust literature and wealth of potential data obviating the need to repeat past findings. Rodents in general are seen as a simplified and experimentally tractable model for far more complex mammals such as people.

Wherever possible, physiological testing of phenotypes will be achieved by using non-invasive methods such as: non-invasive imaging taking advantage of transgenic reporter mice to refine experimental approaches. More invasive procedures will be used only when there is good reason (from the non-invasive experiments) to expect mechanistic insight.

Throughout the course of the license, we will endeavour to refine procedures and approaches. In fact, a number of planned experiments are explicitly designed to improve current state-of-the-art for substance application in experimental animal models (e.g., patch application of tamoxifen and luciferase substrates).

We shall use ex vivo tissue as much as possible to study cellular mechanisms relating of polymer uptake, thus enabling future in vivo experiments to be appropriately designed to minimize animal usage.

Why can't you use animals that are less sentient?

We are trying to implement this where possible. For example, we have established the embryo chicken CAM model (up to day 14 of development) for a number of the different projects which will reduce the total number of rodents and, we firmly believe based on the literature and our own experience we can generate relevant and translatable data, which we will further validate in this programme of research.

Unfortunately, in some cases we need to be able to observe the chick embryos beyond day 14 of development because certain functionally important features are not present before (e.g., blood brain barrier is developing) and, for example, the length of time grafting of tumours, start of (repeat) treatment and day 14 is not sufficient to make valid conclusion on changes in tumour growth and, thus, interaction with or efficacy of the novel materials.

Moreover, we have established a number of in vitro assays to gather as much data about the chances of success for the nanomaterials before going in vivo.

However, the experiments proposed in this programme of work are not feasible in these models only as they are translational, i.e., designed to evaluate novel materials for future use in medicine.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have considerable experience with the in vivo imaging methods and have considerably refined them already over the past 2-3 years. We have implemented standardised post-operative monitoring methods to ensure that outcomes and adverse effects from our surgical procedures are carefully assessed. We use this information to optimise post-operative care and pain management.

We shall use rigorous aseptic techniques to protect against infection of the animals, may that be rodents but also the chicken eggs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We shall take careful note of advice from collaborators and researchers highly experienced in the various methodologies and models to ensure that we refine our experiments as much as possible. We shall follow the Laboratory Animal Science Association and NC3Rs guidance on best choice of models and refinements. For example, for drug administration we shall choose all dose volumes in accordance with the LASA guidelines for the administration of substances.

To ensure effective and rigorous reporting of our results. In publications, wherever possible, we shall aim to adhere to the ARRIVE guidelines which are recognised as

providing excellent transparent standards for reporting of research using animals and were developed by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow advice by the local NTCO, NACWO and NVS. In addition, we will consult the NC3R and Norecopa webpages and the relevant literature as well as attend scientific conferences where possible. Any relevant new refinements or advancements during the course of the licence will be implemented if possible.

64. Technical development of refined phenotyping assays.

Mice	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop new more refined, or to improve existing tests that look at the physical characteristics of an animal, that help understand the function of genes (Phenotyping tests). We aim to undertake this project in order to improve the quality and the reliability of data output, and/or enhance animal welfare.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically altered (GA) mice are currently in widespread use in biological science and have been shown to be of great value in explaining and understanding the function of genes (the basic physical and functional units made up of DNA, that pass information from one generation to the next) and the ways in which the genes interact with

other molecules in the body to express their functions, in a wide variety of biological, physiological and pathological processes. Although many genomes have been sequenced, the function of many genes (estimated at approximately half) are poorly understood.

Over the last 5 years, the techniques based on specific molecules that help scientists study DNA and other proteins, for making changes in the genomes of model organisms like the mouse have become so sophisticated that it is now technically much easier to make multiple alterations in a genome including those mimicking variations in DNA of different individuals or different populations seen in human disease patients. The generation of ever more complex and/or relevant mouse models to be used in the study of genetic disease is driving the need for sophisticated and, importantly, quality controlled tests to properly describe the distinctive nature and features of gene function and generate relevant animal models which can be used for pre-clinical studies to develop new therapies. A phenotype is a set of observable characteristics of an individual, resulting from the interaction of its genotype with the environment, where as a genotype is the genetic constitution of an individual organism. This facility supports individual research laboratories to characterise the result of specific alterations in the genes for their animal models by performing quality controlled phenotyping tests which may be outside of the laboratories area of expertise or not available elsewhere. In this way we are contributing to the development of better preclinical animal models. At the centre of the management of these projects is the development of improved tests, the continued quality control of those tests and the delivery of biologically and clinically relevant data to scientists the world over who work in the field of biology and medicine (the international biomedical community).

The methods of conducting behavioural genetics have changed very little over the past 40 years, in that they rely on test batteries (or a group of tests), that aim to link the outcome from a standard out-of-cage test to a behavioural phenotype. However, in order to conclude that the differences in behaviour between GA mice and mice where no changes to the DNA have been made are due to the genetic differences, the experiments must be controlled for the effects of factors other than the intended change, in this case the change in DNA, that can impact the results of the experiment. Mouse behaviour is flexible, dynamic and adaptive and therefore is influenced by a variety of genetic and environmental factors such as motivation, interaction with the experimenter, experimental design, test order, testing time and environmental enrichment. Therefore, it is incumbent on us to continually strive to refine the existing standards in behavioural phenotyping and to improve animal welfare through improving the quality and robustness of the data obtained.

In recent years, the advances in technology have made it possible to build upon established tests that study the effect on the behaviour response of animals to specific situations, to develop more automated, long-term behavioural testing platforms. These tests enhance and add to the value to the data generated by each individual test not lasting longer than a few hours, thereby building a comprehensive insight into the effects of gene mutations on animal behaviour and neurological function over days and weeks instead of looking at smaller ‘snap-shots’ in time.

Similarly, measuring metabolism in the mouse is also very susceptible to experimental parameters including fasting times, feeding regimes and light cycles. Recent data has been published on the effects of controlled feed regimes, as opposed to animals having access to food all of the time, and how normal testing regimes such as long fasting periods may confound the experiments. Together, all of these factors strongly indicate the need to refine existing protocols to develop tests which are more relevant to human physiology, remove confounding factors such as short observation windows and experimenter bias and deliver more translatable preclinical models.

Through this project we aim to offer a step change in the way mouse behavioural phenotyping is conducted; by trying to remove sources other than the intended change in DNA, that could result in changes in the physical or behavioural characteristics of an animal in the experimental models, refine and improve the experience of the animal and adapt phenotyping tests to being more relevant to the study of human disease. To do this end we will specifically explore different feeding regimes, ways of training animals in their home cage setting as opposed to moving them into specialist equipment and attempt to replace treadmills with voluntary locomotion whilst measuring motor activity. In addition, we aim to also explore mouse Ultra Sonic Vocalisations (USVs) to better understand mouse social interactions within their home cage environments and whether this can be used as a measure of well- being.

Thus by aligning animal welfare with more robustly measurable home cage behaviours we aim to deliver better preclinical research with an improved potential to develop drugs and therapies for use in human beings.

What outputs do you think you will see at the end of this project?

New phenotyping tests that will be refinements on current tests. By the end of this license we aim to be able to disseminate and train other researchers to use at least 3-5 different ways and conditions under which an experiment is conducted including the expanded use of home-cage monitoring, ultrasonic vocalisations (USV) for welfare and phenotype detection and altered feeding regimes.

All validated tests will be published and presented at the appropriate forum. All software designed or statistical methods produced will be available on relevant data-sharing platforms.

Who or what will benefit from these outputs, and how?

The main benefits from this research will be refinement through the generation of robust data by a) capturing behaviours in a familiar, enriched environment b) capturing behaviour observations that are not confounded by novel apparatus (equipment that the mice have never seen before), or human experimenters, c) serving as a permanent digital record that can be used by the wider community and d) generating video and audio data that are amenable to automated analysis techniques thus allowing new analysis to be conducted retrospectively without the need to generate more data.

Within the timescale of this project we are aiming to develop testing which is accepted by the wider scientific community and which contributes relevant, comprehensive data to significant scientific discovery. To this end we would not only focus on the development of the new protocols but also on the dissemination to other labs. Where possible we would aim to make the new experimental design easy for others to implement in their own laboratories by making them adaptable and provide relevant training.

We also hope, through our developing training programmes and relationships with groups such as the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), laboratory animal science associations (LASA/FELASA/AAALAS) and Institute of Animal Technology (IAT) to encourage the inclusion of new technologies widely in UK and international animal facilities and will initially be working with partners in three other facilities to do so.

Ultimately, we aim to improve the experience of the animals undergoing testing whilst delivering a broad and comprehensive dataset.

How will you look to maximise the outputs of this work?

The data will be retained as a permanent digital record of the tests; the aim will be to share this data through seeking collaborations with expert scientists in the field of research who specialise in a very specific area in that field of research and can provide expert advice on the work we are doing. These could be experts in the field of mouse behaviours to medicine and computer data scientists. The data will be disseminated through publications and presentations at appropriate forums.

We aim that the newly refined and developed tests become part of the tests used for preclinical studies and provide more robust, relevant and comprehensive data for screening new therapeutics. In deed we already have ongoing projects with two drug-discovery teams who are exploring the use of Home Cage monitoring to look for more relevant, earlier, indications of disease phenotypes in their mouse models. We would build on this work by bench marking the new paradigms against standard models to encourage uptake with confidence by other labs.

Species and numbers of animals expected to be used

- Mice: 10,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is necessary to use mice for this study because the main objective of this project is to refine existing or develop new tests to refine behaviour phenotyping in mouse models of

metabolic and neurological conditions where non-animal alternatives are not appropriate and/or available. These refinements would need to be tested against the existing standards protocols to validate them as well as encourage uptake from the wider scientific community.

We are studying neonatal, juvenile, adult and aged mice due to the nature of the conditions being investigated. Metabolic and social phenotypes (Social phenotypes are characteristics that relate specifically to interactions with other animals) may be manifested from birth, however, there are currently very few methods that do not rely on a period of separation from the mother or singly housing for a period of time. The work outlined in the current project aims to refine these methods, in order to be able to tease out such early phenotypes without interfering interactions of individuals within a group, such as the litter or the another mouse co-housed in the home cage.

Similarly, in order to investigate some phenotypes, especially those related with learning and memory it would be necessary to age a portion of mice on this project to beyond 12 months of age. As expression of dementia related phenotypes is increased by ageing it is therefore necessary for us to validate the refinements in mature adults that have a fully developed central nervous system.

Typically, what will be done to an animal used in your project?

Approximately 80% mice will undergo a combination of phenotyping tests to develop, refine and validate either the neurological or the metabolic phenotyping assays. Each experiment will use a combination of tests over the life-span of the animals, most of which are non-invasive, a small number involved anaesthesia used for immobilisation for the insertion of transponders to identify or record readouts use radio frequency to take readings automatically and from a distance.

Typically, mice are then terminally anaesthetised and blood and tissue samples taken. All experiments are expected to end by 12 months of age, with the majority of mice being culled by 52 weeks of age.

For some tests it may be necessary to singly house and or have restricted access to food. The aim of the current project is to refine such the set of conditions under which an experiment is conducted so that learning and memory tests may be conducted under reduced access and timed feeding routines instead of restricted access that may last up to 18 hours a day. As well as modifying assays such that they may be conducted under group housed conditions in the familiar environment of the home cage.

What are the expected impacts and/or adverse effects for the animals during your project?

Genetic alterations in the mice used in this project may lead to the development of neurological or metabolic phenotypes. It is expected that mice modelling delay and difficulty in developing communication social interactions with other mice, metabolic or

neurodegenerative conditions may have some adverse effects such as aggression, obesity, progressive loss of movement, coordination, memory and sensory input such as olfaction, sight and hearing.

Mice undergoing restricted feeding routines in order to use a food-reward for motivation will have reduced access to food. In mice undergoing cognitive testing this may be to reduce their body-weight to ~90 % of their free-feeding weight. Studies have shown that in some knock-in mouse models of dementia causing disease, food restriction increases survival, consistent with data for C57BL/6 mice in general. Thus we do not anticipate adverse welfare outcomes associated with food restriction. To improve the validity of our results we will monitor long-term effects of food restriction by assessment of blood glucose before and after food restriction and body mass composition.

For some tests mice will need to undergo anaesthesia (e.g. for the implantation of devices for remote monitoring). All anaesthetic use in mice carries a risk of mortality and a risk of pain (short-term and long- term), which may differ between genetically altered lines.

Blood sampling requires the use of restraint to ensure safe sampling in a controlled manner. This poses the risk of induction of a stress response. The use of assays which minimise the required sample volume will be used and larger volumes of blood will not be sampled when the mice are on restricted food intake protocols.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice on the mild breeding protocol are not expected to suffer any adverse effects and the vast majority will not reach the expected severity threshold (sub-threshold severity).

On the moderate breeding protocol, it is anticipated that any mice carrying the disease-causing phenotype could exhibit a moderate phenotype. Other genotypes will also be born from these crosses, so approximately 25% of the mice may suffer a moderate severity.

Mice on the behavioural phenotyping protocol are all expected to reach a moderate severity. This is partly due to the phenotype of the mice, in which the genetic alteration could lead to a moderate severity in around 50% of the mice (the other 50% being unaffected controls). However, all mice will reach a moderate severity because of a subset of the phenotyping tests causing moderate suffering, for example overnight fasting for blood sampling or food restriction for the purpose of motivation in food- rewarded tasks. Additionally, the combined effect of repeating mild tests over the life span of the animal, in order to validate the assay over the progression of disease, will lead to an overall moderate experience. This cumulative effect of repeating mild-phenotyping tests may also interact with genetic alterations used in this project to model neurological and metabolic

conditions. Whilst these moderate affects will be short lasting they will increase the maximum severity of all animals on this protocol to moderate.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The primary objectives of this project is to refine existing or develop new ways of conducting experiments to refine behaviour phenotyping in mouse models of metabolic and neurological conditions where non-animal alternatives are not appropriate and/or available.

Whilst it may be possible to develop some of these tests in other species, the purpose of this licence is to refine the tests currently carried out in mice. The reason for this is two-fold, firstly many researchers have existing mouse models that they are already testing with the current techniques, we hope to offer them refined improvements in order to benefit mouse welfare and reproducibility in existing models.

Secondly, for complex systems such as behaviour and metabolism, it is often necessary to use a mammalian species to understand genetic alterations in the context of the whole organism. Whilst some preliminary work could and should be done in cells, or using computer modelling or in other species such as drosophila or zebrafish, when it is necessary to move into mice we want to be able to offer the most refined procedures possible.

Which non-animal alternatives did you consider for use in this project?

We aim to refine existing phenotyping assays used in mouse models, however, we would also keep abreast of developments in the wider field to ensure that any techniques that may be better addressed via non-animal alternatives are not developed on this project through use of animal models. Where possible we would use data already generated to develop automated techniques, such as image analysis and pattern recognition and use animals for validation purposes. For example, the use of computer modelling to predict patterns within big data this is especially relevant to time dependent pattern of behaviours, where it is not necessary to generate new data for understanding what is 'the normal pattern' but compare new data generated in GA models to historic data to tease out 'anomalies' that may be indicative of a phenotype.

Why were they not suitable?

The aim of this project is to refine existing procedures in mice. There are circumstances when earlier work will be done in non-animal alternatives, but when research has progressed to the point where a whole organism is needed we want to provide the most refined procedures.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Current samples sizes are estimates based on previous data. As we are refining procedures it is difficult to be certain of the correct sample size, however previous data from tests is used to enter into statistical equations that help calculate how many animals are needed in an experiment) for refined protocols to give us sample sizes needed for individual tests. As we are also developing new test protocols, as a first pass a highly specialised set of calculations that helps scientists decide how many animals would be needed for an experiment, where no previous data is available (G power calculation) may be used to determine sample sizes needed for a desired effect size. Where there is no previous data for power equations, resource equations may also be used. In GA models for neurodegeneration that will be typically used in this project some phenotypes do not develop until mice are 12-18 months of age. In order to ensure we have sufficient sample size at later-time points it is necessary to account for a percentage of mice that may not complete the study rates of 25% (this includes culling of mice to avoid the phenotyping of lone-housed because of loss of cage-mates. Rehousing of females will be undertaken but will need to be included as a variable in subsequent analysis).

An example of a typical study would be, 12 mice per sex and per genotype, thus (2 (genotypes) x 12 (mice) x 2 (sexes)) =48 mice will be required for each experiment. We anticipate undertaking approximately 15 such experiments per year for every year of this project. At least 2-rounds of breeding will be required to generate the mice required for the experiments outlined. Thus, in total we estimate we will need to breed 4000 mice for this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power equation calculator will be used for group size calculations for the phenotyping experiments. In addition, attrition rate calculation (to account for a percentage of mice that may not complete the study, as explained above) will also be used to ensure sufficient power is maintained until the end of the longitudinal studies.

The combination of tests in each experiment will be designed to gather the most meaningful data in order to validate the refinement. Tests which can inform each other will be carried out on the same mouse to remove inter-animal variability (this is the differences between individual mice that can influence the results) and increase the power, thereby decreasing the overall sample size and the scientific utility of generated data. We will also phenotype over the life-span of the animal to get better data from a smaller number of mice and to prove that the new/refined set of experimental plans is as accurate or better at detecting the same experimental outcome as the test it replaces over the progression of disease.

Standard Operating Procedures (SOPs) have been written and used routinely for standard tests and will be written and version controlled for the developing and refined tests. Each iteration of the test in development will be linked to the appropriate version in order to keep track of the assay development and validation in order to inform future refinements. This standardises the way the data is collected and reduces the variability and therefore the sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding will be used to minimise the number of mice being produced for these studies. Genetically modified lines that have already been studied will be sourced from repositories (these are carefully managed stores where the DNA of GA mice is stored for future use), to avoid remaking of lines whenever possible. Any excess stock will be offered to other researchers to minimise wastage. Pilot studies will be undertaken to generate means and standard deviations for work using back-ground strains for which data is not available. Tissues sampled from the animals used in this project will be shared with other researchers and the data produced linked to that generated by the project, to maximise long-term utility.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The overall objective of this project is to refine existing or develop and validate new refined phenotyping assays for metabolic and neurological models. A number of tests on this project are proposed not for routine use but for validation and welfare monitoring, so that other laboratories may adopt these refinements with confidence. In addition, only lines that

have already been characterised through broad based phenotyping will be used to validate the refined or new assays, in order to avert obvious welfare concerns. As the project aims to investigate phenotypes from a much earlier age and over extended periods of time, the refined assays may themselves reveal hitherto unknown welfare concerns.

Test	Why is this the most refined method?
Ear Biopsy	Mice need to be clipped for identification and the same piece of tissue is used for genotyping. Genotyping protocols (protocols are a clearly defined set of steps that must be followed when conducting an experiment; here the experiment is genotyping, which is the process of investigating if the change to DNA has passed on to the pup from the parents or not) have been optimised to use this very small sample size for all types of genotyping carried out at the establishment. This is more refined than other methods such as tail biopsy.
Insertion of Transponder microchip	Mice need to be implanted with RFiD (Radio Frequency identifier) transponder or a telemetry microchip in order to acquire positional data in the home cage or passively acquire telemetric data such as body temperature. The protocol for subcutaneous implantation of microchips has been optimised to use general anaesthetic and a local anaesthetic in order to minimise stress and discomfort during and after the procedure. The procedure further uses surgical glue to seal the wound in order to prevent accidental damage and or loss of the microchip device.
SHIRPA	SHIRPA is an observational test that involves placing the mouse in an arena or a jar and looking for abnormalities. This is non-invasive and can provide a lot of phenotypic insulin tolerance tests). This test is more refined than other methods of measuring glucose which require surgery to implant catheters that remain inside the body for the animal's life time.
Standard Calorimetry	This is non-invasive in home cage like equipment. Bedding is provided and animal shelters are used when activity measurements are not needed.
Metabolic cages	Mice are housed for as short a time as possible, usually 20hours. This length of time is needed to collect a large amount of urine and assess overnight food and water consumption. Red houses are placed in the cages to provide shelter and respite from the grid floor.
Home cage monitoring	This is non-invasive and measured in the home cage. After initial insertion of a microchip this test involves no further pain, suffering or distress to the mouse. This generates large amounts of data with no adverse welfare effects.

Why can’t you use animals that are less sentient?

The main objective of this project is to refine existing or develop new non-invasive assays to refine behaviour phenotyping in mouse models of metabolic and neurological conditions where non-animal alternatives are not appropriate and/or available.

This work needs to be undertaken in an animal with an intact nervous system without anaesthesia because we need to measure how effective the refinements in phenotypic assays are when compared to the standard phenotyping tests.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all tests it is important that the animal has no additional stress, therefore mice are handled calmly and provided the time to get used to testing rooms as well as arenas where possible.

For all tests mice are only housed in modified cages or arenas for the minimum time needed to gather meaningful data. Mice undergoing phenotyping tests have increased monitoring and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests. Mice which have had anaesthesia have extra monitoring until fully recovered and extra checks when back in the holding rooms. When general anaesthetics are necessary, the combinations with least adverse effects will be used, for example for all tests only inhalation anaesthetics will be used. Pain caused by withdrawal of blood from the tail vein is reduced by using local anaesthesia and pain from insertion of subcutaneous implantation of microchip transponders will be minimised by general anaesthesia and local anaesthetic.

This license involves no surgery.

The validation pipelines will be designed with consideration given to the overall experience of the mouse and the number of type of tests any one animal will go through.

The project is specifically aimed at refining existing standard paradigms for assays such as operant testing, where the animals are typically food restricted for 18 hours a day for 90 consecutive days. By refining this food restriction regimen from 18 hours to timed feeding, the duration of the restriction may be reduced by up to 12 hours by focusing on the times of day that the mice are most likely to feed and thus still be motivated to perform a task for a food reward.

A combination of technologies, such as passive observation using video image analysis and modification of the home cage to use smart hoppers that would be capable of dispensing and depriving access to food automatically on a predefined cycle would have the potential to revolutionise such paradigms.

Training for experiments where animals learn to associate tasks with reward within the home cage is another example where the welfare burden on a mouse may be reduced by removing the need to train mice in a novel environment and away from its cage mates for extended periods of time.

By attaching behaviours to ultrasonic vocalisations a whole new dimension to mouse behaviour may be opened, as vocal cues can be a real game changer for indications of socially deficit phenotypes as well as early indicators for aggressive phenotypes.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from LASA guidelines.

The establishment has full AAALAC and ISO9001-2015 accreditation. To conform with these standards, we must work to a high level of quality control on all fronts including husbandry, phenotyping and administrative processes.

Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at https://www.mousephenotype.org/impress

ARRIVE guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will attend general 3R's (Replacement, Reduction and Refinement) symposiums in the UK and abroad over the course of this project. From these I may gather information on refined phenotyping techniques or housing and husbandry methods. Moreover, it is my intention to continue to present any techniques that we develop ourselves in posters and papers in the relevant scientific/animal care forums.

More specifically, members of the team at the establishment will attend specific conferences that focus on all aspects of the neurological and metabolic disease, from humans, to model organisms to in-vitro (experiments done outside the animal e.g. cell lines) and in-silico (computer modelling work such as artificial intelligence and computer learning). Any new developments which could impact these studies will be discussed with the teams at the establishment as well as experts in the field who may advise on this project.

65. Antibodies for research and clinical purposes

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Antibodies, research tools, clinical research, Tumour markers, immuno-based assays, diagnosis

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project will generate antibodies towards disease biomarkers, which have no/or poor antibodies available. These can be used as tools to support research and improve clinical standards.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Research advancement, clinical assays and therapeutics by in large are dependent on the presence of tools such as antibodies. Antibodies have been utilised as probes to help decipher biological and pathological pathways. Importantly, antibodies are key

components of immuno-assays currently employed to aid in disease diagnosis and diagnosis, monitor treatments and provide effective therapeutics.

What outputs do you think you will see at the end of this project?

We anticipate to generate between 100 to 200 new antibodies towards targets that otherwise have no available antibodies. Through the course of the licence, we have developed and will continue to develop high quality antibodies primarily to targets relating to human cancer tumour markers, immunological conditions and a wide spectrum of veterinary species where there is a palpable shortage of antibodies such as salmon and chicken. Outputs include; products that will forward research through publication in peer-reviewed journals, diagnostic assays to aid pathogen and disease detection, prognostic assays to asses health and treatments.

Who or what will benefit from these outputs, and how?

The short-term impact (>6 months) is to advance science, especially where there is a shortage of research tools. Antibodies enable scientists to better understand the function and roles played by the corresponding targets thus enabling scientists to put together the pieces of jigsaw of a particular disease. Under our licence we have demonstrated competence in generating antibodies towards potential tumour biomarkers for research and clinical applications. We developed a number of mAbs with prognostic potential towards colorectal cancer (e.g. CYP26A1, CYP26B1, BCLAF1) (see relevant publications below). Under the previous license we have also generated 200 antibodies towards a spectrum of veterinary species targeting key immune and health markers, supporting such industries in the process.

The long-term benefit (>3 years) is that antibodies are essential components of establishing immunoassays to monitor human and animal health, evaluate vaccine performance and diagnose infections all of which will improve human health and the welfare of farmed species. Antibodies were also developed towards key molecules involved in pathological pathways such as the oxysterol and brown fat pathways (see relevant publications).

How will you look to maximise the outputs of this work?

Through collaboration with multi-international centres, we have generated a substantial portfolio of antibodies to key markers in salmonids, stickleback, zebrafish, tilapia, chicken, horse, seabream, seabass and shark to be used as research tools and immune assays. All antibodies are made available to the scientific community, over 80 of which have been utilised in ongoing research and publications.

Species and numbers of animals expected to be used

- Mice: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use mice (8-12 weeks old). Animals with active immune response is prerequisite to generating high quality antibodies. This project will use mouse (BALB/c) model to generate antibodies.

BALB/c mice are useful for research especially in immunology. BALB/c strains are "particularly well known for the production of plasma B cells on injection with suitable adjuvant," an important process for the production of monoclonal antibodies. In addition, we have an established protocol in place at the for the generation of murine monoclonal antibodies.

Typically, what will be done to an animal used in your project?

A primary immunisation procedure with an appropriate adjuvant “complete Freund adjuvant (CFA)” using an appropriate dose will be administered by subcutaneous injection. At intervals of typically 2-3 weeks, three booster injections in incomplete Freund adjuvant (IFA) will be administered subcutaneously. The final booster injection in saline is then administered intraperitoneally. Blood samples will be optionally taken after immunisation to monitor immune response. Volumes and frequencies for blood sample will be used following the Home Office guidelines. If volumes/frequencies will exceed the recommendations, they will be agreed in advance with the Home Office after consultation with the Named Veterinary Surgeons.

The number of procedures carried out per animal are 6. The duration of the experiments is 10-12 weeks. There are no surgical procedures.

What are the expected impacts and/or adverse effects for the animals during your project?

Post-injection: the injected area may be slightly distended within few hours following the procedure carried out. Animals will return to normal within a short period of time.

It was observed after the intraperitoneal injection that some animals (~20%) showed some adverse- effects (minor temporary adverse reaction which can be resolved by supplementing the animals with additional heat).

Granulomatous reactions at the site of injection may occur in a small percentage (<1%) of animals following injection with adjuvant, which could last up to few days. It is worth noting that granulomas seen in earlier studies did not progress to ulceration. Under this circumstance the animal is monitored, and no further procedures are carried out until the lesion has healed.

If weight loss in some animals becomes apparent the mice will be weighed on a regular basis and monitored.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity is mild. The process is mild throughout the duration of the study.

It was observed after the intraperitoneal injection that some animals (~20%) showed some mild temporary discomfort.

Animals will return to normal within a short period of time.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Live animals have to be used since an active immune response is an essential prerequisite for the production of murine monoclonal antibodies.

Which non-animal alternatives did you consider for use in this project?

A significant amount of our work is carried out in silico and in vitro and only a limited part of the work is performed in vivo (20%) using animals. Moreover, we established a recombinant technology (prokaryotic expression system), the aim of which is to replace the use on non-animal models to generate antibodies.

Why were they not suitable?

At present, almost all of research antibodies including research immunoassays, diagnostic assays, serology-based assays, monitoring immunoassays and therapeutic antibodies, are generated from animal models. There are emerging technologies which includes phage display and recombinant methods making strides to provide non-animal alternatives, but they remain in the developmental stage and few years away from coming to fruition.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals to be used based on our previous work/records. Simply, the objective is to generate 100 to 200 antibodies in a 5-year project which requires ~150 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Reagent companies and research institutes traditionally use two to three mice to produce one mAb specific to the protein target under investigation. Multiple animals are used as a backup as it is possible that on some occasions 1 mouse will not mount an immune response towards the immunogen of interest. At the start of this project licence, we followed this regime but by optimising our protocols, we now use animal with multiple immunogen (3 different immunogens) thus generating multiple antibodies to different targets of interest with no additional adverse effects on the animal. Therefore, we have reduced animal use by at least 6 fold , which is a significant reduction. We anticipate that during the course of this licence we will reduce animal numbers further by increasing the number of immunogens used per animal with no increase in adverse effects to the mouse or concentration or immunisation steps.

As mentioned above, mAbs are the ideal choice in terms of animal cost as once they are developed, they provide an unlimited source of antibody. On the other hand, pAbs are limited in amount and once the antibody supply is exhausted further animals need to be used. Currently we generate only mAbs which reduce animal usage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The novel approach we employ (peptide-technology) has become more sophisticated as we have gathered more experimental data over the duration of the last two licences. This enabled us to generate an AI software to increase success rates in production of antibodies which subsequently reduce the number of animals used. The AI software is made available to the scientific community and were recently utilised in the CSO COVID-19 programme to assist in producing a serology-based diagnostic assay.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal model in this project is mouse strain BALB/c. BALB/c mice strains are associated with the production of plasma B cells following the injection with an antigen, an important process for the production of monoclonal antibodies. In addition, this model has

been used for the purpose of producing antibodies for decades and there are well-established protocols in place for the generation of murine monoclonal antibodies.

The protocols are associated with mild severity levels and minimum stress.

All procedures are carried out by experienced staff members at the designated establishment who are experienced and competent to handle the animals and perform the procedures minimising animal harm.

Why can't you use animals that are less sentient?

To generate antibodies suitable for research applications and clinical settings, mice with active immune response is an essential prerequisite.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- It was observed after the intraperitoneal injection that some animals (~20%) showed minor temporary adverse reaction. Two steps were introduced; (1) animals were put into a heat cabinet for 2 hours to speed up recovery after injection. In order to reduce the side-effect antigen samples were diluted 4 times in saline solution.

- If weight loss in some animals becomes apparent the mice will be weighed on a regular basis and monitored in relation to its physical condition as well behaviour. Any mouse exceeding 10% weight loss would be humanely killed.

- Complete Freund adjuvant (CFA) and incomplete Freund adjuvant (IFA) were used throughout our previous work. FA has been shown to be very effective in terms of reliability and success particularly in relation to smaller compounds such as peptides and it is the standard adjuvant of choice in antibody production. Having said that we are aware of the presence of a number of alternative commercial adjuvants e.g. Sigma Gold. During the licence we plan to carefully monitor any new literature for the use of alternative adjuvants and to pilot some of these adjuvants ourselves by designing the appropriate experiment. Where Complete Freund adjuvant is used it will be used on one occasion only, for the primary immunisation.

In order to reduce the side-effect antigen samples were diluted 4 times in saline solution.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R's Experimental Design Assistant.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attending conferences and international meetings. Follow the latest ongoing research at NC3Rs.

66. Study and manipulation of the tumour immune microenvironment for cancer therapeutics

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer therapy, immune, antibodies, immuno-modulatory, tumour microenvironment

Animal types	Life stages
Mice	pregnant, adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aim to evaluate the basic understanding of the regulation of the immune response against cancer as well as the development of novel anti-cancer therapeutics.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The success of immune-oncology therapies like anti-CTLA-4 and anti-PD-1/PD-L1 has built great potential for novel cancer therapeutics and paved a new era for immuno-oncology, especially for patients with melanoma. Despite great promise, responses are

limited to a fraction of treated patients and, critically, the mechanisms underpinning response and resistance to therapy remain elusive.

Therefore, this program of work aims to understand how the immune response is regulated in general, and how different tumour microenvironment can affect immune function. The program will also aid in the development and evaluation of novel and more efficacious combinatorial therapeutic approaches useful in the treatment of cancer.

What outputs do you think you will see at the end of this project?

The overall goal of this project is to study and interfere with the interplay between the immune system, tumours and their particular microenvironment using mouse models of cancer that better mirror human malignancies. We have already developed several biotherapeutics and have tested their efficacy and effects on tumour killing in mouse models with two of them currently in clinical evaluation. Data generated from these studies will give insight and mechanistic details on their function and toxicity to scientists and clinicians via peer-reviewed journals. Due to the increase in the development of new line of biotherapeutics for cancer I therefore expect the demand to continue to grow over the next 5 years of this PPL in accordance with clinical need.

Expected outputs derived from this PPL:

Products:

Biotherapeutic antibodies. New information:

Understanding single or combinatorial treated of immunotherapy and tumour rejection. Although immunotherapy have been applied to several of clinical trials very little is actually understood about why resistance occurs and immune exhaustion. We aim to answer these important questions.

Publications and public engagement:

The data obtained from this work will be communicated by publications to scientists and scientific conferences.

Clinical Translation:

Some of the products with the best results will be translated to the clinic/tested on patient samples.

Who or what will benefit from these outputs, and how?

Data generated in this study will be used to develop the next generation of immunotherapeutic treatments for broad a range of cancer types, to investigate and refine the mechanisms that underpin current immunotherapies and to produce preclinical data to support Phases I-IV clinical trials.

Because we study multiple different immunotherapies at different stages of development some of our data will have short term impact and some other will see impact after completion of the project. In the short term our work will impact the scientific community as we will provide basic understanding of how this therapies affect the immune system, whilst in the long term we expect to have clinical impact that will benefit patients with cancer as we will be developing and choosing to move into the clinic the most successful treatments and combinations therapies.

How will you look to maximise the outputs of this work?

This project is a continuation of a previous 5 year project which has been highly successful in the production of several biotherapeutics and publications. The work has facilitated numerous new collaborations with experts within the immunotherapy communities as well as clinical translation. This project proposal will maintain these collaborations to ensure continuity between the old project and the new.

We will distribute our data through the most appropriate channels, such as by presentations at national and international meetings, publications and public engagement events.

Species and numbers of animals expected to be used

- Mice: 28100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the most appropriate model species for this investigation as they share similar genetic and physical traits to humans. In addition, whilst they are relatively cheap to maintain and have a short life-span, they can be genetically manipulated to use to understand chronic diseases and therefore excellent models of cancer evolution. Since cancer is a predominantly an ageing disease (with some exceptions such as childhood cancers) we will be using young adult mice in this project. The project also requires the use of genetically modified mice strains where the mice have a compromised immune system to prevent the rejection of murine/human cell lines. It is important to biotherapeutic products in human cells so that they are safe for use in clinical practice.

Typically, what will be done to an animal used in your project?

Because we study the immune response to cancer in animal models, the most common procedure in our license is the injection of tumour cells to induce tumour formation. In most cases the injection of tumour cells will be done under the skin or into the blood stream of the animal (with a syringe) without the need of a surgical procedure. In some cases (for

example when studying brain tumour formation), the injection of tumour requires a short surgical procedure (up to 20 minutes per animal). All procedures (injections and surgery) are performed only by trained experts.

Once tumours have formed and reached a defined size the animals will be given either one dose or multiple doses of a therapy (cell or drug) to evaluate their impact in the immune system and potential ability to control tumour growth. Some therapies are given through an injection into the blood stream whilst others require injection under the skin or directly into the tumour.

To determine if a therapy has an impact on the tumour, we measure the growth of the tumours over a period of time that varies with the type of tumour but that ranges from 21 days to a few months). The methods used to measure the size of a tumour depend on whether the tumour is under the skin forming a visible tumour or whether these are located inside the animal (i.e. lung cancer or brain cancer). For tumours under the skin we can measure the length, width and depth of the tumour with a tool similar to a ruler, whilst for tumours located inside the animal we will use imaging techniques similar to those used in patients with cancer and which are considered to be 'non-invasive'

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that have been injected with tumours may in some rare cases experience weight loss. Animals will be monitored 2 to 3 times a week and if an animal experiences 10% weight loss we will monitor its weight daily. In the very rare event that an animal loses 15% weight, it will be humanely culled.

In very rare cases the therapy may induce ulceration at tumour site which can be a consequence of the immune system destroying the tumour. Ulcerative scoring, body condition and animal behaviour will assessed regularly.

Surgical procedures and cell injections can in very rare cases cause internal bleeding or vascular occlusion (occurs when blood is no longer able to pass through a blood vessel). Animals are assessed rigorously during procedures and directly after upon recovery. Any animal showing evidence of bleeding or vascular occlusion will be humanely culled immediately.

If any animal reaches 15% weight loss with at least one other clinical sign, body condition score >3/4 or exhibits any evidence of with 24 hours: neurological changes such as seizure/fitting, respiratory distress, marked piloerection with hunched posture, reduced mobility, pallor, persistent ocular/nasal discharge, or diarrhoea, the animal will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Non-invasive imaging and tumour volume measurements will be used to monitor tumour development and tumour response we have therefore refined our expected impacts/adverse effects as much as possible as we are able to identify small morphological changes in vivo prior to the onset of clinical signs, thereby using much milder disease.

All tumour models and injection routes are routinely used within the group and undergo constant refinement to keep the severity level and potential adverse effects as low as possible. The severity is maintained as moderate due to the need for tumour modelling, surgical implantation and non-invasive imaging.

Expected mortality: In previous experiments we observed a low (0-5%) mortality as a result of these experimental procedures (NB. mortality is mainly from cell injections rather than the experiments as a whole).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to investigate the potential of different biotherapeutics for cancer immunotherapy to target and kill cancer throughout the body. Immunotherapy is dependent on immune cell infiltration and function into tumour tissue which is highly affected by the tumour environment and which organ the tumour is situated in within the body. Cell assays cannot replicate all of the complexities of the solid tumour environment within a host making immunotherapy therapy unpredictable. This proposal aims to address this by applying imaging to monitor immunotherapy in mouse models of solid tumours.

Which non-animal alternatives did you consider for use in this project?

We use in vitro lab assays (examples include cytotoxicity assays; antibody binding assays; organoid and tumour explant models) and bioinformatics such as single cell-sequencing/RNA- sequencing/TCR(T cell receptor)-sequencing to enable us to identify the therapeutic potential of certain immunotherapies. Computation modelling will be used to observe whether certain cancer types will respond to this therapy prior to moving into a mouse tumour model system.

Why were they not suitable?

Although in vitro assays can replicate some of the events present in cancer they do not replicate the biological, chemical and mechanical properties of the body, organ or solid tumour tissue. To optimise biotherapeutic effects on immune cell function and infiltration to tumours their behaviour needs to be monitored within a host with underlying disease. For this reason there is no in vitro alternative to animals that we can consider. Therefore, the use of animal models is essential to understand the intricate interplay between tumour cells, the tumour microenvironment and the entire immune system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate the numbers of animals we will use from data obtained from previous experiments or from the literature. Moreover, with the expansion onto other cancer types, means and standard deviations will be taken from preliminary pilot studies consisting of 3 to 5 animals. The experimental design of these preliminary pilot studies will include appropriate controls to allow the detection of the effect of change of individual variables. Appropriate statistical analysis methods are then applied to the data obtained to obtain our estimates.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All in vivo studies are designed with assistance from the NC3Rs Experimental Design Assistant.

Preliminary in vitro analysis and computational models will be used prior to animal experimental design to reduce the number of animals used. Controlling variability such as animal housing, drug dosage, use of transgenic and immunocompromised mice, age, sex will be taken into account to reduce number of animals and repetition of experimental design. For patient-derived xenografts, the human patient tumour viability will be checked to ensure tumour growth is achieved. Moreover, both flanks can be used to implant human patient tumour rather than single flank, reducing the number of mice used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In establishing a new tumour model, testing drug dosage or assessing a new single to combinatorial biotherapeutic therapy a small number of mice (3-5) will be used as a pilot study where the mice will be assessed and adjustments made to make sure that models

are robust with minimum severity before being applied to a full experimental cohort. This will reduce the total animal number and constantly refines our protocols.

Tissue, such as tumour, spleen, lymph nodes, blood and other organs will be taken for histology, high- dimensional flow cytometry /protein analysis, and ex vivo validation to ensure our therapeutic cells are within the tumour tissue and to confirm the therapeutic effect and off-target toxicity. We ensure that any tissues generated from experiments are archived and stored appropriately therefore ensuring that unnecessary repetition of experiments is not necessary.

As part of good laboratory practice, all experimental designs including data analysis will be approved by the PPL holder before the experiment can start, and a protocol record for each experimental animal has to be kept by the PIL holder which will include the description of the experimental steps, treatments, and animal monitoring.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most appropriate model species for this investigation as they share similar genetic and physical traits to humans. In addition, whilst they are relatively cheap to maintain and have a short life-span, they can be genetically manipulated to use to understand chronic diseases and therefore excellent models of cancer evolution.

The tumour models we have chosen are well documented and well validated to produce reliable results within a moderate severity band. The tumour inductions are short procedures, and therefore the animal recovery is rapid and no adverse effects are expected. Visible tumours will be measured by callipers.

Whereas internal tumours will be monitored and sized by rapid MRI, CT, BLI or ultrasound scans to generate growth curves. Due to this, tumour growth in all settings, will be closely monitored and will not be allowed to reach a point where it may cause any discomfort to the animal.

Why can’t you use animals that are less sentient?

As stated above the mouse is the most appropriate model species for this investigation as they are the lowest animals in the evolutionary tree in which suitable models of human cancer can be carried out.

Host microenvironmental changes during animal development will influence tumour growth and cell behaviour which will continuously alter until adult hood adding unknown variables to the data and may result in irreproducibile data being generated. Adult animals have reached full organ development and therefore removes this variable, also due to size of the animal proposed adult animals are necessary for the procedures required for tumour implantation, drug dosage injection and imaging to be conducted using refined and practised methods.

Tumour models will be generated in adult mice at ages 6 to 12 weeks to ensure tumour reproducibilty and cell therapy as our data has indicated that increased age effects tumour implantation, animal recovery and immune status in some animal strains. Where assessing whether aged immune system affects tumour growth and treatment, mice over 12 weeks will be used.

The aim of this project is to assess immunotherapy in tumour models which are conducted over a period of weeks not hours we are unable to use terminally anaesthetised animals to conduct all aspects of these experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Surgical implantations will be carried out aseptically to reduces any risk to infection. Animals undergoing surgical procedures will receive peri-operative analgesia (pain relieving agents given before or after surgery). Animals will be monitored intensely after surgical procedures and after cell/tissue implantation to check for clinical signs. Directly after the procedure the animals will be constantly monitored until they have completely recovered from the anaesthesia. Animals will then be monitored for the first 20 minutes then after a few hours within the working day and first thing the next morning. If no clinical signs are shown and the wound shows no infection or bleeding then the animals will be monitored 2 to 3 times a week. Needles used for implantation of tumour cells will be sterilised prior to injection to prevent tracking of cells and the growth of ectopic tumours (tumours formed in abnormal sites) .For IV injections and for blood sampling, blood flow to superficial veins will be increased by warming the mice in an atmosphere of 30 C for no more than 10 minutes.

The procedures within this project are run routinely and in our experience animals recover rapidly after surgery and very rarely require further post-operative analgesia after 24 hours except in the case of suture failure where the wound has needed to be re-sutured (within 48 hours maximum after surgery or under NVS (Named Veterinary Surgeon) advice beyond that).

When assessing animals after surgery and tumour implantation the assessment of pain will be assessed using the “grimace scale” (a method of assessing the occurrence or severity of pain experienced by facial expression changes) and will form part of an animals clinical signs assessment. A post surgical/cell implantation monitoring sheet will be completed each time the animal is checked over the first 24 hours using the animals unique identifier code. The monitoring sheets are specific to each of the protocols and cover the expected clinical signs for that protocol.

Animals will be weighed and tumour volumes measured 2 to 3 times a week. Any animal that reaches 10% weight loss will be weighed daily to make sure that it does not exceed the 15% weight loss.

To maintain that animals are not fasted for longer than designated time frame and if food cannot be removed at the desire time we will make sure that a measured number of pellets will be left in the hopper.

Lastly, we will constantly refine our protocols during the 5 year duration being guided by our analysis developments and the support of the NACWO (Named Animal Care and Welfare Officer) and NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All in vivo studies are designed with assistance from the NC3Rs Experimental Design Assistant and will abide by the ARRIVE guidelines. Myself and my group regularly consult the NC3Rs resources available in conjunction with our establishments guidance, training and meetings.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All PPL holders must attend yearly 3Rs meetings. We are committed to the principles of the 3Rs and will continue to seek the support of local NC3Rs representatives.

67. Investigating tick-borne bunyavirus interactions with ticks and how these interactions affect transmission and pathogenesis of viruses in a small animal model

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Ticks, Bunyavirus, Disease, Transmission, Therapy

Animal types	Life stages
Mice	juvenile, adult, embryo, neonate, pregnant
Hamsters	juvenile, adult
Rabbits	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To study bunyavirus associated disease in mouse models.

To understand how the interactions between bunyaviruses and ticks contribute to the spread of viruses and the severity of the disease experienced by mammalian hosts.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ticks are small arachnids of the subclass Acari. They are external parasites and live by feeding off the blood of mammals, birds, reptiles and amphibians. Ticks are divided up into one of two families, the Ixodidae (hard ticks) and the Argasidae (soft ticks), however this proposal will only concern the use of Ixodidae ticks. Ticks have four stages to their lifecycle, namely egg, larva, nymph, and adult. Ixodid ticks generally have three hosts, taking at least a year to complete their lifecycle. Each life stage (instar) requires one blood meal on a suitable host to progress through the life stages. Larvae and nymphs feed on small rodents such as mice while adults preferentially feed upon larger mammals such as dogs, cattle/horse/deer and occasionally humans. Due to their blood feeding nature, ticks are responsible for spreading many diseases that affect both humans and other animal species.

The term “arbovirus” refers to a diverse grouping of viruses that are transmitted by arthropods such as mosquitoes or ticks. Many arboviruses such as dengue virus (DENV), Zika virus (ZIKV) and Rift Valley fever phlebovirus (RVFV) are transmitted by mosquitoes. However, other viruses such as tick-borne encephalitis virus (TBEV) and Crimean-Congo haemorrhagic fever orthonairovirus (CCHFV) are transmitted by ticks. Insects and ticks are classified into distinct subphyla of the arthropods, the Insecta and the Arachnida respectively. The adaptation of individual viruses to spread by specific arthropods has a profound influence on the global distribution of diseases they cause, rate of disease spread and the ways in which we may prevent future outbreaks.

In recent years, we have witnessed a global increase in the incidence of tick-borne diseases and their spread into naïve populations causing potentially fatal illnesses. Data published in 2019, by the United States Centres for Disease Control, show that reporting of tickborne disease has doubled from 22,527 cases in 2004 to 50,865 in 2019.

Viruses such as severe fever with thrombocytopenia syndrome (SFTSV) have recently emerged and been reported in several asian countries (China, Republic of Korea, Japan, Taiwan & Pakistan) in the last five years. Data reported by the Chinese Centres for Disease Control reveal that between 2010 and 2019, there were 13,824 cases of SFTS disease reported in mainland China, including 713 deaths (average yearly case fatality rate of 5.2%). However, case fatality rates have varied between reporting countries from 5.2% in China to 32.6% in the South Korea.

Other viruses such as Bhanja virus (BHAV), produce a febrile illness in humans with photophobia, vomiting, inflammation of the brain and slight or partial paralysis. While Uukuniemi virus (UUKV) only causes a mild 'influenza-like' illness in humans. Unlike SFTSV, both BHAV and UUKV have caused disease in Europe and have been detected in endemic tick species. Currently, the only preventative measure available to treat these diseases is to avoid tick bites.

Despite the clear impact of these viruses on human health, we lack knowledge on many aspects of the basic biology of these pathogens and their invertebrate hosts.

The molecular interactions of tick-borne viruses with the mammalian host are vastly understudied compared to other arboviruses transmitted by sand flies and mosquitoes, while interactions between tick-borne viruses and ticks have been barely investigated at the molecular level at all. Despite causing severe disease and having an increasing global incidence, there are currently few effective antiviral drugs or vaccine candidates available to treat diseases caused by infection with viruses transmitted by ticks. There is also a continuing need to understand how and why these viruses are only transmitted by certain

species of ticks and how the biology and lifecycle of the tick vector contributes to the disease severity experienced by the mammalian host.

Here, our aim is to use small animal models to investigate bunyavirus transmission and pathogenesis using relevant tick species reported to transmit the viruses in nature.

What outputs do you think you will see at the end of this project?

Tickborne disease is placing an increasing burden on human and animal health worldwide. Despite this increase, little work is conducted on how and why pathogens like viruses are transmitted by ticks to other mammals through their bite. We hope to gain new insights into the biological mechanisms of virus transmission from the arthropod vector (an organism that does not cause disease itself but which spreads infection by conveying viruses from one host to another) to its mammalian host. To achieve this, we will need a source of ticks to use for these studies. As obligate ectoparasites that feed on the blood of their hosts, ticks require animals to progress through their lifecycle. We hope that these protocols will establish robust systems to raise and maintain colonies of laboratory reared ticks.

We seek to understand the contribution of the arthropod bite to the severity and spread of a virus within the host animal. We would like to discover the contribution of tick saliva to severity of disease, how viruses are transmitted in a population of ticks feeding on the same animal, how long it takes an animal to become infected following tick bite and finally, how long does it take for an animal to pass the infection on to an unfed tick.

The results of our study will be disseminated in the form of publications, presentations at meetings, and through press releases and other social media platforms.

Who or what will benefit from these outputs, and how?

These research outputs will be published in leading interdisciplinary journals so that they can be used by a variety of research and health professionals. The short-term benefits will primarily be specific to scientific researchers investigating tick-borne viral diseases.

Medium to longer term beneficiaries will include other researchers studying a variety of tick-borne pathogens or scientists/industry partners that are looking to develop anti-tick vaccines or therapeutics using live ticks.

The overall impact and goal of such work is to reduce the global burden of tick-borne viral disease.

How will you look to maximise the outputs of this work?

We will have extensive collaborations with entomologists (studying insects), acarologists (studying mites and ticks) and virologists (studying viruses). We will disseminate new knowledge in the form of publications, presentations at meetings, and through press releases and other social media platforms.

Species and numbers of animals expected to be used

- Mice: 2000
- Hamsters: 150
- Rabbits: 30

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

The types of animals to be studied in this licence (mouse, hamster & rabbit) have been chosen as they are natural hosts for ticks in the wild. Ticks feed on increasingly larger animals as they progress through their life stages, and this is reflected in the animal use described.

The reason for the use of a wide range of animals used is two-fold: Firstly, as ticks mature through their life stages, they feed on increasingly larger animals. Tick larvae will feed on small rodents such as mice, whereas adult ticks will feed on larger animals such as rabbits; Secondly, if we find that the laboratory ticks do not bite/feed upon on a particular species of animal, we will need an alternative species to conduct experiments with. Pilot studies will be conducted to determine which species are preferred by our tick colonies and in time the licence will be amended to remove the species that are not needed.

Furthermore, previous work conducted has determined genetically modified mice bred to be deficient in the interferon alpha/beta receptor (IFNAR-/-) to be a robust model for tick-borne viral disease. This will be important for the assessment of the contribution of tick bite and saliva to viral pathogenesis.

The choice of juvenile and adult life stages of the host animals is based on published reports describing their suitability for tick feeding to maintain healthy tick colonies.

Typically, what will be done to an animal used in your project?

Animals will be infested with a strictly controlled number of ticks to allow them to take a blood meal. In some cases, the ticks or animals may be previously infected with bunyaviruses.

Animals may be administered drugs, tick saliva, antibodies or viruses prior to, during or after tick feeding.

Typically animals will be on procedure for 30 days. However, mice receiving primary and/or booster inoculations with vaccine candidates prior to tick infestation will be on procedure for up to a maximum of 90 days.

At the end of all procedures the animals will be euthanised and tissues and organs will be harvested for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Some procedures are associated with mild severity rating and animals are not expected to suffer above and beyond anything that would not normally be experienced through tick infestation in the wild. Ticks secrete components in their saliva to prevent the host animal feeling pain or generating an inflammatory/itch response associated with the biting event. Also, ticks only take a blood meal once each life stage (instar), therefore we do not expect an individual tick to bite the host animal multiple times. Animals will not be exposed to ticks

more than once, repeated exposure may be detrimental to the feeding tick due to the generation of an immunological response in the host animal.

We therefore do not believe tick infestation will cause anything above moderate distress. When animals are infected with viruses, either directly using a needle or through the bite of an infected tick, we expect the animal to experience weight loss, piloerection, hunching or tremoring. We do not expect any adverse signs in any animal to exceed moderate rating. Any animals showing 3 moderate signs, or any single severe sign will be humanely killed. Animals undergoing all procedures will be monitored carefully and regularly by the personal licence holder to minimise distress and suffering.

All substances (such as viruses, antibodies or immunomodulatory agents) will be administered at doses known to be non-toxic, based on the availability (in the literature or otherwise) of their toxicity profile, and also based on their in vitro cytotoxicity profile. Pilot studies will be used where previous data is unavailable.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most procedures to be carried out are associated with a mild severity rating. For animals (mice, hamster or rabbit) infested with ticks, we would expect 95% or more of animals to experience mild severity. The number of ticks applied to an animal will be calculated to ensure that animals never experience anaemia due to blood feeding.

Mice are the only species that will be used for infection studies. For mice that we have infected with viruses (either directly or using a previously infected tick), we estimate approximately 50% of mice to experience mild severity and 50% of mice to experience moderate severity.

We do not expect any animal to exceed a moderate rating. Any animals showing three or more moderate or any advanced signs will be humanely killed.

What will happen to animals at the end of this project?

- Killed Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ticks and other arthropods (an animal with an external skeleton that lacks a backbone) are ectoparasites (a parasite that lives on/in the skin) of mammals by nature. They require to feed on the blood of a host mammal for their survival and for the progression through each of the different life stages (larvae, nymph and adult). The mammalian host varies between different tick species and even between different life stages. For example, Ixodes ricinus

(the castor bean tick) will feed on small rodents such as mice, birds, rabbits, reptiles and bats during the larval and nymphal life stages, whereas adults feed on large mammals such as sheep, cattle, dogs, deer, humans, and horses.
Therefore, to raise large and healthy colonies of ticks it is preferable to allow them to feed as naturally as possible within a laboratory setting.
For the disease pathogenesis and transmission work, only living animals can exhibit the complex interactions between cells in tissues, the immune system and the virus, which together, help determine how the virus can spread in different tissues and organs, and how it causes the disease. Therefore, animal models that mimic human disease are crucial in studies designed to understand the disease process and how viruses are transmitted from the tick vector to the mammalian host. The viruses used in these studies cause illness in humans, these studies will not provide improvements to our understanding of animal disease.

Which non-animal alternatives did you consider for use in this project?

Several groups have developed artificial feeding systems for some species of ticks. These systems allow for a small number of ticks to bite through artificial (plastic or silicone) membranes placed over small chambers of animal blood. These chambers can then be spiked with virus to allow ticks to take a virus-infected blood meal. We will use such systems to infect ticks with viruses to study the replication kinetics and infection biology of the virus within the tick itself. These chambers only allow small numbers of ticks to be maintained in the laboratory and are not suitable to sustain a colony for research purposes.

Cell culture systems can be used to perform biological analysis of the viruses in question in the context of infection.

Why were they not suitable?

Thus far, it has not been possible to develop membranes thin enough to facilitate biting and feeding of larval ticks. This is due to the very small mouth parts present on the tick in this juvenile life stage. This process will therefore only be useful for the nymphal or adult life stages of some tick species. Other reasons for not adopting this system are the very low attachment and engorgement rates for feeding ticks in this artificial setting. Even with fresh blood samples, thin membranes and chemical stimuli (such as host pheromones), artificial feeding rates are not considered robust enough to support the establishment of tick colonies. There are still some intrinsic limitations to the technique, including rearing many ticks, feeding efficiency, and tick fitness.

While considerable progress in the in vitro tick feeding of Ixodes ricinus was made by the development of an artificial tick feeding system using silicone membranes the attachment and engorgement rate of ticks fed on artificial membranes is lower than ticks fed on experimental animals and artificially fed ticks showed a decreased ability to produce new offspring. Also, the addition of antibiotics to sterile blood meals alters the tick gut flora with unknown consequences for pathogen transmission.

For Haemaphysalis longicornis, the only reported artificial feeding systems involve the use of a membrane made from mouse skin not silicone.

For Rhipicephalus sanguineus, larvae and nymphal ticks were not able to bite through the silicone membrane due to their comparatively smaller mouth parts than I. ricinus and

adults were only fed on artificial membranes for experimental studies. The R. sanguineus ticks used in these studies were originally derived from a laboratory colony that had been fed for several generations on laboratory rabbits or laboratory-bred beagle dogs to be able to provide sufficient numbers to conduct the studies.

From an ability to cause disease and spread of viruses perspective, cell-based systems are useful in advancing our knowledge on the basic processes related to the molecular biology and replication of bunyaviruses, they do not mimic many aspects of the complex multicellular environment of tissues and organs of living animals. Transmission studies of arthropod-borne viruses can only be conducted in the presence of the arthropod (tick) and its host.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For hamsters and rabbits, numbers have been based on experimental usage of external collaborators over the past 3-5 years. Collaborators have maintained a medium-sized tick colony using these numbers.

Numbers of animals needed has been back calculated from the number of ticks required. Tick numbers predicted to be obtained from infesting one hamster with 2 adult ticks or one rabbit with 50 adult ticks (performed in one, single infestation event) would be ~30 adult ticks (hamster fed) or ~780 adult ticks (rabbit fed). Each life stage or feeding is calculated with a 50% success rate imposed at each stage of development (we predict this is the minimum success reasonably expected). We believe the numbers of animals used will be sufficient to sustain the population of ticks needed for these studies, along with supplementation from field caught ticks.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We sought advice from biostatisticians to determine the animal group sizing.

Data from previous cell culture and animal work also has informed experimental design. For example, the amount of virus administered or the pre-treatment of animals with anti-interferon (IFN) antibodies to permit infection with some viruses.

These prior data mean a reduction in the number of animals used for infection experiments can be achieved to resolve our scientific questions. This can be further refined as new data are obtained.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have factored in sharing of tissues where appropriate with our collaborators to minimise the number of animals in the study.

We will conduct pilot studies to ascertain the feeding preferences of the different life stages of the three tick species to be used in this study. If it is observed that one or more of the tick species do not feed appropriately on a given animal type, the number of those animals used will be reduced. In the event that no tick species bites a given animal species, that animal species will be removed from the project licence.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse, hamster or rabbit animal models to establish our tick colonies as these are representative species that Ixodid ticks feed on under natural conditions.

Mice will be administered with antibodies, drugs or attenuated virus vaccine candidates prior to, and/or after, infection with bunyaviruses.

Animals will be typically on procedure for up to 30 days.

At the end of all procedures the animals will be humanely killed, and tissue and organs will be harvested for analysis as described below.

All protocols are designed to cause the least pain and suffering to the animals.

Why can’t you use animals that are less sentient?

The animals chosen are the least sentient animals that are suitable for our studies. Ticks are ectoparasites that feed on the blood of the host animal. Different tick species and tick life stages feed on a range of animals from small rodents to larger animals such as rabbits. We aim to replicate the natural feeding and biting behaviours of the ticks in our colony by allowing them to feed on animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be monitored daily and will be humanely killed if necessary, following veterinary advice. We will use local AWERB and other guidelines for dosing and for blood sampling, establishing clear humane endpoints, monitoring animals frequently, not allowing infections to develop into severe illness.

We will impose strict limits on the number of ticks that can be applied to an animal (based on the amount of blood withdrawn) and limit an animal to only one round of tick biting.

Animals on procedure will be given housing enrichment and additional ‘treat’ food (e.g. baby food for mice, as necessary) to improve their welfare while infested.

All laboratory animals will be handled using non-aversive methods as this has shown to have a positive effect on scientific data due to a reduction in baseline stress and anxiety of the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office and NC3R guidelines and those published such as:

Carbone and Austin (2016) Pain and Laboratory Animals: Publication Practices for Better Data Reproducibility and Better Animal Welfare. PLoS ONE 11(5): e0155001. doi:10.1371/journal. pone.0155001.

Percie du Sert et al. (2020) The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research. PLoS Biol 18(7): e3000410. https://doi.org/10.1371/journal. pbio.3000410.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Keeping abreast with any new information and guidelines through the NC3R website and through our animal facility. We will constantly liaise with the animal facility staff and attend relevant presentations from them to ensure that we are up to date with the information and that they are implemented.

68. Neural mechanisms of pain control

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Pain, Nociception, Affect, Neuromodulation, Sensation

Animal types	Life stages
Mice	juvenile, adult, pregnant
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify neural mechanisms generating the sensory and behavioural dimensions of acute and persistent pain and develop neuromodulation strategies to control pain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Persistent pain is a major problem for patients, healthcare providers and society. Current treatments lack efficacy and can cause harm, as has occurred with the ‘opioid epidemic’ in which pain treatment has led to addiction resulting in many tens of thousands of deaths, particularly in the USA but also worldwide. There is a lack of effective treatments to alleviate persistent pain and therefore an urgent need to improve understanding of its underlying cause and identify novel interventions to mitigate it, such as harnessing the

brain's own pain-relieving process as part of a therapeutic strategy. The work conducted under this licence aims to advance understanding of the mechanisms responsible for persistent pain, identify new treatments and translate these into the clinical setting. The findings of the outlined studies will be of value to pain neuroscientists, patients, clinicians and industry.

What outputs do you think you will see at the end of this project?

The anticipated benefits of the study will be to advance understanding of:

The specific neural pathways within the CNS involved in pain perception and how these become altered in states of persistent pain.

Neuronal mechanisms of pain control and why they fail in persistent pain.

The mechanisms by which pain alters cognition.

In so doing the work aims to identify more effective ways of treating persistent pain and to progress these towards the clinical setting.

Who or what will benefit from these outputs, and how?

The chief beneficiaries of the study outputs will be the academic, clinical and industrial research communities, who will use the knowledge to drive future research, deploy new diagnostic approaches and to inform drug and therapeutic discovery strategies. Information generated will be published in high impact peer-reviewed journals (as well as on preprint servers like BioRxiv) and presented to appropriate audiences at national and international meetings. We will communicate our findings at public and patient engagement events and include patients as research partners during the development of our research strategies. We expect that our outputs in the long term will benefit pain patients and the wider society.

How will you look to maximise the outputs of this work?

We will continue to collaborate with academic research colleagues at both a national and international level to best exploit our research findings – the majority of our work involves international collaborations. We have plans in place to continue to work with industry partners in the pharmaceutical industry. We will disseminate our research through traditional peer reviewed publication and scientific meetings but will also publish our research (successful or otherwise) as open access pre-prints and will share the data via appropriate repositories. We will present to the public and at patient engagement events. We will protect any intellectual property so that it can be developed commercially and turned into treatments.

Species and numbers of animals expected to be used

- Mice: 2,400
- Rats: 2,250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents have been chosen for these studies because they have the least neurophysiological sensitivity as species within which pain-related behaviours that mirror aspects of human pain can be modelled. Rodents share many of the anatomical and physiological aspect of the human nervous system and consequently have been used extensively in similar studies worldwide. Non-mammalian species (e.g. arthropods and zebra fish) are not appropriate as they either lack many of the brain structures of interest or, if present, lack the organization and connectivity with higher centres that we seek to understand. Additionally, they have different neurochemical mediators and distinct receptors, so their pharmacology is often not directly comparable to human.

Both mice and rats will be used for the outlined studies. Mice offer the advantage of ease of genetic manipulation, which facilitate the study of specific populations of neurons. Rats on the other hand offer advantages for pain behavioural studies in that they are calmer, more inquisitive and are better able to train and perform in assays of cognitive functions. Additionally, their larger size offers advantages for some types of electrophysiological experiments

Typically, what will be done to an animal used in your project?

The majority of animals will undergo a surgical procedure, most commonly a small burr hole craniotomy, typically for injection of a viral vector or introduction of a fibre optic probe or electrode. In cases where viral transduction is required, animals are returned to a group housed environment for 2-4 weeks (to enable sufficient expression of effector proteins). Animals with implants will initially be singly housed until the skin around the implant is healed (2-3 days) before being returned to group housing. A subset of the animals (20%) will have sensitisation of an area (typically hindpaw) by either nerve injury or administration of an inflammatory agent to produce a validated model of neuropathic or inflammatory pain (lasting up to 12 weeks which is necessary to see the stable expression of the sensory and affective phenotype).

Animals having behavioural testing / neuronal recordings (30% of animals on the protocol) will have sessions of acclimatisation to behavioural apparatus. They will have tests of different sensory modalities (e.g. touch – with a fine filament, brush, heat - from an infrared illumination, cold - from an acetone drop) applied at different intensities until they show withdrawal responses. This sensory testing will not involve more than 48 stimuli per session, with no more than one test session per day. Across the duration of the experiment (maximum of 12 weeks) there will be no more than 20 sessions in total.
This will allow precise assessment of sensory function across several modalities and its response to interventions such as analgesics during a single testing session and how that may change with the development of a pain model. The animals may have activation or inhibition of neuronal circuits using pharmacological or optogenetic methods and the effect on nociceptive processing or pain associated behaviours will be assessed before, during and after the intervention.

Some of the animals (10%) will have their food intake limited to 90% of their normal intake. This is to motivate the performance (using food rewards - appetitive behaviour) on operant tasks to test affective bias and decision making. They will only be fasted for the period of

training and conduct of the assays. They will have free access to water. The typical length of behavioural training is 4 days of familiarisation followed by a maximum of 21 days of task acquisition. The upper length limit is 48 days of task acquisition/behaviour.

At the conclusion of the study the animals will be killed via a Schedule 1 or non-Schedule method as appropriate. Some animals (20%) will have recording of neuronal activity to assess the responses to application of sensory stimuli while under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals on this project will have recovery anaesthesia for surgical procedures (60%). The animals are expected to recover uneventfully from the general anaesthesia and surgery and to resume normal behaviour within 24 hours.

The food restriction regimes used are not expected to adversely affect the wellbeing of the animals.

Some animals will experience pain following induction of sensitisation by either nerve injury or administration of an inflammatory agent as part of an experimental pain model of human disease (10% of mice and 25% of rats). They will typically show a degree of gait alteration with less weight bearing and sporadic spontaneous foot lifts / attending to the sensitised paw. These animals will continue to interact socially, to be mobile and able to self care and are not expected to lose weight. The condition and welfare of these animals will be carefully monitored throughout to ensure that they do not exceed a moderate severity level. Any animal deemed likely to exceed that severity limit will be killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Rats
- Non recovery 20%
- Mild 10%
- Moderate 70%
- Mice
- Non recovery 35%
- Mild 25%
- Moderate 50%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Each of our objectives has at its core the study of pain, sensation and its regulation with a focus on identifying treatments with the potential for translation into a clinical setting. Pain is the product of integrative processing by many classes of neuron both peripheral and central. Even the somewhat simpler process of pain perception cannot be adequately represented in reductionist in vitro models nor in silico given the complexity of the cellular and molecular specialisation and the impact that the sensory neurones have upon much of the neuroaxis. The aim of this study is to integrative physiological processes (for example the transition from acute to chronic pain) that are controlled by the central nervous system and which cannot be adequately recapitulated in anything other than intact animals

Which non-animal alternatives did you consider for use in this project?

We considered computer modelling and recordings from cultured cells such as stem cell derived neurons as alternatives. We also considered the use of human models. We use these for some studies and these have advantages in being able to directly link the findings to pain percept. Several of our research objectives aim to improve the ability to record in humans in the future.

Why were they not suitable?

Computer modelling requires biological data to build informative models and make accurate predictions – at present there is no model of any aspect of the pain pathway that has any predictive validity. Cell cultures cannot be used to make inferences about pain as this requires an intact nervous system integrating information from many sources. Human studies have clear limits in the ability to isolate and control the experimental conditions (through exposure, insertion of recording and stimulating electrodes and the use of genetic and pharmacological tools to probe neuronal circuits) to definitively identify neuronal mechanisms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have considerable experience in the conduct of pain experiments and the use of stimulation paradigms, recording methods and behavioural assessment. We have used this information to estimate the numbers of animals needed. For the GM colonies this has been scaled to take account of whether the strain of animals will be homozygous or heterozygous for the gene of interest. For definitive pain studies, where an intervention is made to reduce a pain-like behaviour, we have taken a meaningful effect as being a 30% change in the response (based on IMMPACT guidance). For studies using new methods

or models we have used data from the literature. For novel interventions we will run pilot experiments and use the data to estimate the group size required for definitive studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will make extensive use of within animal controls which immediately halves the number of animals needed for a study and also reduces the variance so increasing the power to detect effects. We will use inbred strains of animals to further reduce variance. The methods we are developing such as multi-unit peripheral nerve recording will further reduce the need for animals as they have a greater yield of data than conventional recording approaches. We will use animals of either sex and will stratify on this variable in our analysis to identify any sex specific differences. We use standardised surgical approaches and follow defined protocols for the application of defined stimuli and behavioural testing.

We make use of the NC3Rs experimental design assistant when planning our investigations and making proposals to funders.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible we will use homozygote lines of GM mice. We will make use of pilot studies for any new experimental protocols. Tissue from animals will be used for in vitro experiments such as brain slice recordings or skin-nerve preparations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a number of well-established rodent pain models (such as nerve injury models of neuropathic pain, skin incision models of post-surgical pain and inflammatory models of mono-arthritis) that are closely comparable to aspects of human pain conditions with translational validity. We will make standardised assessments of the animal's sensory responses using carefully titrated stimuli and also make observations of their behaviour and decision making to assess the impact of pain on cognition. For studies of pain, information will be gained from experiments in non-sensitised animals, which will be used to inform the design of experiments in models of chronic pain. This approach will minimise the numbers of animals used. In all cases the least severe model, consistent with obtaining the necessary data, will be used. For each protocol we have clearly defined humane end points. For some animals we will assay their cognitive and behavioural responses and in these cases the period of sensitisation will be kept to the minimum that is scientifically meaningful while also ensuring that longitudinal observations yield the maximal amount of useful data.

Why can’t you use animals that are less sentient?

Rodents have been chosen for these studies because they constitute the least sentient species within which human pain-related behaviours can be modelled. Non-mammalian species (e.g. arthropods and zebra fish) are not appropriate as they either lack many of the brain structures of interest or, if present, lack the organization and connectivity with higher centres that we seek to understand. Additionally, they have different neurochemical mediators, ion channels and distinct receptors so their pharmacology and physiology is often not directly comparable to human. Rodents share many of the anatomical and physiological aspect of the human nervous system and consequently have been used extensively in similar studies in many other laboratories worldwide. We will make use of terminally anaesthetised experiments for some measurements – particularly electrophysiology. By combining experimental approaches using investigations wherever possible in reduced preparations e.g. brain slices to address some of the cellular and circuit level questions in combination with targeted genetic approaches we will be able to minimise the numbers of procedures and the burden on sentient animals. Additionally, we will only progress to assay interventions in behaving animals that we have shown to be effective in these ex vivo experiments on electrophysiological / histological measures of nociceptive sensitisation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have refined and developed our approaches. The animals used in these studies will be acclimatised to the unit prior to any procedure. Surgery will be performed aseptically under general anaesthesia with appropriate post-surgical analgesia. Animals will be closely monitored and allowed to fully recover after surgery before any subsequent procedures (unless post-surgical pain is the variable of interest). The surgical procedures and implants for our chronic recording experiments have been refined over many years to minimize their severity and to reduce the numbers of animals required to meet our objectives. Animals will be group housed (whenever possible) with environmental enrichment. Animals will be monitored for signs of distress or weight loss, and will immediately be removed from the study if these are detected. For experiments in which conscious animals are necessary, we carefully monitor them throughout all sessions.

We continually seek to refine our experimental approaches to keep up with the state of the art in our research field. We have been early adopters of new methods (such as chemogenetics) that have allowed improved, more powerful experimental designs using within animal comparisons and reduced need for implants. We have also introduced high density neuronal recording systems that has increased data yields and reduced the numbers of animals needed for experiment. By monitoring spontaneous rather than evoked behaviour and using automated assessments based on video recording we have sought to both reduce stress and make behaviours more naturalistic. During the course of this project licence, we expect this process of refinement to be continually embedded in our thinking about experimental design and methodological improvement. We will consult with NVS/NACWO throughout the duration of the project and will regularly review the options for refinement of our procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidance to improve our reporting of research using animals, maximising information published and minimising unnecessary studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are members of academic societies that have a clear focus on 3Rs and experimental approaches for the study of pain and physiology. We attend and present at 3Rs events along and are informed by the regular circulation of information from the NC3R's and keep abreast of developments at www.nc3rs.org.uk.

69. Immunotherapy of amyloidosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Amyloidosis, antibodies, immunotherapy, type 2 diabetes, Alzheimer's disease

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Amyloid is an abnormal material, derived from the body’s own substances, that accumulates within the body causing a number of different diseases. The body removes amyloid very slowly, if at all. We have previously shown that amyloid removal can be accelerated by administration of antibodies directed against it. Antibodies are the proteins the body produces to protect against bacteria and viruses by clearing them from the blood and tissues. We have designed novel antibodies intended to clear away amyloid from the tissues and thereby benefit patients suffering from diseases associated with amyloid. This project aims to demonstrate this desirable activity in vivo, to identify the most effective of such antibodies and to characterise their mode of action so that they can be developed into new medicines for treatment of patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Amyloidosis is a relatively rare but inevitably fatal disease, caused directly by amyloid deposition in the tissues. It kills about one person per 1,500 who die in developed countries. In contrast, type 2 diabetes and Alzheimer's disease, which are also associated with amyloid deposits, are extremely common and carry immense medical, social and economic costs. Treatments for amyloidosis are limited, are often dangerously toxic and do not exist for some forms of the disease. Treatment of type 2 diabetes is challenging and often poorly effective. There is no disease modifying treatment for Alzheimer's disease. These conditions are thus all major unmet medical needs. Our invention of a new approach to treatment, using antibodies, offers a unique opportunity to stop amyloid-related diseases from getting worse, thereby reducing illness and saving lives.

What outputs do you think you will see at the end of this project?

The primary output will be identification of new antibodies that are most effective foramyloid removal and the characterisation of their mode of action in vivo. This new scientific information will be widely shared by publication in high impact scientific journals and presentation at national and international scientific meetings.

The secondary, but vitally important, output of the project will be the information essential for ongoing development of one or more selected antibodies towards clinical testing in patients. The cost of successful development of a new medicine from its invention to its registration as a licensed medicine is around £500 million to £1 billion. Securing this scale of investment demands very compelling evidence of the target validity and the safety and efficacy of the proposed intervention. The results of the present study will comprise the crucial initial evidence.

Who or what will benefit from these outputs, and how?

In the first months the outputs will be new scientific information on the capacity of unique new antibodies to promote regression of amyloid deposits in vivo. If positive results are rapidly obtained, the mechanism of the treatment effect will be characterized within one or two years. This knowledge will be widely shared in the scientific community. Meanwhile the results will enable ongoing development of the optimal antibodies into potential medicines for clinical testing in patients with the fatal, largely untreatable, amyloid-related diseases. If the programme is successful, the effective disease modifying new treatment that will emerge, potentially within 2-5 years after the end of the project, will reduce illness and suffering, retain and restore quality of life, and prolong life in some of the most intractable diseases. Successful modification of the prevalent diseases, type 2 diabetes and Alzheimer's disease, will also carry massive social and economic benefits for humanity and society in general.

How will you look to maximise the outputs of this work?

All positive new knowledge obtained in the project will be widely disseminated as soon as possible via the scientific and medical literature, national and international meetings.

Positive results will also support the resourcing essential for medicine development. The ultimate purpose of the study is to create new medicines to reduce morbidity and mortality in both rare and prevalent diseases that currently lack effective disease modifying treatments and are therefore major unmet medical needs.

Very importantly, we will also publish all negative outcomes. If the newly created antibodies either do not promote amyloid regression in vivo and/or are not safe and well tolerated, we will ensure that this information is widely and readily available when the programme is abandoned.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Amyloidosis is exclusively a disease of adults. It does not occur before adulthood in humans or in any other species. Adult mice, with mature, fully developed systems, are therefore appropriate for this study and mice are the only experimental animals in which forms of systemic amyloidosis can be induced that resemble the human disease closely enough to be informative. Furthermore, the mouse models have been extensively refined to minimise harm to the animals and reduce the numbers used.

Untreated human systemic amyloidosis causes progressive organ failure and is inevitably fatal. Even with the best available treatments, up to 25% of human patients with systemic amyloidosis still die within 6 months of diagnosis. However, in contrast, the amount of amyloid formed in the refined mouse models is very limited and the mice develop no symptoms nor any clinical or biochemical signs of organ damage.

Past use of the mouse systemic amyloid A type amyloidosis model has directly enabled major improvements in the diagnosis and treatment of amyloidosis worldwide. Our unprecedented new transgenic mouse model of systemic human transthyretin (TTR) amyloidosis (ATTR) incisively extends our ability to develop improved treatment for what has lately been recognised as probably the most prevalent form of human systemic amyloidosis.

Median survival in human systemic amyloidosis in 1979 was 15-18 months from diagnosis, whereas it is now almost 10 years in the best specialist centres. Nevertheless, with about one in four patients with systemic amyloidosis still dying within 6 months of diagnosis, new treatment to save these lives, such as this project aims to develop, is urgently required. The present mouse models also provide unique proof of concept information directly relevant to potential applications of the new treatment in all the different forms of human amyloid related diseases.

Typically, what will be done to an animal used in your project?

For induction of amyloid A type amyloidosis, each animal will receive a single intravenous (IV) injection of so-called amyloid enhancing factor, followed by 10 daily subcutaneous (SC) injections of 10% casein in saline, spread over two weeks. All the mice have developed systemic amyloid A type amyloidosis by the end of the course of casein injections. Control mice receive no further treatment. The experimental mice receive one intraperitoneal (IP) injection of the putative therapeutic antibody. All animals are humanely killed between 1 and 28 days after the antibody dose. In some protocols the mice also receive either one IP injection of an innocuous isolated pure protein in saline solution, or three innocuous IP injections of liposomal clodronate before being killed.

All injections will be administered to conscious animals. Amyloid enhancing factor is an extract of amyloidotic mouse spleen, containing amyloid fibrils which serve to trigger new amyloid formation in vivo and thus greatly accelerate and enhance systemic amyloid deposition in the recipient mice. This enabled powerful refinement of the mouse model, notably reducing the number of animals needed and the duration of each study.

For induction of transgenic human ATTR amyloidosis, each transgenic mouse expressing the amyloidogenic S52P human TTR variant on the mouse TTR and α2 antiplasmin gene deletion background, will receive one IV injection of human ATTR fibrils to seed systemic deposition of human ATTR amyloid deposits. All mice develop the desired amyloid deposits, especially in the heart, by 3 months after seeding. At this point, some test mice will receive isolated pure human serum amyloid P component (SAP) by IP injection, an innocuous normal human plasma protein, in saline solution, followed 24 hours later by polyclonal IgG antibodies against human SAP by IP injection. Other test mice will receive one of the new putative therapeutic antibodies by IP injection. Control mice receive no treatment after the seeding injection. All mice are killed 14-28 days after the antibody injection.

What are the expected impacts and/or adverse effects for the animals during your project?

The subcutaneous casein injections produce local chronic inflammation with slight thickening of the skin but no lasting effects and no related unusual behaviours. None of the other materials being injected cause any clinically appreciable adverse effects and we

have never observed distress beyond that associated with restraint and the transient discomfort of the injection itself. There is no weight loss or abnormal behaviour.

The amount of amyloid that will be deposited in the tissues is consistently below the threshold of organ damage and clinical disease and does not affect the natural life span. Amyloid A type amyloid is principally in the spleen and liver with variable small amounts in the kidneys but there is no impairment of liver or kidney function and splenic amyloidosis is clinically silent. The transgenic human ATTR amyloid deposits similarly do not cause clinical illness. However, the amyloid load in both models is sufficient to enable its reduction by our treatment to be sensitively and precisely detected. All mice will be humanely killed promptly at the end of each of protocol.

Antibody treatment was invented and developed specifically to safely remove amyloid deposits from the tissues and this is exactly what happens. Extensive studies in the mouse model happily showed no adverse effects at all. Furthermore, translation of the invention into a treatment for human patients with systemic amyloidosis was safe and well tolerated and produced unprecedented, clinically beneficial, removal of amyloid. The new and completely different antibodies that will be tested in the present project are designed to be inherently even safer than those investigated previously as well as more effective and with a broader range of action. No adverse effects are expected but if they occur, the antibodies responsible will not be tested further.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 100% mild severity category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Amyloidosis is a very complex disease in which the body's own proteins form abnormal fibres, called amyloid fibrils, that accumulate and persist in the space between and around the cells of tissues and organs. The body has very efficient mechanisms that normally remove all dead cells and protein debris from the tissues but amyloid is not adequately cleared in this way. Amyloid deposition disrupts the normal structure of the tissues, damaging their functions and causing disease. Reducing the rate of amyloid accumulation

can arrest disease progression and sometimes restore damaged organ function, providing clinical benefit. However, most of the available treatments for amyloidosis are invasive, potentially lethally toxic and/or of limited effectiveness. There are no treatments at all for some forms of amyloidosis. There is therefore an urgent need for new treatments that swiftly and safely remove amyloid from the tissues. The present project aims to develop such treatment but its potential efficacy in living patients cannot be demonstrated by in vitro studies.

The critical steps required for effective amyloid removal are as follows. Firstly, the antibodies introduced into the circulation must reach the amyloid deposits in the tissues and bind specifically to them. Secondly, the bound antibodies must efficiently activate an extremely complex system of different interacting blood proteins, called complement, that the body uses to remove unwanted materials from the tissues. Thirdly, complement activation must attract a specific subset of cells, called macrophages, that patrol the tissues to conduct waste disposal, so that they accumulate around the deposits. Fourthly, these macrophages must then fuse together to form huge giant cells. These are the only cells in the body capable of surrounding, engulfing and destroying the massive amyloid deposits of systemic amyloidosis.

This extremely complex interlocking series of processes, deliberately set in motion by the antibodies, cannot be replicated in vitro. In vivo testing is essential to establish that the antibodies can reach and bind to amyloid deposits in the living mouse. Complement is an extremely complex, highly dynamic system of at least 21 different interacting proteins, the full relevant activities of which cannot be precisely reproduced in vitro. There are many different types of macrophages and, although some can form giant cells in vitro, there is no evidence that these artificially created cells have the same functions as the authentic cells that form in vivo in response to the antibody treatment. The present, newly created antibodies have been designed to be safe and optimally effective in amyloid clearance but the only possible way to demonstrate these properties, and thus to justify their eventual clinical testing in humans, is to perform the planned in vivo studies in mice.

Which non-animal alternatives did you consider for use in this project?

The novel antibodies to be tested have been selected in vitro from a phage display library, without any animal involvement. They have been created by recombinant technology in the desired antibody class known to activate the complement system because that is the proven basis of our treatment invention. They have been expressed by cell culture with no animal involvement. This is the limit of what can be achieved without testing in living animals.

The objective of the present project is to identify one or more of our novel antibodies that may be suitable for development as drugs to remove amyloid deposits from the tissues of patients. Amyloidosis itself and the many, different, interacting processes involved in the mechanism by which our intended treatment works in the intact living body, are extremely

complex. They cannot be usefully represented by cell or tissue culture studies. Thus no non-animal alternatives for this project exist.

Why were they not suitable?

There is no non-animal alternative for demonstrating that, after introduction of the antibodies into the circulation, they will bind to amyloid deposits in the tissues, activate complement and attract macrophages to the site, nor for investigating the antibody dosage required to produce these effects in the whole living animal. There is no non-animal alternative for demonstrating that the attracted macrophages will fuse into giant cells with the unique ability to surround, engulf and destroy the amyloid. There is no non-animal alternative for demonstrating that these desirable processes can be activated safely in the intact living animal. Robust relevant evidence of this safety and efficacy is essential to justify the development of appropriate antibodies towards clinical testing in human patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animal numbers are based on extensive published experience with the present disease model. All mice, treated as described here, develop amyloidosis. The numbers of 10-12 mice in each test and control group are the minimum necessary to yield statistically significant differences when the antibody treatment is at least 50% effective in removing amyloid. The PREPARE guidelines and the NC3Rs (design assistant) website guidance will be followed when possible and the studies will be appropriately blinded and randomised.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our mouse amyloidosis models very closely resemble different forms of the human disease. Indeed, as animal models of a complex human disease, they are almost uniquely similar to their human counterpart. Induction of amyloid A type amyloidosis, in mice as in humans, depends on sustained production by the liver of greatly increased amounts of the circulating blood protein, serum amyloid A protein (SAA). This increased production is an automatic response to acute and chronic inflammation. In the mouse, the least severe effective inflammation is elicited by a series of SC injections of casein.

In contrast with variable and unreliable induction of experimental mouse amyloidosis by other groups using 6 weeks of daily casein injections, we have refined the method by using amyloid enhancing factor, an extract of amyloidotic tissue containing preformed amyloid fibrils, to accelerate amyloid deposition. In addition, we have used our novel non-invasive whole body imaging procedure to confirm the presence and amount of amyloid without subjecting mice to unnecessary procedures. We have thereby greatly reduced the number of injections, increased the efficiency of amyloid induction to 100% and thus substantially reduced mouse numbers in all experiments.

Our new mouse model of human ATTR amyloidosis, similarly closely replicates key aspects of human hereditary systemic ATTR amyloid caused by amyloidogenic mutations in the human TTR gene. In particular, the presence of ATTR amyloid deposits in the myocardium is critically important and our design, including both overexpression of the transgenic amyloidogenic TTR variant and knock down of α2 anti-plasmin, delivered 100% efficiency in speedier production of larger amounts of amyloid. This contrasts with all other mouse models claimed to be representative of human ATTR amyloidosis and substantially reduces the number of animals to be used in this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. All mice used for study of amyloid A type amyloidosis will be purchased from the leading licensed suppliers(s) of experimental mice routinely used by the facility where the project will be conducted. We are relying on their conduct of responsibly efficient breeding. The minimal necessary numbers of transgenic mice with ATTR type amyloidosis, sufficient only for robust experimental results, will be efficiently bred in house.

2. The experimental protocols, including the numbers of animals, were optimised in our previously published work and this successful past experience provides a robust basis that makes pilot studies redundant. There is no evidence to suggest that the isolated, pure, microbiologically clean antibody preparations which we will test will not be safely tolerated. The protocols already specify the minimum numbers required to provide statistically and biologically significant results. Pilot studies would therefore use more animals but could not contribute new or useful information.

3. Computer modelling has no relevance to our programme at this stage. We require robust, reproducible evidence that our newly created antibodies have a beneficial effect in vivo in the one available animal model. The optimised protocols to be used in this model were developed and used under our previous licences. They have been extensively reported and received universally favourable objective recognition and acclaim, as well as academic and commercial financial support for being both appropriate and effective.

4. Unfortunately, there is no scope for sharing tissue between different experiments within the programme in order to reduce animal numbers. Each individual experiment absolutely requires its own control and experimental groups. Our input on the details of the

experiments enabled our statistical adviser to perform robust power calculations to confirm the minimum number of mice in each group needed to deliver statistically and biologically significant results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The inbred wild type C57BL/6 strain of mice we shall use are ideal for the present project because we have highly refined, very well developed and thoroughly characterised models of systemic amyloidosis in them, which very closely resemble human disease. The induction of amyloid A type amyloidosis requires a single intravenous injection and 10 subcutaneous injections, all of which are of mild severity. There is no appreciable untoward effect other than the extremely rare, less than 1 in 100, occurrence of skin ulceration. If this occurs, the affected animal is promptly humanely killed. The induction of transgenic human ATTR amyloidosis requires just a single IV injection in the genetically modified mice.

We have seen no deaths in work conducted under previous Project Licences. We have very extensive experience of administration of a wide range of different antibodies to mice, with no deaths or appreciable untoward effects, and we therefore do not anticipate any adverse effects with the present antibodies. All mice will be killed promptly by a humane method at the end of each experiment, not more than 60 days after the first injection has been administered, to provide the tissues required to detect the effect of treatment.

Why can’t you use animals that are less sentient?

The mouse amyloidosis models are the only logistically tractable models that exist in mammals. There are no relevant models of amyloidosis in other types of animals. The unavoidable time course of several weeks prohibits the use of anything other than unrestricted conscious animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring for any adverse effects, including pain, will be the highest priority, although the procedures do not cause more than minimal discomfort, for which pain relief medication has not previously been required. The use of anaesthetics for some subcutaneous

injections has been added recently. This will make the injections less stressful for the staff involved and also for the animals, especially towards the end of the second week of amyloid A type amyloidosis induction.

Two of the substance types to be administered by intraperitoneal (IP) injection, namely human serum amyloid P component (SAP) and the various anti-amyloid antibodies, cannot be formulated at sufficiently high concentration for the required doses to be administered in single small volumes. One or two larger volume injections, up to a maximum of 50 ml/kg, will therefore be used, but only one injection per day. This avoids giving multiple smaller volume injections on several consecutive days which is much more stressful for the animals. IP injections of up to 50 ml/kg are safe and well tolerated in adult mice (AA). The Table below reports our most recent past experience of 50 ml/kg IP injection of materials of precisely the same type that we shall now be testing using this route. In all these experiments, all the mice that received 50 ml/kg IP injections were closely and repeatedly observed by the present licence holder who gave the injections and by the technical staff of the UCL Royal Free Campus BSU facility. No behaviours suggestive of, or consistent with, pain, discomfort or distress were ever observed. No mice died. In a small subset of experiments in which plasma biochemistry was monitored, no abnormalities were detected despite the mice having substantial renal and hepatic amyloidosis. We are therefore confident that the injected materials themselves are harmless.

Furthermore, the absence of adverse effects or any deaths among nearly two thousand animals receiving one or two injections of 50 ml/kg ml each is strong evidence that these volumes are safe and well tolerated. For the avoidance of doubt, none of the other materials to be administered to the mice by IP injection or any other route will involve volumes exceeding the Campus guidelines.

Furthermore, in addition to the usual careful observations, all mice receiving IP injections greater than 20 ml/kg will be weighed at least 2 hours afterwards, to monitor the clearance rate of the injected volume.

Finally, IP injection volumes greater than 20 ml/kg and up to 50 ml/kg will only be needed in (a) protocol 2, which will probably only be deployed 2 - 3 times; (b) in protocols 2 and 11 involving human serum amyloid P component (SAP), which will likely be deployed 2 - 5 times; (c) in all other protocols only if protocol 4, the dose response study, demonstrates that optimal efficacy requires antibody doses greater than 4 mg/mouse. If such high doses are needed for measurable efficacy, the project might be terminated. If acceptable antibody activity is detected, however, the total number of experiments to be done under all the protocols will probably be between 13 - 25.

Intraperitoneal injections, one or two within 4 days, each 1 ml, in ~20g mice with systemic AA amyloidosis					
	single injection volume/mouse	concentration	number of mice injected	distress or other observed adverse effects	deaths
Human SAP	1 ml	10 mg/ml	800	0	0
Polyclonal sheep IgG	1 ml	50 mg/ml	350	0	0
Monoclonal IgG	1 ml	up to 5 mg/ml	620	0	0
		Total	1770	0	0

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The guidelines issued by LASA and NC3Rs, encompassed by Babraham Campus guidelines, will be strictly followed with the single exception regarding the maximum IP volume required for just the two types of administered substances specified and justified in the previous section above.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs resources (website, publications, etc.). In addition, we scrupulously scan the literature in the amyloidosis field, with automatic notification of all relevant publications as well as citations of our published work by others. This is a reliable way of detecting any advances in the 3Rs that may be relevant to the present programme.

70. Strategies to improve donor organ function in a porcine model

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to treat organs from donors in such a way as to improve their suitability for transplantation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Because of the increasing clinical need, it is necessary for transplant clinicians to consider the use of increasingly sub-optimal donor organs. Although transplantation is highly effective (more than 90% of liver transplant recipient are alive 12 months after surgery), the discrepancy between the supply of donor organs and the need for them results in patients dying on the waiting list. A patient is now more likely to die on the waiting list for a liver transplant than in the first post-operative year. However less than two thirds of deceased donors in the UK result in a liver transplant; this is because many organs are deemed to be

high risk (more likely to fail post-operatively) due to various factors including: fat deposition; hypoxic injury; older age; cardio vascular disease; diabetes.

Improving donor organs suitability for transplantation This will increase the number of organs available for patients on transplant waiting lists without increasing the risks that the organs will fail to function.

What outputs do you think you will see at the end of this project?

During the term of the previous PPL much progress has been made in terms of the refinement of normothermic machine perfusion and, importantly, it's application. In particular the earlier work on liver perfusion has been developed substantially in the context of the liver, and there is now a design for a prototype device which requires evaluation and testing as part of a pre-clinical development programme. Regarding the pancreas, normothermic machine perfusion has proved to be very challenging and we are now studying a number of technical variations based, particularly, on different approaches to temperature transitions as well as haemodynamics. This work will require considerable input from animal based studies. Also, for all organ types, the issue of delivery of organ specific therapy is very much the target. This includes drugs, cells and genes to mitigate the ill-effects of organ retrieval and preservation

The underlying purpose of this project is to develop strategies to allow the reliable transplantation of donor organs that are outside current safe limits. Normothermic perfusion is likely to be central to this strategy as a therapeutic modality in its own right, but it also provides a model in which other strategies can be tested in a consistent manner without subjecting large numbers of animals to transplantation. It is likely that more than one effective strategy will be identified and that the effect of these will be additive or synergistic.

The measurable outputs of the study will include (i) publications, (ii) presentations to specialist conferences, (iii) translation of novel organ reconditioning strategies to clinical practice.

Who or what will benefit from these outputs, and how?

The potential benefit of this work is very considerable. At present 10 to 30% of patients on the waiting list die before receiving an organ transplant and many more who would benefit from a transplant are not placed on the waiting list. There is a very large population of potential donors from which organs are not transplanted because the risk that the transplant will fail is too great. If it were possible, first, to repair and quantify injury to the organ sustained before retrieval, second, to minimise the damage that occurs to the organ during preservation and then reduce the impact on reperfusion this will result in more organs for transplantation. In addition assessing the viability of the organ before committing a patient to a transplant, then such 'marginal' donor organs could be used in large numbers and safely.

The data and interpretation that result from this work will be made available to other research and clinical groups around the world. Normothermic perfusion is increasingly seen as a vital development in transplantation to improve the quality and testing of donor organs and strategies developed as part of this project will be adopted elsewhere (as has proved the case in the past).

How will you look to maximise the outputs of this work?
We will publish the results of our studies and present these at national and international conferences. We will work with commercial collaborators to ensure that any benefits of the work are translated into clinical practice as efficiently and rapidly as possible.

Species and numbers of animals expected to be used

- Pigs: 180

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We need to use these animals as they will respond to an intervention in a similar physiological way to humans. It is important that the organs we use are similar in size and function to human organs. The pig is widely regarded as the best pre-clinical model for organ preservation studies, prior to trials in patients.

Typically, what will be done to an animal used in your project?

Each animal will receive an injection as pre-medication which will make it drowsy and remove distress. A general anaesthetic will be given, using appropriate methods. When the animal is fully anaesthetised, a breathing tube will be placed in the airway in order to maintain the anaesthetic safely. Tubes will be laced in an artery and vein the neck in order to monitor the condition of the animal during the anaesthetic and provide fluid. The operation will include a mid-line incision in the abdomen, mobilisation of the relevant internal organs and the insertion of a large tube in the aorta for the purposes of retrieving blood and/or administering cold preservation solution to the organs. The procedure will be terminated by administering a large dose of a drug.

What are the expected impacts and/or adverse effects for the animals during your project?

To avoid distress, animals will be sedated before the anaesthetic. The anaesthetic will be monitored by a fully qualified veterinary surgeon. No animal will be recovered from the procedure.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

Non Recovery 100%.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals, as they will respond to an intervention in a similar physiological way to humans. We need to use animals to see the response they have to the therapies we use to see whether they would be likely to work in humans.

Which non-animal alternatives did you consider for use in this project?

Cell cultures.

Why were they not suitable?

Whilst suitable for initial hypothesis generation, the behaviours and function of a whole organ cannot be predicted by extrapolation from the behaviour of individual cell lines in isolation. Such data would not be admissible as a justification for proceeding to clinical application

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based this on our experience in recent years regarding the frequency with which our research programme has required studies of this sort and used this on which to base a 5 yearly total.

Wherever possible we will retrieve multiple abdominal organs from the same animal (liver, kidneys, pancreas) . This will reduce the number of animals required to support the necessary studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For all pig studies we use the minimum number of animals necessary for the results to be scientifically meaningful. Depending on technical aspects this is approximately 6 pigs per experimental group. We are aiming to identify strategies or treatments that show a clear benefit that do not need large numbers in order to demonstrate significance.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will make the maximum use of the results from every experiment. We will validate findings from the pig model using discarded human organs prior to designing trials in man.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The pig has been chosen for these experiments as it is widely accepted at as the best model for studies that can be related to use in humans. The anatomical and physiological characteristics are similar to those of humans and the pig is known to be more susceptible to preservation damage than the human. The preservation characteristics of the organs and the perfusion methods that are available are substantially different in smaller animals, and so any experiments done in rodents would not be applicable to humans.

Why can't you use animals that are less sentient?

The size requirement is a critical factor in these experiments and the pig is the most suitable model. These experiments will be conducted under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will insure that the sedation and anaesthetic protocols are optimised and consciously seek methods to refine these. We will continuously seek ways of reducing the need for animal studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the published resources atwww.nc3rs.org.uk.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through routine review and discussion within both the transplant research group and the team at the Biomedical Services.

Regular communication and updates with the team at Biomedical Services.

71. Investigating immune responses in mice

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

antibodies, affinity, diversity, immune modulators

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project proposes to investigate if the immune response in mice can be improved by giving them substances to enhance it. Mice will be immunised with and without enhancement to compare the antibodies they make and show that enhancement leads to better quality antibodies

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Generation of antibodies to make new medicines by immunisation is a well-established process, this project will investigate methods to improve their quality. This knowledge can then be used in the discovery of new antibody treatments and vaccines for patients.

What outputs do you think you will see at the end of this project?

From this project we will see if enhancing the immune response in mice leads to better quality antibodies. This knowledge can then be applied in the discovery of new antibodies to treat patients.

This work will form part of a PhD thesis that will be published and will lead to peer reviewed journal publication(s) to further scientific knowledge in the community of antibody discovery.

Who or what will benefit from these outputs, and how?

If successful, the main benefit is that it will provide a method to generate pools of antibodies which have more diverse properties. This can then be used in therapeutic antibody discovery and allow project teams to select better antibodies with greater binding and specificity attributes to be developed in to medicines. If this then became a standardised technique it would lead to a reduction in the number of animals required for antibody discovery as multiple immunisation groups would be avoided.

The potential future implications of this project would not be limited to therapeutic antibody discovery but could also be applied to vaccine development for pathogens such as Covid, HIV or influenza.

How will you look to maximise the outputs of this work?

If successful, this work would be used in therapeutic antibody discovery and allow project teams have a better panel of antibodies to choose from in developing new treatments for patients.

Species and numbers of animals expected to be used

- Mice: 120

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We are using transgenic adult mice that have stably genetically altered to use human antibody genes and therefore make human antibodies that can be used to treat disease in humans. As we are aiming to develop new improved methods of immunisation to make better antibodies for treating human disease these mouse strain is the best choice.

Typically, what will be done to an animal used in your project?

Immunisation involves giving a substance to an animal usually by injection under the skin (subcutaneous). The mice will only experience a very short and slight discomfort. Anaesthesia may be used for restraint purposes.

Mice may be given immune modulator treatment either post immunisation by subcutaneous injection or throughout the entire study by injection in to the intraperitoneal cavity.

Once the immunised mice have generated suitable levels of antibodies, as confirmed by taking blood samples and testing in an assay, they will be humanely killed and their immune tissues (lymph nodes, spleens, etc) will be removed to enable us to isolate the antibody producing cells.

At the end of each immunisation study, any remaining mice will be humanely killed by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

Around 90% of immunisations will cause no more than transient mild pain to the mice. A small number of mice can exhibit some general signs of being unwell: for example, they may show: weight loss, show behaviour which is quieter than usual (subdued), changes in their posture, changes in their coat, shaking for a short time, runny nose or make more noise than usual. Mice are expected to recover over a 48 hour period.

Rarely (<2%) adverse effects that can occur are inflammation at the site of immunisation that can cause swelling, scab formation or bleeding.

After the mice have been immunised there is a approx. 1% chance that a mouse may suffer an extreme allergic reaction (called ‘anaphylactic shock’) where mice will develop difficulty breathing and/or low blood pressure that could lead to suffering. This is nearly always associated with final boosting. When this happens, the mice are immediately humanely killed to prevent any suffering.

The immune modulators are not expected to have any adverse effects of their own, and any adverse effects observed would be mild, transient and associated with the dosing route.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that 90% of mice will be in the mild severity

It is possible that up to 10% of mice may go in to moderate severity

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This PhD project is to investigate the effect of immune modulators on the immunisation process in mice to see if they can improve the outcome in terms of making better antibodies. There are no non-animal alternatives that can mimic the immune system in how it generates and develops an immune response. Therefore, it is not possible to investigate the effects of immune modulators on this process without the use of animals.

Which non-animal alternatives did you consider for use in this project?

We do have access to non-animal antibody discovery platforms have been considered.

Why were they not suitable?

These are not suitable as they cannot mimic how mice generate and develop an immune response. Non-animal methods are not capable of mimicking the process of antibody generation following immunisation and the subsequent maturing of that response. As such it is also impossible to investigate the effect of immune modulators on this process using non-animal antibody discovery platforms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any.

These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on a typical study design, that has been extensively used over many years, and animal numbers that are required to give significance to the output.

Added to this is additional mice in case it is necessary to repeat all of the studies should there be complications in understanding the outcomes or unexpected observations that need to be investigated further.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Design of experiment involving consultation/review by a statistician is used by default as part of the robust study design initiative when planning immunisation groups.

A statistician will also be part of the review panel for the in-vivo work to ensure that statistically significant observations can be made and compared for each animal group used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our historical immunisation data with this transgenic mouse to calculate how many mice have responded to immunisation in the past and therefore predict how many will be needed for these studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using our most optimal mouse immunisation model for generating a robust immune response to immunisation in this project. As part of this work we will be comparing the immunisation outcome of mice that follow the standard immunisation procedure and compare this to the outcome of standard immunisation combined with immune modulator treatment.

Mice will be handled by non-aversive methods such as tunnel handling and environmental enrichment will be added to their cages.

These immunisation procedures will be of the shortest duration with the minimum number of injections (hence minimising any pain, suffering, distress and lasting harm) required to generate the data to answer our experimental questions. All the reagents used will have been certified as fit for purpose prior to animal work starting.

Support for animals will be provided as necessary, e.g. heat mats post immunisation, enriched softened food and pain relief.

Once we have the data required no further immunisations to produce additional data will be initiated.

Where animals have to undergo repeated injections as part of the protocol, injections sites will be changed between each injection. Also the sites of injection will be monitored daily for inflammation and/or irritation to allow immediate intervention if required.

Why can't you use animals that are less sentient?

Less sentient species do not have a functioning immune system equivalent to that of mice making them unsuitable/unusable for this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Prior to immunisation, all immunogens and immune modulators are stringently checked for contaminants and sterility to ensure there is no potential for causing illness during the immunisation. Furthermore, any immune modulator used is thoroughly researched for any potential adverse effects that could occur prior to being used.

Our immunisations have been refined to minimise any distress because of the immunisation process. Our examples of this are:

- Minimising pain during the immunisation by using fine gauge needles and using anaesthesia when multiple injections are required.
- When using substances that improve the immunisation process, we make sure these do not cause any additional suffering or distress on the mice by thoroughly researching the immune modulator. Any identified adverse effect would be discussed with the NACWO and NVS.
- We provide supportive care (e.g. provision of soft diet and warming) for any mice that are affected by immunisation to reduce any pain and help them recover as quickly as possible

If any of our mice reach predetermined humane endpoints during the immunisation protocol, they are humanely killed to prevent any further suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The published principles and philosophies behind the PREPARE (2018) and original ARRIVE (2010) guidelines have been incorporated into the sponsoring company's internal project planning standards of care and standard operating procedures. All work carried out under authority of this licence will undergo assessment of the study design during planning stages as part of a peer review process that is based on those guidelines, and will include statistical consultation. Facilities and processes are audited by independent bodies such as AAALAC International which has published guidelines and procedures to ensure work is carried out to high ethical and humane standards. The following published documents will advise on experimental design, animal welfare and husbandry during the life cycle of this licence:

i. Kilkenny C et al (2010). Improving Bioscience Research Reporting: The ARRIVE Guidelines for Reporting Animal Research. PLoS Biol 8(6).
ii. Smith A et al (2018). PREPARE: guidelines for planning animal research and testing. Lab Anim; 52(2):135-141.
iii. Percie du Sert N et al. The ARRIVE guidelines 2019: updated guidelines for reporting animal research. BioRxiv. 2019: 703181.
iv. NC3R's - Responsibility in the use of animals in bioscience research: expectations of the major research council and charitable funding bodies (2019).
v. Guidance on the operation of the Animals (Scientific Procedures) Act 1986. (Home Office 2014).
vi. LASA - Guiding principles on good practice for animal welfare and ethical review bodies. (2015)

vii. Prescott MJ, Lidster K. Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156, (2017).

viii. Review of harm-benefit analysis in the use of animals in research. Report of the Animals in Science Committee Harm-Benefit Analysis Sub-Group chaired by Professor Gail Davies (Nov 2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We routinely receive 3R's updates within the company that are sent to everyone involved in animal experimentation from the NIO.

Our AWERB meetings also highlight any 3R's news to PPL holders. Any that a relevant to this project work will be considered and implemented.

We also receive email updates from EARA.

Our research department uses non-animal alternatives for antibody discovery where possible to deliver therapeutic antibodies.

72. Generating new models of human cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, models, genetics, therapy, oncogenes

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To generate and preserve genetically altered mouse strains in collaboration with other scientists working in cancer biology and their collaborators.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer directly affects 1 in 2 people in their lifetime and whilst great strides have been made in detection and treatment there is still much to be learned. For the past 25 years genetically altered animal (GAA) models, particularly mice, have been instrumental in cancer gene discovery, validation and characterisation, and as pre-clinical models.

What outputs do you think you will see at the end of this project?

New Information: This project will deepen our understanding of the underlying causes of cancer in general and of specific types of cancer which currently have a poor prognosis such as pancreatic cancer. Knowledge of the genetic causes will dramatically improve our ability to diagnose, treat and prevent cancer which affects one in two of the UK population.

Publications: Work arising from these studies will be published in scientific journals and presented at national and international meetings to disseminate knowledge (to scientists and clinicians). We will also publicise our results to the public at open evenings, social media, and on our website.

Products: The overall goal of this project is the identification of drug targets which might be used as a therapeutic for the treatment of cancers. This work will also lead to the development of new more accurate and more refined models of human cancers which may be widely used by collaborators.

Sperm or embryos from mouse strains generated in the course of this project will be frozen and archived. These will be made available to other scientists worldwide on request.

Who or what will benefit from these outputs, and how?

This work is aimed directly at individuals with cancer, who will benefit firstly from a better understanding of how this disorder affects them. This should allow a better management of the clinical consequences of condition in affected individuals. The knowledge gained will also be of interest to the scientific community (short term) by expanding knowledge of different cancer types. By the end of this project this work may allow us to develop new therapeutic approaches (long term) helping patients who are suffering with cancer.

How will you look to maximise the outputs of this work?

We will collaborate with a number of different labs both locally and further afield. This will help ensure that the models we generate are used as effectively as possible and that the consequences of the genetic changes will be widely understood in different tissue and cancer types. Our mouse models will be preserved as part of a frozen archive. These new mouse stains will be made readily available to other researchers in the field to study and develop treatments for cancers. In addition, our work will be published in scientific journals and we will attend relevant scientific meetings to discuss and disseminate our findings with other researchers.

Species and numbers of animals expected to be used

- Mice: 34000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cancer, a major health issue worldwide, is a multistep disease resulting from a series of genetic mutations in genes referred to as oncogenes and tumour suppressors. Understanding how these genetic lesions change the normal cell to a cancerous one is vital if we are to prevent and treat cancer. Only in the context of the complete living animal can we fully understand how cancers develop, invade and spread to other organs. Using genetically altered animal (GAA) models with the same genetic mutations identified in the human disease (so called ‘patient-like’ animal models) we can investigate the biological consequences of these lesions in cancer progression and identify those genetic events and signalling pathways which work together to drive invasion and metastasis. Such information will enable us to design new and targeted therapeutic approaches.

Typically, what will be done to an animal used in your project?

Some animals will undergo hormone injections. Other animals will undergo surgery for vasectomy or embryo implantation.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of new GAA strains we develop are unlikely to display any adverse effect, as only a single gene copy will be affected. Some animals will undergo hormone injection, which is expected to result in no more than transient discomfort and no lasting harm. Some other animals will undergo surgery for embryo implantation; these animals will experience some degree of pain/discomfort will occur as a result of surgery, but this will be minimised by the administration of pain relief medication.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals on this project will have a subthreshold severity meaning they will show no harm. Some (<25%) will be mild severity. A smaller number (<10%) will be moderate severity.

What will happen to animals at the end of this project?

Killed

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although many aspects of cancer research can be conducted using cell lines the development and treatment of cancer can only be properly assessed within the context of the whole animal.

Which non-animal alternatives did you consider for use in this project?

Our mouse experiments are an extension of robust laboratory investigations from work on cultured cells and only progress using mice when sufficient rationale is obtained based on cell culture, including embryonic stem cells and where possible colonies of cells resembling mouse tissues. Where possible we use cell lines derived from human tumours (including 3D organotypic lines).

Why were they not suitable?

Studies using isolated cultured cells cannot totally model the complexities of cancer development in the living organism. It is well recognised that immune and tissue environment play an important role in disease progression where these cannot be fully reproduced in the test tube. For example, drugs which are effective in cultured cells may not be as effective in the whole organism, if they can't reach the tumour or are chemically altered by body cells. So it is always important to analyse promising agents in the whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are estimated based on the numbers used during the course of the last project licence. These techniques are all standard techniques allowing the generation of new genetically altered mouse strains.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Although these are all standard protocols, we ensure by monitoring the literature and attending relevant meetings that the methods we use are as close to the state-of-the-art as possible. All reagents we use in mice are firstly tested in the lab to ensure that these work well before animal use. For embryo production we use a special mix of hormones which allows use to generate double the amount of embryos produced by donor mice, halving the number of mice used in these procedures.

When generating a new GAA strain, genetic background will be carefully considered to minimize the number of subsequent breeding steps required to produce cohort mice. Breeding will be optimised, wherever possible, to produce only the genotype required e.g. homozygous breeding pairs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, unnecessary generation of new GAA strains will be avoided by searching external databases, examples of which are listed below: International Knockout Mouse Consortium (http://www.knockoutmouse.org/); NC3R's Minimising the use of GA mice (https://www.nc3rs.org.uk/minimising-use-ga-mice); Mouse locator (Locator@cancer.org.uk); Jackson Laboratory (http://www.jax.org/ http://jaxmice.jax.org/index.html); Cre transgenic database: http://www.mshri.on.ca/nagy/Cre-pub.html). In addition to the resources listed above we will also check scientific literature to see if strains are available elsewhere.

Preservation of frozen gametes and embryos to archive lines is carried out to avoid generating additional animals, and the need to maintain colonies by continuous breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This licence uses genetically altered mouse models, which aim to recapitulate the same genetic mutations observed in human cancer. Although the protocols for generation of genetically altered mouse strains are well established, we will continue to review the relevant literature and will implement any refinements that are appropriate.

Why can't you use animals that are less sentient?

The mouse is a mammal and warm-blooded which shares many features of human metabolism not found in other cold-blooded species such as flies and worms. With the ease of manipulating the genetics of the mouse, this makes the mouse the best model organism to understand the genetic changes observed in complex diseases such as cancer. In addition, there has been a huge body of work analysing cancer biology in the mouse, and there are already many strains of mice carrying cancer relevant genetic alterations. These can be used in combination with the new mouse strains we generate to effectively understand cancer biology. Consequently, to ensure that these models are efficiently and effectively used we need to generate these using mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In many cases we use models, which specifically target genetic changes to the cell type of interest during adult development thereby reducing the non-specific off-target effects often observed in complete knockout animals.

A small number of animals will undergo surgical procedures. Surgery is carried out under anaesthetic in a sterile manner with appropriate pain relief. Following surgery animals will be maintained in a warm environment, and carefully monitored until fully recovered and returned to home cage. Normal diet may be supplemented with treats to encourage eating and drinking after anaesthetic.

To minimise suffering all mice on procedure will be monitored daily and humanely killed when exhibiting signs of altered health status or other specified end-point is reached. Our animal unit is proactive in enrichment with for example tissue, fun tunnels and nesting material.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all of our studies we will refer to the Guidelines for the welfare and use of animals in cancer research (Workman et al, 2010) and ensure best working practice. All newly generated strains will be assessed according to the published guidelines for best practice (e.g. Wells et al. 2006).

In addition, we adhere to both the PREPARE guidelines: Planning Research and Experimental Procedures on Animals: Recommendations for Excellence as well as the 'Animal Research: Reporting In Vivo Experiments (ARRIVE) Guidelines'. These are complementary checklists for researchers designed to improve the planning and reporting of animal research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continually review our processes and take advice from the Named Veterinary Surgeons, Home Office Inspectors and the NC3Rs website. Our technical staff are very adept at adopting 3Rs advancements such as non-aversion handling and single-use needles.

73. Signalling in normal and abnormal blood cell function

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cancer, Blood, Stem cells, Therapy, Platelets

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to identify how blood stem cells receive signals and how this drives the formation of mature blood cells, especially red blood cells and platelets. We are particularly interested in finding out how this signaling is altered in blood diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood is one of the most important tissues in the human body. Red blood cells transport oxygen to muscles and organs, white blood cells fight infections and provide immunity and platelets control clotting which prevents excessive blood loss after injury. Blood cell production (called "haematopoiesis") is a remarkably complex process by which blood stem cells divide and mature into functional circulating blood cells. A healthy adult makes and turns over about 4 million new blood cells every second. It is therefore critical that we maintain the correct number of blood cells on a day-to-day basis to make sure our tissues remain oxygenated and our immune system is functional. It is also essential that haematopoiesis responds to certain conditions (e.g. bleeding or infection), by either increasing or decreasing the pools of certain types of blood cells and either increase or decrease certain types of blood cell.

In blood diseases, it is common for these systems to become unbalanced. For example, in blood cancers the number of certain types of blood cell are too high and usually do not function normally and block the production of healthy cells. In other diseases, we don't make enough of a certain blood cell type which means they can't do their job properly which can lead to conditions such as anemia and bleeding. In my lab, we investigate how signaling molecules (called cytokines) interact with blood cells and alter their production or destruction. We have found that this control system can be altered in certain types of cancer and other blood diseases. Our research focuses on determining the mechanisms responsible for altering this control system and developing new agents that can intervene and restore normal haematopoiesis.

What outputs do you think you will see at the end of this project?

We will gain a better understanding of how blood cells develop, determine the long-term effects of chronic conditions, and possibly discover new types of agents that may help treat blood cancers. We will communicate our findings widely to basic scientists and medical researchers by publishing open access peer reviewed papers. We will communicate to the public and to schools via our contacts with local patient groups and outreach programs. If our findings point to a mechanism by which minor chronic conditions can develop into severe, long-term disease, this could lead to researchers undertaking further studies in human patients.

Who or what will benefit from these outputs, and how?

Beneficiaries of this research includes the scientific and research communities, as well as patients with blood disorders. We have identified a number of new pathways and agents furthering our understanding of how blood disorders develop. By using this new knowledge, we hope to find ways to prevent or treat blood diseases. This will allow other researchers, including those that work with patients and patient material, to develop new hypotheses and make further discoveries. Our work may eventually lead to the development of new therapeutics and more effective treatments for certain types of blood cancers.

How will you look to maximise the outputs of this work?

Working collaboratively across the university and with researchers at other universities in the UK and internationally has been an important part of my lab's research strategy. We will present new data at national and international conferences such as the British Society for Haematology and the American Society for Hematology to ensure that it is disseminated throughout the scientific community. To promote reproducible and robust science across the UK and internationally, it is important that unsuccessful, as well as successful, experiments are disseminated. Therefore, we will publish any failed approaches on open access servers such as BioRxiv. Scientific research is largely funded by the public, through taxes or through charities, therefore the public have a right to understand what research is being done and our findings. Communicating science to the public is encouraged in my lab and students an postdocs participate in outreach events. We also host a number of patient support groups so our findings are disseminated to members of the public who may have directly or indirectly been affected by haematological disease.

Species and numbers of animals expected to be used

- Mice: 1150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have a blood cell production system that is similar to that of humans. This allows us to explore how blood is produced, what goes wrong in blood diseases and how we might be able to stop blood diseases from developing by using new treatments. We use adult mice from ~8-12 weeks of age because their blood cell production system is fully functional from this stage.

Typically, what will be done to an animal used in your project?

The mice in our experiments could be treated in several different ways. For some, we may just take very small amounts of blood (like a pin-prick) and look at the different types and numbers of blood cells they have. These experiments tend to last a few months, as we need to see whether any change in blood cell number or type carries on for a long time, or changes when the mice get older.

Others will be injected with chemicals or proteins that alter the number and type of blood cells they produce. They may be injected a number of times and will have small amounts of blood taken at regular intervals to see what effects (if any) the chemicals or proteins

have on blood cell production. Generally, these experiments last a few weeks, but we might keep the mice longer to see if there are any long term effects or whether blood cell production just goes back to normal.

Some mice may receive a bone marrow transplant. In these cases, mice will be exposed to radiation to kill the cells in the bone marrow that make blood, and then be injected with bone marrow cells from another mouse to so they can start making blood again. Mice are closely monitored during this time as they might get sick after being exposed to radiation. However, we have lots of ways to make sure this doesn't happen. These experiments tend to last up to 6 months or even longer as it can take quite a long time for blood cell production to become normal again. To see how the transplant is working, we will take very small blood samples every 4 weeks and look at the types and numbers of blood cells the mice have.

What are the expected impacts and/or adverse effects for the animals during your project?

For most of our experiments, the mice will only experience mild discomfort for short periods of time (such as blood sampling or injecting chemicals/proteins). Any discomfort will be temporary. It is possible that some of the chemicals or proteins may make the mice feel unwell. Mice that are treated with radiation can become unwell, usually about 1-2 weeks after they have been exposed to radiation. This might cause them to temporarily lose some weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild: 650 adult mice
- Moderate: 500 adult mice

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We make trillions of new blood cells every day. This is an incredibly complex process that takes place predominantly in the bone marrow - a semi-solid tissue found in centre of long

bones (e.g. legs) or in porous areas of bone (e.g. pelvis and vertebrae). It is essential that we maintain the right balance of different blood cell types to allow muscles to receive oxygen (red blood cells), so we clot properly following injury (platelets) and can fight infection (white blood cells). If this process becomes unbalanced, it can lead to diseases of the immune system or even blood cancers. Controlling what type of blood cells are produced and how many, requires a delicate interplay between signals released from other organs (such as kidneys and the liver) and changes in the bone marrow environment. Therefore, it is not possible to accurately recreate blood cell production in the lab, so we are not able to understand how blood diseases develop without using mice. As the blood cell production system is similar between mice and humans, we are able to gain a good understanding of this process using mice.

Which non-animal alternatives did you consider for use in this project?

As blood cell production is so complex, there are no non-animal alternatives for these studies. There are some in vitro (using cells in the lab) assays that allow us to determine how certain agents or diseases effect blood cell development. We will use these where possible and if these assays are appropriate. These are especially useful if we need to determine the effects on human cells.

Why were they not suitable?

The in vitro alternatives fail to provide the complexity of the blood cell production, which relies on the highly regulated coordination between many different tissues (such as the liver, kidneys and spleen) and bone marrow. It is not possible to make an accurate model of this in the lab.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

As the number and types of blood cells in circulation is tightly controlled, any significant change is easy to identify. We estimate the number of mice we will need to use for each experiment, and how many mice we need for each group. For example, 1 group will be "control" (no treatment) and the other will receive an "agent" (e.g. chemical or protein). Using data from previous experiments, we can estimate how many mice we will need in each group to identify what would be considered a significant biological effect. For example, the normal platelet count in mice is ~800,000 in each microlitre of blood. If we expect the agent to reduce platelet count, we would want to see a reduction of at least

50% (i.e.~400,000/microlitre). We are then able to calculate how many mice we will need to get a strong and reproducible difference.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use a number of online tools to calculate how many mice we need for each experiment, such as the NC3R's Experimental Design Assistant and programs that help us estimate the number of mice we need (http://powerandsamplesize.com/Calculators). One of the most important factors in estimating exactly how many mice we need to an experiment, and therefore making sure we don't use too many, is using our previous data to understand what effects we can expect to see and how similarly mice respond to certain treatments. It is equally as important to make sure you use enough mice to generate good data. If our groups are too small, differences might not be statistically significant, meaning that we will have to repeat the experiment and use more mice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

If we are doing an experiment where we are unsure what the effect on the mice will be, we start with a small number of mice first. We then monitor these mice very closely to see what effects (if any) the treatment or experiment is having on the number/type of blood cells. This allows us to understand if the experiment is working, how big an effect is and whether there are any adverse side effects that we didn't expect. Once we have this information, it allows us to more accurately plan a larger experiment. At the end of an experiment, when the mice are killed, we try to collect as much different tissue as possible. This tissue will be frozen and stored in the lab where it can be used by researchers to look at how our experiments may have altered different organs and tissues in the mice. This prevents us, or other groups, from starting new experiments using more mice to investigate effects on these tissues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use a number of different types of mice for our studies. Often, we will use "normal" mice (called C57/Bl6, or wild type). These mice are widely used in research as a standard. We also use genetically altered (GA) mice. These mice often lack certain genes, or their

genes are altered in some way so they can be used for research into different types of blood diseases. Although the GA mice we use do have certain blood disorders, it doesn't cause them any pain and they don't suffer or die prematurely compared to wild type mice.

The methods we use have been designed and modified over a number of years to significantly reduce pain or distress to the mice. For example, we don't pick mice up by their tails when taking them out of the cage, as this can cause distress. Instead, we either cup them (let them walk into the palm of our hands) or let them walk into a tube before picking them up. We anesthetize mice before taking blood so they are unconscious during the process, only take blood samples when needed and make sure we change the site where we take a blood sample regularly to prevent the area become sore or inflamed.

For bone marrow transplants, where possible, we are using a GA mouse (called W41) that only needs about 20% of the normal radiation dose, this reduces any adverse effects.

Why can’t you use animals that are less sentient?

We use mice because the way they make blood cell is similar to humans. We need the mice to be at least 8 weeks old because their blood system is then fully developed.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are monitored closely after procedures by weighing them regularly and checking on how many and what types of blood cells they have. Mice that have received radiation prior to bone marrow transplantation are given antibiotics for 2 weeks to reduce the chances of bacterial infection.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the guidelines published by the UK Government on best practice for animals in research (https://www.gov.uk/guidance/research-and-testing-using-animals).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We refer to the guidelines published by the NC3Rs (https://nc3rs.org.uk/3rs-advice-project-licence- applicants-refinement) for direction on general refinement measures and to access resources for specific experiments. I read the monthly NC3Rs newsletter and share them with the researchers in my lab that are involved in animal research. I regularly monitor progress on the annual challenges and have previously applied for research funding from The NC3Rs. Our NACWO also sends users of the animal facility regular NC3Rs updates and organizes visits from members of external organisations (e.g. the NC3Rs, RSPCA (https://norecopa.no/PREPARE)) to speak at our 6-monthly users group meetings. During the previous approved PPL, we implemented new NC3Rs

recommendations by changing our mouse handling methods and using needles only once for all our experiments and we will continue to respond to new advances published by NC3Rs.

74. Targeted tumour therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunotherapy, Oncolytic virus, HOX genes

Animal types	Life stages
Mice	adult, pregnant, neonate
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To assess the ability of anticancer agents, either alone or in combination with other anticancer agents, to treat or prevent tumour growth

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To assess new targeted treatments for cancer. To provide data to support new clinical trials for cancer patients.

What outputs do you think you will see at the end of this project?

We will use cancer killing viruses which retarget the patient's immune system against the cancer. This form of treatment is called viral immunotherapy. Bladder cancer offers intriguing opportunities for viral immunotherapy. Bladder cancer is the seventh most common cancer in the UK, with over 10,000 new cases annually in the UK. Approximately 70% to 80% of patients with bladder cancer are initially diagnosed with an early form of the disease called non-muscle invasive disease. Superficial, non- muscle invasive bladder cancers (NMIBCs) are managed with surgery followed by chemotherapy and/or immunotherapy. The use of bacteria Bacillus Calmette-Guerin (BCG) as an immunotherapy for bladder cancer and its proven effects of reducing recurrence and progression and improving disease- specific survival have revolutionized the treatment of this malignancy. However, the potential for serious side effects of local and systemic bacterial infection as well as the fact that there is a significant (30%) group of non-responder patients to this treatment highlights the need to develop future immune-based therapies that overcome these problems. Our group has developed a novel viral immunotherapy based on a cancer killing virus called Coxsackievirus A21 (CVA21). We have shown that CVA21 has strong immunotherapeutic properties in experimental bladder cancer models and in patients in a clinical trial. A new license would allow us to study a new range of cancer killing viruses expressing bacterial proteins to better target and create a more potent immune response for this disease and for other cancers.

Prostate cancer is the most common non-cutaneous cancer in men worldwide, with an estimated 1,600,000 cases and 366,000 deaths annually. Despite the high long-term survival in localized prostate cancer, metastatic prostate cancer remains largely incurable even after intensive multimodal therapy. Prostate cancers are generally considered to be 'cold' tumours with minimal T cell infiltrates, lacking a type I IFN signature and chemokines and containing immunosuppressive cells such as myeloid derived suppressor cells. This non-inflamed phenotype is thought to be largely responsible for the disappointing lack of sensitivity of prostate cancer patients to immune checkpoint blockade (ICB) therapy. Whilst cancer immunotherapy with checkpoint blockade (ICB) therapy has revolutionized the treatment of patients with certain malignancies, clinical trials in prostate cancer have shown ICB to have very limited efficacy. The potential benefits of these orthotopic models is to allow our group to study a combination of ICB with other immunotherapies, to increase the potential of ICBs seen in other malignancies.

Oesophageal cancer – of which adenocarcinoma (OAC) is the predominant subtype in the United Kingdom - is a highly aggressive malignancy, ranking sixth among all cancers for mortality, with 5-year survival rates of approximately 15%. Surgically resectable disease is primarily treated with chemo+/- radiotherapy and surgery. Systemic chemotherapy is associated with significant side effects and morbidity. While chemotherapy or chemoradiotherapy may modulate the tumour microenvironment (TME) towards tumour rejection, they are unselective treatments with significant systemic toxicity.

Hence novel approaches to the treatment of OAC are required. Immunotherapy may achieve more precise and potent immunomodulation with delivery of biological agents. Creating novel immunotherapeutic strategies which utilise multiple agents to achieve the greatest effect offers the opportunity for significant advances in the treatment of OAC. Innovation in therapeutics has been hampered by a lack of animal models which replicate the tumour microenvironment with an intact immune system.

Who or what will benefit from these outputs, and how?

We hope in the short term, to obtain knowledge for the wider scientific community, which will be disseminated through scientific papers and international conference's. Data from each protocol can be used to help design drug dosing regimens and minimise/eliminate adverse effects in other protocols within this license. Our group has a sustained and proven track record in development of basic science and clinical translation in the fields of cancer killing viruses and therapies that turn the immune system against cancer. Our group has a collaboration with our local NHS Hospital which has a pharmacy, with a dedicated gene/viral therapy facility and a treatment centre with the infrastructure to conduct and manage early phase trials with such biological agents. Thus, in the long term, data generated from this license may translate into clinical trials, which may lead to novel treatments or combinations of treatments for cancer, specifically, for oesophageal adenocarcinoma, prostate and bladder cancer.

How will you look to maximise the outputs of this work?

We will obtain knowledge for the wider scientific community, which will be disseminated through scientific papers and international conference's.

Species and numbers of animals expected to be used

- Mice: 3890
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mouse and rat cancer models represent a mammalian system that is well characterized and available in defined genetic backgrounds, greatly reducing the number of variables that could influence experimental outcomes.

Typically, what will be done to an animal used in your project?

Tumours will be inserted into the animals by injection or surgery. Animals with a confirmed tumour, will be treated with anticancer agents over maximum of 4-6 weeks. Tumour load may be assessed by ultrasound, IVIS or x-ray imaging. In some instances, treatment may lead to the regression of tumours. These animals may be re-challenged with fresh tumour cells to look for long lasting immunity against the specific tumour type. Alternatively, immune cell components, may be depleted by antibody neutralization, to understand which immune cells are important in the regression of the tumour. Animals will be culled according to scientific or humane endpoints.

What are the expected impacts and/or adverse effects for the animals during your project?

In all tumour models we monitor changes in: hunching, an altered demeanour, tumour dimensions and tumour ulceration. To minimise suffering of the animals timely monitoring and careful observation of the mice will ensure that any harms are kept to a minimum and when they occur, dealt with promptly.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In our last licence, using experiment tumour models 97.1% of animals show no signs or symptoms of clinical illness and were culled at scientific endpoints (mild). But 2.2% of animals showed an alter gait, 0.22% showed hunching/low demeanour and 0.33% Tumour ulceration and therefore these animals were culled at Humane end points (moderate).

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

One of the key aspects to our research is to study the role that our novel anti-cancer agents play in modulating the immune system to kill cancer. For this we require a live animal with a fully functioning immune system.

Which non-animal alternatives did you consider for use in this project?

In vitro (test tube experiments)

Each treatment is tested in cell culture for tumour killing properties. This data is then compared against well studied anti-cancer agents such as chemotherapeutic agents (eg Cisplatin) on the same tumour cell line. Also, from tissue culture experiments, we can obtain information on the type of cell death caused by anti-cancer agents and whether proteins that will affect the patient's immune system are produced.

Ex vivo (experiments on patient biopsies)

Ex Vivo testing of anticancer agents using the slice culture model using patients tumours

Our group has developed the tumour slice model which is another way we can screen anti-cancer agents. The model allows us to slice tumours taken directly from human patients and from animal models. Cell lines grown in in vitro culture normally contain a single type of cell which is propagated in a single layer. In contrast tumours are complex and multi-layered structures. The tumour tissue slice cultures are preserved in the native state of the tumour, for further study. Tumours are obtained directly from operating theatres at NHS Hospitals. Tumours are slice using a vibrating blade. Tumour slice cultures are maintained under atmospheric oxygen levels. A tumour can be divided into up to 30 slices which allows multiple drugs and viral doses to be tested at any one time. This system has allowed our group to refine and reduce the number of animals needed for our cancer therapeutic studies by allowing us to look at the novel therapies directly in primary human tumour cells. It can also be used with animal tumour slices.

Why were they not suitable?

Limitations of cell culture (test tube experiments)

1. Cells in tissue culture do not contain morphologic structures seen in the tumour in patients. Cell culture also does not contain the mix of population of cells seen in tumours ie stroma and immune cells.

2. Cell culture assays can only be studied over a number of days whilst animal experiments can give us scientific information over weeks. This limits treatment and response time for studying the anti- cancer agent.

3. The cell culture model does not allow us to examine cancer-immune cell interactions. It is essential for our studies to understand the interaction of the immune system with cancer cells and with anti- cancer agents.

Advantages of slice cultures

1. Tumour killing properties of anti-cancer agents can be studied by staining slices with proliferation markers or staining cell death markers.

2. Induction of proteins that may alter the patient's immune system can be measured Which could suggest whether an anti-cancer agent will prime an immune response.

Limitations of slice cultures

1. Currently tissue slices can only retain tissue morphology in culture for between 96 and 127 hours. This limits treatment and response time for studying cancer agents.

2. The slice culture model does not allow us to examine cancer-immune cell interactions. It is essential for our studies to understand the interaction of the immune system with cancer cells and anti- cancer agents.

In conclusion the slice culture model offers a way of pre-screening anti-cancer agents directly onto patient biopsies. It allows us to quantify tumour killing properties of these agents and measure immune response proteins. Unfortunately, however, this does not replace animal studies completely because it doesn't represent a fully active immune system and therefore, we can't fully study the effect of anti- cancer agents.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

It is difficult to estimate the number of animals that will be used before pre-screening of anti-cancer agents has been carried out in vitro. Protocol-1 is a protocol to standardise tumour growth. Previously in 2018 we used 30 mice to study tumour growth in mice. We also expect to use the same number of mice for this objective in this licence to test tumour growth (up to 30 mice per year and up to 150 mice or rats in total over 5 years). However, overall, we will use approximately 50 mice or rats per year (250 mice in total) because an additional 20 mice or rats per year will be required to grow tumours for use in the tissue slice culture model system described above. Protocol-2 is a rodent cancer heterotopic models. Based on our returns from 2016 341 mice were used to test two different types of oncolytic virus therapy or/ and checkpoint inhibitor and another 24 mice were used in HOX gene therapeutic peptide studies. A total over 5 years of 1825 mice. Similar data was obtained on previous project licence. Therefore, we have estimated up to 2150 animals per five years of the project license would be used in protocol 2 of this licence (2000 mice, 150 rats). Protocol-3 is a treatment and prevention vaccination model. Based on our returns from the last set of experiments under this protocol in 2015 97 animals were used for four oncolytic virus vaccine lysates experiments. Based on these previous studies we therefore estimate for this licence we will use up to 750 mice, and 250 rats per five years of the project license for protocol 3. Oesophageal adenocarcinoma (Protocol 4/5) is a new area of research for our group.

Protocol-4 will produce N= 60 L2-IL-1β (Tg[ED-L2-IL1RN/IL1B) mice that have been bred with wt C57BL/6J mice, for use in protocol 5. To breed this group of animal, we require 9 breeding females, each will have 5 litters. Breeding of these GAA mice is controlled by a breeding plan, devised by NACWO, NVS and members of our lab, to minimise animal wastage (https://www.ncbi.nlm.nih.gov/books/NBK43325/). Detailed calculations are shown in appendix 6.

Protocol-5 will use 60x animals produced on protocol-4 to study effect of anticancer agents on oesophageal adenocarcinoma. Protocol 6 is an intra- bone (metastatic) tumour model, which may need 20x animals to set up. Our current design of experiments will use 15x mice per treatment group with two treatment groups in each experiment. We may carry out this protocol 6x times on the license, therefore in total we may use 200 mice per five years of the project license. Protocol 7 is an Orthotopic Prostate Murine Model. This protocol has the same design of and number of experiments as protocol 6, it also will need similar numbers of animals for its set up, therefore we may use 200 mice per five years of the project license. Protocol 8 is an orthotopic bladder tumour model. In the last year this protocol (Previous Project Licence) was carried out we used 97 rats (485 rats/5years) in this procedure.

Therefore, we estimate we will use up to 500 rats or mice (per five years of the project license. Protocol 9 It is difficult to estimate the number of animals that will be used before pre-screening of anti-cancer agents has been carried out in vitro. Group sizes will depend on, which protocol the animals enter after protocol 9. We expect to use 50 mice/10 rats per year and therefore 250 mice/50 rats throughout the license.

As described above, our group has developed in vitro and ex vivo pre-screening procedure for anti- cancer agents, to limit the use of animals used in our studies. If an anticancer agent does not show the desired efficacy in vitro then in vivo experiments will NOT be carried out. It is difficult to estimate the number of animals that will be used before pre-screening of anti-cancer agents has been carried out in vitro, but based on our previous licences we estimate up to 4490 animals will be used over the five year period of the project license. Due to the broad variety of projects being currently investigated in this laboratory the numbers and protocols have been stipulated to cover all eventualities now and in the future. In practice, the actual numbers of animals in use at the moment is below this estimate. It is our intention to continuously reassess in vivo projects and refine them.

The design of the individual experiments will ensure that the animals used are both necessary and sufficient; more animals than necessary would lead to an unethical loss of life with no additional gain in information, whilst insufficient numbers of animals would mean that the animals used are wasted because the scientific question cannot be answered using that data.

Because the tumour models / treatments to be tested are not confirmed before pre-screening of anti- cancer agents has been carried out in vitro, it is difficult to be definitive about the required sample sizes at this stage. However, the following principles will apply,

and we offer past data from similar work as examples to help inform the sample size calculations required here. If new relevant data become available before the experiment is to be carried out, preliminary sample size calculations for the relevant experiments will be revisited to ensure the calculations are based on the most up to date information. Due to the exploratory nature of the work, the experiments will be powered at 80%. In general, the significance level will be 0.05, but where multiple comparisons are required (for example experiments with more than two groups) the family-wise-error-rate will be held at 0.05 by making an adjustment to the significance level appropriate to the number of planned comparisons. All sample sizes will be inflated by a factor of 10% to allow for attrition, for example if animals need to be killed at humane endpoints and therefore cannot complete the study. Where we have used standard deviations from previous studies to inform the calculations, we will increase the standard deviation assumed by 10% to allow for differences in variability across studies.

Protocols 2, 3, 5, 6, 7, & 8 involve parallel group design experiments, with tumour volume post- treatment as the outcome measure. Baseline data for tumour volume will also be measured. Most of these experiments will involve two parallel groups, a control group and an active treatment group.

However, Protocols 2 and 3 govern the testing of heterotopic models screening a wide range of anticancer drug combinations and may include experiments with three or four groups, typically one control group and two or three active treatment groups. All the experiments will be analysed by ANCOVA (analysis of covariance), with treatment group and baseline measurements as covariates and will output estimates of mean tumor volume, adjusted for baseline. Using ANCOVA adjusts for baseline differences between groups and has greater power than a t-test leading to smaller required sample sizes. The sample size calculations for ANCOVA require an assumption of the correlation beween baseline and outcome tumour volume, if this is not available from previous work. Where this is the case, we have assumed a moderate correlation of 0.5. The sample size will then be the number required to detect a difference in tumour size post-treatment between the two groups using ANCOVA adjusted for baseline, with 80% power, alpha of 0.05 and assumed correlation r between baseline and outcome measures, where r is obtained from previous studies or is set at 0.5. For experiments with more than one treatment contrast of interest, the study will be powered to detect the smallest pairwise difference and adjusted for the number of treatment contrasts being studied. It is likely that some treatment contrasts will require large sample sizes; in this case, the study is not powered to detect such a difference, but the results may serve as signals of efficacy and used to help inform future research.

In the following paragraphs, we outline some examples in further detail and the sample sizes can be seen in the Table 1. Protocol 5 will be testing the effect of anti-cancer agents on orthotopic oesophageal tumours. There are few data published in this field about reductions in tumour size using these treatments, so we will base our calculations on published data on human breast cancer organoids in nude mice from Sach et al 2018. In this study, the control group had an average tumour size of 235 mm3, with standard

deviation (SD) of 135 mm3). Average tumour size in the treated group (Afatinib) was 75 mm3 (SD 20 mm3) (appendix 5a). This study will require 9 animals per group, after allowing for 10% attrition. The experiments for Protocols 6, 7 and 8 are similar, and calculations will be conducted as described above, using the most up to date relevant data available to inform the calculations. All assumptions made for such calculations will be captured and available for scrutiny.

Protocols 2 and 3 cover heterotropic models that may require more than two parallel groups. In this case, we will power the study for several independent t-tests and will allow for multiple comparisons by reducing the signficance level for each test to control the total Type 1 error rate.

We will use Protocol 2 as an example of how this will work.

We will use data from a study on the trampC2 prostate model in which the average tumour size in the control group is 208 mm3 (SD 189 mm3). There are three possible treatments of interest; reovirus, PD- 1, and reovirus / PD-1 combined. The mean tumour size and SD for each treatment group are 120 mm3 (SD 111 mm3), 143 mm3 (SD 89 mm3) and 21 mm3 (SD 23 mm3) respectively (appendix 5a). There are six potential treatment contrasts here if every pairwise comparison in included, but the potential effect sizes may be so small in some cases that a) there is insufficient signal of efficacy to warrant further research into that treatment comparison and b) the sample size required to detect such a small difference would be very large (see Table 1). The study will therefore be powered to detect the three potential differences that are of greatest interest. In this study, 18 animals per group would have 80% power to detect the difference between reovirus and the combined treatment, if such a difference exists, and if the standard deviations in the two groups are similar to those seen in Annel. It would also be powered to detect differences between PD-1 and combined treatment, and between the control.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to limit the number of mice used in our experiments we will firstly test our novel anticancer agents both in in vitro cell culture models and using an ex vivo tumour slice model. The in vitro models will allow us to establish the half maximal inhibitory concentration (IC50) for the cell line that we are using and establish the potency and mechanism of action of the anticancer agents that we are studying.

As described above our group has developed a tissue slice culture model system. This system has allowed our group to refine and reduce the number of animals needed for our cancer therapeutic studies. We can obtain tumour tissue from protocol 1 (Standardisation of tumour growth after injection of live tumour cells). After the tumour growth model has been studied and the animal is culled the tumour can be divided into up to 30 slices which allow multiple drugs and viral doses to be tested at any one time. These may give us an indication of possible drug and viral doses for use in protocols 2-3 therefore refining and

reducing the number of animals needed for a project. A further source of in vivo tissue material could be obtained from the PBS control tumours from protocols 2-3. This will therefore maximise the amount of scientific information obtained from each animal used in a procedure. A wide spectrum of treatment types and routes described are used to screen a wide range ofnovel anticancer drug combinations and establish efficacy and toxicity in vivo. We have refined routes of treatments such as IV, IP, injections, infusion, gavage etc based on a comprehensive review of the scientific literature and extensive experience acquired in previous license. Data from this protocol (1, 2 3 and 9) can be used to help design drug dosing regimens and minimise/eliminate adverse effects in orthotopic protocols (4, 5, 6, 7 and 8) within this license. Imaging in vivo will allow us to obtain longitudinal data giving us more information and reducing numbers of animals needed for our studies. Throughout the life of the license, we will analyse the data produced and conduct regular reviews of the literature, enabling us to gain more knowledge to help assess appropriate sample sizes.

Advice has been sought and taken from our University statisticians on the design of all experiments in this license, and this will be an ongoing process throughout the life of the licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All animals used in 1, 2, 3, 6, 7, 8 and 9 protocols will be supplied by registered breeder such as Envigo and Charles River. Only the correct number of animals, will be purchased, based on sample sizes which will be set using power calculation’s. Protocol 4 allows us to breed GAA (L2-IL-1β (Tg[ED-L2- IL1RN/IL1B) mice, for the induction and treatment of oesophageal adenocarcinoma tumours in protocol

5. Breeding of these GAA mice is controlled by a breeding plan, devised by NACWO, NVS and members of our lab, to minimise animal wastage appendix 6. Wherever possible tissue, will be shared within research groups within the university and other institutions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of work carried out under previous project licences has be SC tumour flank model such as C57/BLACK mouse /B16.F10 cells a model of melanoma. These

heterotopic models, which are generally viewed as benign, so are seen to address researchers' obligations to minimise suffering. In this new licence we will still use these heterotopic model to obtain scientific data, but also they can be used to help design drug dosing regimens and minimise /eliminate adverse effects in orthotopic protocols within this PPL.

In this new licence a small number of studies will be carried out using IV injection. Other tumour cells that will be used in either SC or IV tumour flank models include K1735, A375 (melanoma), AY-27, EJ, T24, Ku19-19, 5637, RT112, TCCSUP-1, VMCUB, MB-49 (bladder) DU145, LNCAP, Tramp c2. PC-3, (prostate) SKOV-3, PEA1, 2, (Ovarian) MDA-MB-231 ZR-75-1, MCF7, SK-BR-3, (breast), CT-26, CaKi- 2, HT29, SW620, HCT-116 (colon) PL45, PANC-1, PSN 1, AsPC1, HPAF II, BxPC3 (Pancreatic) A549,

H520 (Lung) LN-18 , U87 (Brain) and Renca (renal). These will be grown in immuno-competent (C57BL/6, BALB/c and C3H/H) or immuno -deficient mice (Nude, Scid). These are examples of possible models to be used, but other models may be investigated either by a comprehensive review of the scientific literature or pilot tumour growth studies (see protocol 1) as recommend by Workman et al 2010 [37]. Pilot tumour growth studies using small numbers of animals can indicate patterns of local and metastatic tumour growth. Any adverse effects due to tumour progression can assess and the clinical score sheet can be adjusted. These studies can help identify the correct humane endpoints.

Data from these studies can help define group numbers in order for experimental time frames.

Based on the data from heterotopic models, we will be able to carry out orthotopic models in such areas as oesophageal adenocarcinoma (protocol 4-5), intra- bone (metastatic) cancer (protocol 6), prostate cancer (protocol 7) and bladder cancer (protocol 8). These models can be used to obtain more clinically translatable data on novel anti-cancer agents.

Protocols 4 and 5 Oesophageal cancer – of which adenocarcinoma (OAC) is the predominant subtype in the United Kingdom - is a highly aggressive malignancy, ranking sixth among all cancers for mortality, with 5-year survival rates of approximately 15%. The TME is a complex interaction between the tumour, host immune cells, fibroblasts, chemokines and other factors such as hypoxia and acidosis. An orthotopic model is the best way of replicating the TME, as the tumour develops within the native organ architecture of the cancer to ensure close similarity to the human TME. The L2-IL-1β genetically modified orthotopic mouse model allows for the generation of OAC in-situ at the squamo-columnar junction of the mouse, as seen in OAC in humans. This model will give us a TME that we can trial novel immunotherapies to advance the care of OAC beyond what has been possible to date.

Protocols 6 and 7 will allow us to study the effect of anti-cancer treatments on two forms of cancer: primary and metastatic cancer. Protocol 7 describes an orthotopic prostate cancer model involving the surgical injection off prostate tumour cells into the anterior

prostate lobe of mice. Protocol 6 With this orthotopic intra- bone (metastatic) model, we will surgically inject cancer cell lines into the tibia, leading to the development of orthotopic metastatic tumours with a clinically relevant TME.

Protocols 8 To obtain the most appropriate microenvironment for transitional cell carcinoma (bladder) cancer, tumour cells must be allow to attach to the bladder lining and grow into the bladder void. This can only be achieved by damaging the bladder layer using this protocol. Implanting tumours into the tissues of origin within the animal results in development of cancer in an appropriate microenvironment which includes for example stromal cell infiltration, including specific immune cells. A major component of our research is to study the role that our novel anti-cancer agents play in immunogenic cell death and modulating the immune system.

Why can't you use animals that are less sentient?

Reliable models of cancer which have been used in peer reviewed studies previously have been proposed. These have led to successful translation into human trials. The mice and rats proposed are representative of the human diseases: the molecular and immunological properties of the tumour cells are assessable in these models, particularly in response to therapy, and closely mirror the human context. The models are also selected on the basis of our previous experience with them, reliability and reproducibility of results, and that the experiments are completed in a short time to minimise distress to the animals (Workman et al 2010).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

There is a wide spectrum of treatment types and routes described in this licence for screening a wide range of novel anticancer drug combinations and establish efficacy and toxicity in vivo. We will be constantly refining routes of tumour implantation/treatments such as IV, IP, injections, infusion, gavage etc based on a comprehensive review of the scientific literature and extensive experience acquired in previous PPLs. An example of the type of well fare refinement we will try to bring in is discussed in Protocol 8 (Treatment of orthotopic bladder tumours with anticancer agents). A major objective of this protocol (8) is to refine our model by trialling replacements for the acid/alkaline wash such as poly-L-lysine or trypsin treatments, to limit the severity of the model. Imaging in vivo will allow us to obtain longitudinal data giving us more information and reducing numbers of animals needed for our studies. The health checks we propose are based on knowledge acquired in previous PPLs and comprehensive review of the scientific literature, these will be under constant review throughout the life of the PPL.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The Workman et al. (2010) guidelines for the welfare and use of animals in cancer research are an invaluable resource, setting out appropriate humane endpoints and

relevant clinical signs to monitor. We will also use the NC3Rs website which provides a number of resources to help with further refinement to our research. This include advice and guidance on common procedures such as blood sampling, which we have used in this application. This website also have species specific pages dedicated to non-aversive mouse handling and genetically altered mice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All the members of the lab, who are carrying out in vivo' studies, will attend the Biomedical Research users group meeting at university of surrey. Also a researcher from the team is a member of AWERB of Surrey University. These animal welfare meetings will allow our lab to have an understanding of current 3R issues within the research community. Throughout the life of the PPL, we will analyse the data produced and conduct regular reviews of the literature, enabling us to gain more knowledge to help refine protocols and procedures in terms of the 3Rs.

75. Understanding how climate change affects mammalian immunity and control of infection

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Infection, Immunity, Heat, Mammals, Climate crisis

Animal types	Life stages
Mice	neonate, embryo, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the effect of short term (heat wave) and long term ambient temperature differences on mammalian immune function and its response to infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Global warming is a reality of major concern. Currently, the global average temperature has increased by 1oC as compared to pre-industrial times, with clear effects on entire ecosystems, flooding and natural disasters. Worryingly, by 2050, global temperatures are predicted to have increased by 2-5oC, exacerbating already visible consequences from global warming. In addition we are seeing an alarming increase in heat waves were

temperatures are between 8 and 11oC higher than average temperatures. Rising temperatures impact many aspects of animal life and health, and have lately been shown to severely weaken an animal's ability to fight off infections. If our body's immune system (our defence mechanism against bacteria, viruses and other bugs) cannot fight infections properly, the body becomes vulnerable, leading to severe illness or even death. Thus, global warming could make humans more vulnerable to dying from infections such as the flu. This is particularly concerning as rising temperatures also affect how bugs behave, allowing them to become more dangerous to the body or to spread into new regions. Understanding how higher temperatures weaken the immune system is crucial to design strategies that will help prevent humans from becoming more vulnerable to infections.

What outputs do you think you will see at the end of this project?

We will understand how a rise in temperature affects the immune system and subsequently what impact this may have on our ability to control infections. This will be in the context of acute 'heat wave' type increases in temperature or prolonged exposure to smaller temperature changes of about 2-3oC, mimicking global warming. Thus, we will gather new information in this project, which will be published for the scientific, medical and political communities and support future research opportunities.

Who or what will benefit from these outputs, and how?

In this study, we aim to elucidate how higher temperature can change the ability to defend the body against infections. Understanding the mechanism behind these changes will give an insight into how we may be able to prevent or treat reduced ability to fight infections due to higher temperatures. From the results of our mouse studies, we can get an insight into how humans may react to similar temperature stress. As well as adding to our general knowledge about the effect of global warming on the human body, our data may enable scientists, doctors and politicians to create strategies that help avoid or treat decreased ability to fight infections due to higher temperatures. This could include strategies to improve the effect of vaccinations or the treatment of an infectious disease during a long hot period, especially in developing countries where people cannot always shield from the heat in climate controlled buildings. Finally, demonstrating that global warming will make our immune systems weaker can be used as yet another argument to advocate for policies to combat climate change.

How will you look to maximise the outputs of this work?

This work will be part of a larger collaborative program including programs working on cells, fish infection models and human trials. The results will be shared at the earliest opportunity through publication and at conferences. Large data sets will be deposited on databases for external access. We will disseminate all findings of our studies, including unsuccessful approaches or non-significant data, through publication in peer-reviewed journals, presentation at scientific conferences, and through meetings with other researchers.

Species and numbers of animals expected to be used

- Mice: 9700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To better understand how global warming affects our body's ability to fight infection, we cannot simply start experimenting on humans, but need to use a model system. The more similar the model is to humans, the more reliably we can make conclusions about humans based on the findings of our study. We have selected the adult mouse as a model animal for our work, as it has a fully developed immune (bug defence) system similar to that of humans. In fact, the mouse immune system is made up of the same parts as the human one and uses the same strategies to get rid of bugs, bacteria and viruses in our body. In fact the mouse is also widely used and very well characterised, which means many different scientific tests have been developed for it which we could make use of to investigate in our study. For example, the well characterised genetic code of the mouse, would allow us to later look into the role certain genes and inheritance plays when it comes to vulnerability after being exposed to high temperatures.

Typically, what will be done to an animal used in your project?

Animals in this project will typically be subjected to increased ambient (meaning 'outside') temperatures for a period of time and then infected with a bug (virus / bacterium) or vaccinated. This will involve either an injection, such as intravenously (i.e into a vein) or intranasal (i.e into the nose) and oral gavage (a tube inserted via the mouth into the stomach). Samples of blood will be taken from a tail vein (blood vessel) at predetermined time points. Animals will be monitored during the infection period by weight and in some infections by sampling of faeces. At the end of the experiment all mice will either be humanely killed, or blood collected under deep, terminal anaesthetic where they will be asleep/unconsciousness throughout. The experiment will be typically 1 month long. Some long-term breeding under increased temperature will occur over multiple generations. These animals will then be treated as above.

What are the expected impacts and/or adverse effects for the animals during your project?

As the mice will be infected with bugs they are likely to suffer some discomfort. In wild type animals at standard room temperature all the infections we use cause disease, but do not kill the mice. Mice infected with bacteria will have moderate weight loss of 5-15% over 7-14 days and will have mild clinical signs of infection, slight piloerection (hair standing on end as a sign of pain or discomfort in mice), and hunched walking. With flu infections the

weight loss will be 15-25% less than the starting weight over 10 days and mice may develop increased breathing rates.

With increased ambient temperature exposure, we may expect to see increased weight loss and more pronounced clinical signs. We will have pre-defined end points for our infections to capture animals and minimise any suffering.

Mice that are immunised can show mild signs of discomfort that are fleeting and should last no more than 24 hours. These mice are not expected to show any long term adverse effects.

Keeping animals at temperatures over 30 degrees could increase incidences of poor lactation in breeding females and heighten aggression in males.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice Mild 40%
- Moderate 60%
- Severe 0%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We only use live mice when we cannot use alternative approaches, such as working with human or animal cells in a dish (these could be blood cells or cancer cells for example that have been taken from patients). It is not possible to mimic all aspects of the interactions between the different stages of a real infection process meaningfully outside of the whole animal. Additionally, it is not possible to study the complex interaction between bugs and the host that they infect (e.g. humans) outside of a whole and living animal. We recognise that our mouse model system has limitations and cannot reproduce all the conditions associated with parallel human infections or vaccinations. However, mice have similar immune systems to humans, making observations in mice comparable to those in humans. As mice don’t always react the same way to bugs that attack humans, we use mouse-specific pathogens to evoke a more meaningful response that can be paralleled in

humans. These mouse-specific pathogens include an adapted version of the flu virus that causes similar symptoms in mice to the ones humans experience from the flu, or an adapted bacterium that mimics stomach infections causing diarrhoea etc in humans.

Which non-animal alternatives did you consider for use in this project?

Cells and organoid systems (recreating organs or parts of them from cells in the laboratory, for example part of a gut) have been considered.

Why were they not suitable?

It is not possible to mimic all aspects of the interactions between the different stages of a real infection process meaningfully outside of the whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

By keeping our experimental conditions well controlled we are able to perform highly reproducible and statistically meaningful experiments using the minimal number of animals. The experimental approaches described herein have been vigorously evaluated over the past two decades. We have access to and have used an experienced statistician to help guide experimental design. Post-doctoral scientists in our group have been on experimental design courses to help understand sources of bias and variation and how best to reduce them. Where possible in our design we blind people to genotype/treatment groups with different people doing infections or analysis. Based on our experience with pathogen infected mice, we use 5-6 mice per group as this is a sufficient sample size given the differences between means and within-group variances we typically observe. We will share any new mouse models we generate with other researchers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have been running these infection models for the last 20 years and during that time we have generated thousands of data points in wild type mice in normal conditions. From this we know what the sources of variations are and have therefore been able to control for them. We have worked closely with Biostatisticians when setting up high throughput screens using these models to reduce the numbers of mice we need to use to get meaningful results. We have used the NC3R's experimental design assistant for work we have done on previous studies and will continue to use it in future studies. The PREPARE

guidelines have also been consulted for formulation of this project, and these will be followed to ensure continued communication between the animal facility and our team.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As part of the work in this program we will use pilot studies to inform us on the control experimental conditions we need to use. These will indicate if we need to alter food intake in control animals, as mice at higher temperature don't eat as much food and if mice at thermoneutrality (29oC) have the same base line outputs as mice at room temperature (21oC) and therefore which mice should be used as controls. We have used the infections in this licence as part of a large screening programme over the last 15 years. The models are set up in a way that allows us to identify differences in test conditions (be that individual gene deleted mice or in this case increased temperature).

The work is also a part of a larger program of work within the department where data will be generated for other experimental models including work in fish and humans. The data generated in these programs will also inform the work herein. Samples collected from any mice as part of experiments planned will be stored long term at -70oC. This will make the samples available for future analysis.

There is potential that other groups may want to use post-mortem tissues that we do not take from mice that have been exposed to increase temperatures.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have established that the mouse can be used to identify bug (also referred to as 'pathogen') and mammalian genes that influence infection and immunity. The wild type parental bugs that we use are almost exclusively disease-causing for the mouse and thus likely to yield important and relevant phenotypes and associated data. Although the pathogens we use are mainly mouse pathogens they are good correlates to human specific diseases. We believe that the similarities in the mouse and human genomes are such that we can infer between the two and we have closer links than ever before with patients in the clinic. Over the years we have gained tremendous experience with our infection models and, through careful observation, we are able to minimise the potential suffering of the animals.

We have been able to identify key clinical signs that indicate illness in infected animals and consequently such animals can be quickly and humanely killed.

Why can’t you use animals that are less sentient?

It is not possible to mimic all aspects of the interactions between the different stages of a real infection process meaningfully outside of the whole animal. It is not possible to study the complex interactions between the host (e.g. humans or mice) and infectious agents / bugs (e.g. the flu virus) outside of whole living animals or in animals that don’t have a mammalian immune system. We recognise that our mouse model systems have limitations and cannot reproduce all the conditions associated with parallel human infections or vaccinations. However, mice have many similarities to humans, including in terms of their immune system. We also use mouse-specific bugs to evoke a more meaningful response that can be paralleled in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are monitored throughout all experiments and we collect daily scores composed of a set of physical signs of illness such as piloerection (raised hair as a sign of pain or discomfort), hunched walk and mobility along with weight loss. The cut-off for these physical signs lies within the guidelines for moderate severity, i.e. loss of pre-set percentage body weight being our main indicator, along with mobility (ability to feed and water). The scoring for piloerection etc. are also used as secondary indicators. My team are experienced in animal infection models and are trained to the high standards that I expect. The technicians that work in our holding facility and do the majority of the animal husbandry will also be trained by my team and will communicate abnormal behaviours in the mice early. At our establishment we have dedicated Named Animal Care and Welfare Officer who are impartial and can give advice/ make decisions on animals that lie outside of the normal adverse effects expected for the infections outlined within this project.

Potential refinements include increased monitoring if test animals show earlier clinical signs or weight loss. We will give wet mash food to animals that lose more weight quickly. Floor food will be given to animals that are to be infected to limit weight loss from the start of the infection.

Litters from breeders at higher temperature will be monitored closely for development as temperature may affect lactation in mothers. Any evidence in pups not developing or litter losses will be discussed with NVS and appropriate actions taken.

All animals will be given environmental enrichment and be socially housed to encourage natural behaviours and reduce stress. Males will be monitored for increased aggression and additional enrichment added to combat or appropriate splitting of fighting animals if needed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use guidance from the NC3Rs website and the Laboratory Animal Science Association (LASA) to ensure experiments are conducted appropriately. In particular we will follow the 'Guiding principles on good practice for Animal Welfare and Ethical Review Bodies'.

We will follow the PREPARE guidelines for planning experiments and will follow the ARRIVE guidelines reporting of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will keep informed on advances through the NC3R's website, Norecopa website, our establishment website and newsletter. We will discuss any advances with the relevant people at our establishment and implement them accordingly.

76. Early safety assessment, investigatory and efficacy studies

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

safety, pharmacology, drug-development, efficacy, physiology

Animal types	Life stages
Mice	adult
Rats	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to provide a service to pharmaceutical companies who required an assessment of the safety of their potential new medicines on vital body organ function (heart, lungs, central nervous system (CNS)). The project will also allow the efficacy of some potential new medicines to be assessing on behalf of Sponsor companies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Before regulatory authorities will grant permission for testing potential new medicines to humans, they require the safety of the compound to be assessed in animals. Standard toxicology and safety pharmacology studies are performed to fulfil regulatory requirements prior to first-time-in-man clinical trials. If safety liabilities are identified in these regulatory studies, options to change the chemical scaffold of the molecule at this late stage are limited. This can result in wasted money, resources and animals on compounds which are not ultimately suitable for development as potential medicines.

Consequently, there has been a drive to incorporate safety assessment earlier in the drug discovery/development process when studies can be performed to identify potentially undesirable pharmacodynamic effects or overt toxicities and thus identify unsuitable targets and/or eliminate unsuitable drug candidates. At this earlier stage, compound series are still being identified and optimised and modifications may be made more easily to improve safety. Whilst early in vitro safety screens have become more widely used, early in vivo screens in rodents are also often employed within the discovery phase to investigate potential undesirable effects on physiological function. Effects on vital organ systems (cardiovascular, respiratory, CNS) can be made using specialist equipment.

Use of rodents is beneficial since compound requirements are low and synthesis is expensive at this early stage.

In addition to their use in early screens, rodent models are also used as investigational follow-up studies to evaluate pharmacodynamic or pathophysiological effects of test substances observed in previous pre-clinical or clinical studies. Studies can be performed to investigate the mechanism of an observed toxicity.

Anaesthetised rodent models also lend themselves to early efficacy assessments of candidate compounds. Efficacy is generally assessed by administration of a stimulatory substance in addition to the candidate drug. Body fluids, tissues or organs can then be collected for measurement of relevant biomarkers.

Under this licence new medicines (e.g. cancer therapies, medicines for gastrointestinal disorders or CNS diseases) will be tested in small animal protocols with the aim of identifying undesirable effects on the cardiovascular, respiratory or central nervous system. The medicines will usually be small molecules but, occasionally, peptides/proteins, antibodies and antibody drug-conjugates may be tested. Both early screening studies assessing effects of test compounds on vital organ systems and investigational studies to determine mechanisms of observed effects will be performed. Studies to assess the potential efficacy of test compounds will also be conducted. This information helps Sponsors prioritise the most promising candidates for further development, eliminate unsafe medicines and make necessary changes to candidate

molecules to make them safer for animals in future animal testing and for humans in clinical trials.

The following references support the need for the work related to this project:

Ventricular Repolarization (QT Interval Prolongation) By Human Pharmaceuticals.

Available at: https://www.ich.org/page/safety-guidelines

What outputs do you think you will see at the end of this project?

The project will generate new information on the safety of many potential candidate medicines which will be used by the Sponsors in their drug discovery and development programmes. Examples include quantitative profiles of the effect of potential medicines on:

- arterial blood pressure, heart rate, ECG (electrocardiogram) parameters, contractility of the heart,
- brain activity via EEG (electroencephalogram) recording
- breathing rate, breathing volume (tidal volume)
- body temperature and activity

By recording additional physiological parameters, using surgical interventions or using blocking drugs, the project will also generate data outputs that may help Sponsors determine:

- the mechanism of any adverse effect (e.g. is the decrease in blood pressure due to dilation of blood vessels or effects on the heart)
- the site of action of an adverse effect (e.g. via action on the brain or via an action in the periphery)

The project may also generate new information on the efficacy of potential new medicines by measuring relevant biochemical markers in certain body fluids (e.g. urine, blood, plasma).

Other outputs include:

- information on the tolerability of the test compounds
- information on the pharmacokinetics of the test compounds (e.g. maximum concentration [Cmax] , time of maximum concentration [Tmax], half life, area under the concentration vs time curve [AUC]).

Who or what will benefit from these outputs, and how?

Outputs from early rodent safety or efficacy screens will help Sponsors improve their compound selection process during the drug discovery phase. Studies performed on candidate, or competitor compounds (compounds already on the market or in development by other companies) will help to assess the safety risks that may be associated with the selected drug target and also determine whether the pharmacological class or chemical series has inherent safety liabilities associated with it. This should promote the development of compounds with a more acceptable pharmacological and toxicity profile.

By testing the effects of test compounds in the therapeutic range and above (supra-therapeutic), the data outputs will help Sponsors assess the onset, dose-response and reversibility of any adverse effect of their compounds. This will help with stop/go development decisions and help select the most appropriate candidate for further development. Progression of safer drugs will reduce the severity and/or incidence of adverse effect in regulatory preclinical animals studies and will contribute to the safety of clinical trials, reducing the chances of side effects in healthy volunteers and patients. It is expected that these benefits would be realised within the lifetime of this licence since most compounds tested would be preclinical candidates which, if successful, could be expected to progress into clinical trials within 2-4 years.

Identification of safety issues early in the discovery phase will provide the opportunity to investigate the mechanism of the toxicity and its relevance to man before clinical trials are considered. A mechanistic understanding of any adverse effects may help Sponsors assess the risk/benefit of further development. Identification of mechanisms of toxicity that may not be relevant to humans may allow development of medicines that would otherwise not have been available. Indeed, such mechanistic investigations are often requested by regulatory agencies. Where a compound with a known safety liability progresses to clinical trials, a mechanistic understanding of the liability, gleaned from prior preclinical studies, can help improve the clinical risk management plan. It is expected that there will be reduced attrition of potential medicines in development, as a result of better early selection, and faster delivery of new medicines to patients.

How will you look to maximise the outputs of this work?

Where possible, we will publish data from the studies performed, in collaboration with Sponsors, in high quality journals. There are often restrictions surrounding publications of live project compounds but opportunities for publication often exist once approval is granted or on data for compounds that do not proceed to clinical trials.

Any refinements that we make to our protocols and animal models will be presented at a relevant scientific meeting (e.g. Safety Pharmacology Society) and also disseminated by

publication in a relevant journal (e.g. Journal of Pharmacological and Toxicological Methods; IAT Journal) so that other may learn from our experiences.

Species and numbers of animals expected to be used

- Mice: 375
- Rats: 1025
- Guinea pigs: 245

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The rat is generally the rodent species of choice in drug safety testing and some efficacy testing. The physiology of the cardiovascular, respiratory and central nervous systems has been well characterised in this species. There is a wide knowledge of the response of rats to various chemical entities and many drugs show similar effects in rats and humans. Rats are therefore considered an appropriate species to use for evaluating the potential adverse effects to humans of new drugs on vital organ system function.

Mice may be used if for some reason they are a more appropriate species than the rat e.g. for drug kinetic reasons or if their expression of a drug target is more similar to humans than rats. Mice are often used in efficacy or toxicology studies for reasons such as this and adverse effects previously observed in these studies may need to be investigated in the same species.

Guinea pigs are used preferentially for studies on cardiac electrophysiology as the expression of ion channels in the heart is more representative of the human situation compared to rats and mice and it has been shown to be a predictive species for drug effects in humans. Guinea pigs are also a more appropriate species to use in respiratory studies if the compound is suspected to cause airway hypersensitivity responses, since the receptor pharmacology more closely resembles that of the human airway. Use of a small animal model results in a low compound requirement which is of benefit in early drug development.

Adult animals will generally be used since most drug tested will be for indications in adult humans.

Typically, what will be done to an animal used in your project?

Animals used in this project may be used in terminal anaesthesia protocols, recovery anaesthesia protocols or in conscious animal studies.

Terminal anaesthesia: In terminally anaesthetised studies an animal will be anaesthetised and surgically prepared to allow recording of various physiological parameters. This includes:

- placement of cannulae in blood vessels to measure blood pressures and for intravenous (i.v.) dosing of the test compound
- placement of ECG leads under the skin to measure the electrical activity of the heart
- measurement of respiratory parameters using a flow transducer, or accelerometer placed on the skin. The breathing of some animals may be controlled by artificial ventilation
- placement of biopotential leads on the cranium to record an EEG

Following surgery, the animals will be allowed to stabilise and then one or more doses of the test drug will be administered to assess its effects over time on the physiological parameters. The animals remain anaesthetised for the whole experiment and recordings may be made for up to 5h after which time the animal is humanely killed without regaining consciousness.

Recovery anaesthesia: Recovery anaesthesia is required in some studies to surgically implant telemetry devices. These devices allow the following physiological signals to be measured:

- arterial blood pressure via a catheter implanted in the aorta, femoral or carotid artery
- ECG via biopotential leads positioned on the xiphoid process and subcutaneously or intramuscularly
- EEG via biopotential leads positioned and secured on the cranium

The body of the implant device is usually secured in the peritoneum or under the skin. Animals are monitored closely throughout and after the surgery and are given medication to minimise the pain that may be experienced afterwards. Once they have recovered from surgery (after at least 2 weeks) they may be dosed (usually orally) with test drugs and the effects of the compound on physiological parameters over time is recorded remotely without having to disturb the animals. When a test compound needs to be infused intravenously recovery surgery may also be required to implant a cannula in a vein. This is better option than using a temporary intravenous catheter which would require long-term restraint and stress. Animals implanted with telemetry devices are usually used and then re-used for other drug assessments following a washout period.

Conscious animal studies: To assess the general effects of test compounds on the central nervous system, normal (non-implanted) animals are dosed with a test drug and the effects on the animals' behaviour are observed in their home cage, in a separate observation cage or whilst being handled. Conscious animals can also be placed

temporarily into whole body plethysmography chambers (for up to 8h) in which they can move freely and which allow their breathing to monitored non-invasively. This detects effect of the test drug on the lungs and the respiratory system.

In most studies, blood samples are taken from the animals to measure how much of the test drug is in the body. In terminally anaesthetised animals this is usually taken from a cannula in a blood vessel. In conscious animals, the blood is taken via a tail prick and the number of samples and volume of blood taken are minimised.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect to see many adverse effects due to the dosing of the test compounds since Sponsors will usually have prior in vivo data on the test compounds such as results from efficacy studies, pharmacokinetic studies or preliminary toxicology studies, including maximum tolerated dose (MTD) studies. When there is no prior tolerability information, a pilot study will be performed in a small number of animals to assess the tolerability of the test compound and possible adverse effects. This will ensure safe and relevant doses are administered to the animals in successive studies. To ensure a thorough assessment of safety at therapeutic and supra-therapeutic doses it may be necessary to dose up to or near the MTD (the MTD being a dose that may cause target organ toxicity but is anticipated to be tolerated and will not jeopardise the study by causing morbidity or mortality).

Some animal may therefore experience adverse effects as a result of the dosing of test drugs such as weight loss, piloerection (raised fur), hunched posture and subdued behaviour. When they occur, the adverse effects of the test drugs will be expected to occur around the time of the maximum drug concentration in the blood and will be of short duration dissipating as the drug is cleared from the body. Humane end-points are applied as necessary to minimise the suffering of the animals.

Adverse effects may also occur as a result of the dosing procedure. Animals will be dosed by routes similar to those used in humans, e.g. by mouth (orally) or by injection (e.g. intravenous, subcutaneous) and these require short-term restraint or confinement. When dosing, animals will be restrained and the drug administered directly into the stomach via a syringe and gavage tube or into a vein. This may cause a period of discomfort whilst the procedure is being performed. Transient discomfort may occur during the sampling of blood, usually via a tail prick, which is required in most studies to determine the amount of test drug in the body.

Some animals may experience short-term discomfort following surgery to implant telemetry devices or to implant intravenous catheters for longer duration injections. Subdued behaviour and some signs of discomfort may be seen in the days after surgery and weight loss is often observed during the week post-surgery. Analgesics and anti-inflammatory drugs are given to relieve post-surgical pain.

Some animals may experience adverse effects due to single housing and lack of social contact. Single housing is usually required after recovery surgery for 1-2 days, during some telemetry studies when intravenous dosing is required and also during conscious assessment of lung function (for up to 8h).

Singly housed animals will be housed adjacent to each other animals so they have visual contact at all times.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?
Rats: Non-recovery: 85% Moderate and/or Mild adverse effects 15%

Guinea Pigs: Non-recovery: 85% Moderate adverse effects 15%

Mice: Non-recovery: 70% Moderate adverse effects 30%

The majority of animals used in this project will be used in non-recovery procedures only.

Approximately 15% of rats and 30% of mice and 15% guinea pigs may experience moderate adverse effects due to surgical implantation of telemetry devices or vascular catheters. Mild adverse effects are likely to be experienced during the subsequent dosing of test compounds and blood sampling although occasionally these could be moderate.

Some rats, not implanted and used for conscious respiratory or CNS assessments, may experience mild effects or moderate adverse effects due to the dosing of test drugs and blood sampling.

Examples of mild adverse effects include slight weight loss, partial piloerection (slight raised fur), transient hunched posture and subdued behaviour or transient discomfort due to dosing restraint or blood sampling. Examples of moderate adverse effects include more marked weight loss, marked piloerection (marked raised fur), intermittent hunched posture, subdued behaviour even when provoked, intermittent tremors (marked but not continuous).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sponsors will assess efficacy in available in vitro and ex vivo tissue systems and will assess safety using non-animal methods where possible. However, to understand if a potential new medicine has the desired effect in vivo or to investigate how it affects the function of vital organs, either directly or indirectly, it is still necessary to use a whole animal in which all organ systems are present and their physiology is intact. This is in accordance with international regulatory guidelines that specify the generation of safety data in two species, one of which must be a rodent.

Which non-animal alternatives did you consider for use in this project?

It is likely that in vitro/ex vivo assays will have been used to select the compounds that will be tested in animals in this licence as part of the usual screening cascade that occurs in the discovery and optimisation stages of drug development. Non-animal alternatives such as these have already reduced the demand for some of the projects conducted under this licence. For example, use of stem cell-derived cardiac myocytes enables Sponsors to perform some early cardiovascular screening (assessing QT liability) without the use of animals. Selection between candidates will now usually be made based on these in vitro results, rather based on in vivo data from multiple studies, and often only the final selected compound is tested in animals. These in vitro data will be used alongside any in vivo data generated under this licence to form an integrated risk assessment used ultimately to minimise the risk to volunteers and patients in clinical trials.

Why were they not suitable?

Whilst in vitro/ex vivo assays are used by Sponsors in the screening and selection process, to understand how a test compound may affect the function of vital organs, either directly or indirectly, it is necessary to use a whole animal in which all interrelated organ systems are present and their physiology is intact. This is in accordance with international regulatory guidelines that specify the generation of safety data in two species, one of which must be a rodent.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

As a Contract Research Organisation, the number of animals used will primarily be based on the number of studies performed for Sponsors. The estimates are based on actual numbers used in previous years on a similar project licence (30/3403).

2 non-recovery mice studies per year are likely with a group size of n=4-6 and 2-3 groups per study (approximately 125 over 5 years).

30 mice are likely to be used in conscious telemetry, respiratory or CNS studies per year (usually n=4-6 per study) (approximately 150 over 5 years).

20 mice are likely to be used in tolerability/pharmacokinetic studies per year (usually n=2-6 per study) (approximately 100 over 5 years).

10 non-recovery rat studies per year are likely with a group size of n=4-6 and 2-3 groups per study (approximately 625 over 5 years).

50 rats are likely to be used in conscious telemetry, respiratory or CNS studies per year (usually n=4-6 per study)(approximately 250 over 5 years).

30 rats are likely to be used in tolerability/pharmacokinetic studies per year (usually n=2-6 per study) (approximately 150 over 5 years).

3 non-recovery guinea pig studies per year are likely with a group size of n=4-6 and 2-3 groups per study (approximately 190 over 5years).

8 guinea pigs are likely to be used in conscious telemetry studies per year (usually n=4-6 per study) (approximately 40 over 5 years).

5 guinea pigs are likely to be used in tolerability/pharmacokinetic studies per year (usually n=2-6 per study) (approximately 25 over 5 years).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Study directors working under this licence have extensive experience of designing these study types and aim to use the minimum number of animals that allows the study to reach its objective. We also have an on-going collaboration with statisticians in a partner company who perform statistical health checks and advice on the design of the study, the number of animals per group, randomization and the method of statistical analysis.

Prior data analysed by our partner, and in preparation for publication, has shown that test drug effects on physiological parameters can be detected with acceptable sensitivity in small groups of animals (n=4-6) in non-recovery studies. Increasing the group size to n=8 improves the sensitivity of detection only marginally. The good sensitivity with small group sizes is likely to be due to the fact that the measurement of safety endpoints and efficacy biomarkers is conducted under terminal anaesthesia which may reduce the variability. We will continue to utilise this technique so that animal numbers are reduced.

Our previously published data has also shown that small drug-induced effects on physiological parameters can be detected with acceptable sensitivity in conscious animals using telemetry with a group size of n=6. Again, increasing the group size to n=8 has only

marginal benefits in terms of the power of detection. We routinely use optimal data summarising techniques (e.g. superintervals) in conscious animal studies which contributes to the good sensitivity.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All studies will be designed to maximise the amount of useful data obtained using from each animal. Pilot studies will also be used where necessary to ensure that safe and optimal doses are selected for the main studies. This will prevent studies having to be repeated, and animals used unnecessarily, due to poor dose selection.

Assessment of the safety of a test drug usually requires a dose-response to be investigated (at therapeutic levels and above). In non-recovery studies and conscious animal studies multiple doses of test drug will be tested in the same animal where possible rather than using separate animals for each dose. In conscious studies this will be achieved by using cross-over designs and appropriate washout periods between doses.

It may be possible in some studies to incorporate physiological endpoints from multiple organ systems into the same study, potentially negating the need for separate studies. E.g, cardiovascular and respiratory endpoints in a single terminally anaesthetised study; cardiovascular and EEG recordings in a single conscious telemetry study.

Blood sampling may also be included alongside the safety assessment, especially in non-recovery studies, to allow the effects of test drugs to be correlated to the concentration of drug in the blood/plasma. This may obviate separate satellite pharmacokinetic animal studies. Samples of tissues or body fluids taken at the end of the study may be frozen and stored for further analysis.

In some non-recovery studies, it may be possible to obtain efficacy data alongside safety data in a single study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- Protocol 1: Safety and efficacy assessments in terminally anaesthetised rodents

The majority of animals used in this project will be used in the non-recovery terminal anaesthesia protocol. Use of terminal anaesthesia minimises pain, suffering and distress to the animals. Surgical preparation will be done aseptically. Whilst the anaesthesia itself may blunt certain physiological reflexes (although this can be mitigated by appropriate choice of anaesthetic), this can make the model more sensitive in detecting drug-induced effects which is often advantageous if used during the early discovery drug development phase. Pre-dosing of conscious animals prior to the terminal phase may be required in some studies (approx. 10% of terminal studies). If any pre-dosing is required, the doses used will usually have no adverse effects having been tested previously either by the Sponsor or in a pilot study (this licence). Occasionally doses administered may cause mild or moderate adverse effects. This is more likely to occur when assessing doses in excess of the predicted therapeutic range which is a requirement for safety testing.

- Protocol 2 Tolerability/Pharmacokinetic studies

In most of the main studies conducted under the other protocols, information about the tolerability of the test compound will already exist and doses will be selected accordingly. Where prior tolerability data is absent, a pilot study will be performed ahead of the main study in separate groups of animals using an ascending dose design. Suffering of the animals will be minimised by using a small group size for assessing each dose (usually n=2) and using small dose escalations, escalating only if the previous dose was tolerated. The results of this study will enable confident setting of tolerated doses for the main study which will minimise suffering of the larger group of main study animals. Animals may also be dosed to assess the concentration of test drug in the blood/plasma (pharmacokinetic study). This will usually be performed to support a separate safety study conducted under this licence. Assessing the pharmacokinetics in a separate group of animals is often preferable if the amount of blood sampling required would compromise the safety data. The number of blood samples and the volume of blood taken will be minimised by using a micro sampling technique, where possible, which also minimises the distress and restraint required.

- Protocol 3 Monitoring of physiological parameters in conscious rodents

The gold-standard method of assessment of drug-induced changes in cardiovascular parameters and the electroencephalogram (EEG) is with the use of conscious freely-moving animals using implantable telemetry technology. These techniques, which will be employed under this licence, allow the assessment of drug effects in an unperturbed physiological system with all reflex mechanisms and regulatory systems intact. For studies using telemetry, animal suffering related to the implantation of the telemetry device will be minimised by the use of aseptic surgical techniques with appropriate recovery anaesthesia and analgesia and post-surgical monitoring.

The amount of animal restraint required will be minimal on oral dosing telemetry studies (estimated to account for 70% of telemetry studies) and any blood sampling will be limited (due to its adverse effects on the recorded parameters). When test compounds need to be

administered by intravenous infusion, it will usually be more appropriate to surgically implant a venous cannula for dosing (approx. 20% of telemetry studies). This allows the animal to move freely whilst being dosing in its recording cage and minimises the suffering that would otherwise have been caused by prolonged restraint. The implanted catheter is usually connected to a skin button and swivel and tether system which necessitates single housing for the duration of the dosing and recording. Single housing is necessary to prevent possible damage to the equipment and cannula by cage mates which could result in a failed experiment and euthanasia of the animals. Environmental enrichment such as bedding and chew-sticks may still be provided to alleviate stress induced by single housing and the use of protective caps on the skin buttons enables group housing during non-dosing days. Alternatively, for short intravenous administrations, it may be preferable to physically restrain the animals in a restraining tube and insert a temporary catheter into a lateral tail vein (approx. 10% of telemetry studies).

- Protocol 4 Behavioural testing in conscious rodents

The Irwin test is a standard method for assessing the effects of a test compound on the central nervous system (CNS). It is the most suitable procedure since it permits evaluation of behavioural, neurological, autonomic and peripheral nervous effects with non-invasive monitoring and minor animal handling. No surgical procedures are necessary and animals can be group-housed for the majority of the study.

Animal suffering should be restricted to dosing, limited blood sampling and potential adverse effect of the test compound.

- Protocol 5 Respiratory assessment in conscious rodents

A standard method of assessment of respiratory parameters is in conscious freely-moving animals using plethysmography. This technique measures respiratory parameters indirectly but it is advantageous since it is non-invasive and the animals are not required to be restrained during recording. Some suffering may, however, be caused by the stress of single housing required within the plethysmography chambers. Pair-housing is not possible during respiratory recording as the pressure signal within the chamber would be affected by the respiratory pattern of the companion. Suffering will be minimised by group-housing when not having measurements taken and limiting the time spent in plethysmography chambers to a maximum of 2h pre-dose and 6h post-dose which should allow sufficient time for the onset and offset of potential drug effects to be recorded. The size of the chambers allows for freedom of movement of the animal and wet food is placed into the chamber for recording periods >4h post-dose as it has been shown to reduce body weight loss. Chambers are made from transparent perspex and multiple chambers will be arranged so that animals are within sight of other animals under test. Animal suffering may also be caused by dosing, blood sampling and potential adverse effect of the test compound.

Why can't you use animals that are less sentient?

Adult rodents are used standardly for the assessment of safety or efficacy of new medicines according to international regulatory guideline since the physiology of their cardiovascular, respiratory and central nervous systems is well characterised and is similar to humans. There is a wide knowledge of the response of rodents to various chemical entities and many studies have shown concordance of drug effects on physiological function between rodents and humans. Rodents are therefore considered an appropriate species to use for evaluating the potential adverse effects of new drugs on vital organ system function. Less sentient invertebrates exhibit more differences in physiology compared to humans and are less likely to predict the potential effects of a test drug in humans. The majority of studies performed under this licence will however be conducted under terminal anaesthesia reducing animal sentience.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Most procedures will be conducted under non-recovery anaesthesia, minimising harms to the animals.

Animals will be group housed as standard and provided with specific materials to provide enrichment. Rats are housed in large double-decker IVC cages, guinea pigs in floor pens and mice in standard IVC cages. We also have a socialisation programme in place where rats are housed in larger groups in a multi-storey playpen for periods of time. This will be utilised for animals that are kept for longer periods of time (e.g. re-used telemetry animals). Any periods of restraint or single housing required during a study will be kept to the minimum required to achieve the study objectives.

Where prior data does not exist, pilot studies will be used to assess the tolerability of any test drug that is required to be given to conscious animals in a study. Doses that cause some adverse effects may be required to be given to animals so that a full dose response safety profile is explored. In all studies, adverse effects experienced by the animal and the number of animals per group will be kept to the minimum to achieve the objectives. Where animals receive multiple doses of a test medicine, sufficient recovery time will be allowed between successive doses. Dosing will be conducted by trained licensees and flexible oral dosing catheters will be the default catheter that is used for any oral dosing.

Capillary microsampling will be used preferentially in all studies when blood samples are required. This technique reduces animal suffering since the volume of blood collected per sample (usually approx 30uL) is smaller than standard samples and the collection process is more rapid and requires less animal restraint. Sampling can usually be performed by one person with the animal being held in one arm.

Appropriate anaesthetics and analgesics will be used during and after any surgical procedures required. Peri and post-operative monitoring is performed closely using a detailed score sheet immediately after surgery for 3-5h with additional checks as required. Enhanced welfare checks with pain scoring are performed for a week after surgery

followed by standard daily welfare checks. Animals are expected to make a rapid and uneventful recovery from surgical implantation of telemetry devices. Animals will be humanely killed in the event of any unexpected post-surgical complications that cannot be easily remedied using only minor interventions.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the advice of Procedures with care website for dosing and blood sampling http://www.procedureswithcare.org.uk/

Dose volumes will be used according to standard published guidelines (Morton et al., 2001; Diehl et al., 2001; LASA Good Practice Guidelines, 1998)

Standard published guidelines will be followed for blood volume removal (Diehl et al., 2001, NC3Rs website) and capillary microsampling will be the default method used.

Lab Anim. 2001 Jan;35(1):1-41.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive updates from the NC3Rs and read animal science journals (IAT Journal, Laboratory Animals) which are good sources of useful information on animal welfare. M Skinner is a member of the University 3Rs committee. We implement any appropriate changes to methodology that will have positive impact on the animals' welfare.

We also strive to continually improve the welfare of animals by making refinements in our facility and publishing outcomes. Examples under a previous licence include the used of double-decker cages for rodent telemetry and the use of a rodent socialisation cage.

77. Cellular and molecular mechanisms of the mouse embryo development

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

mouse embryo, development, cell identity, stem cells, embryonic stem cells

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project seeks to understand early mammalian development with a special focus on how the different cell types of the embryo are formed and organised in the early embryo.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Approximately 50% of human pregnancies fail at this early stage of development and we know very little due to the inaccessible nature of the human embryo at these time points. Therefore, gaining a greater understanding of how early mammalian development occurs will bring us insight into this significant medical problem. These studies will provide us with insights into how the major cell types of the embryo - the supporting placenta and yolk sac, and the embryo itself – are formed in the first week of development and importantly how

and why mistakes in this process lead to loss of the embryo. We carry out work in the mouse system as the mechanisms and biology are likely to be directly relevant to human development and to understanding how pregnancies fail at these early stages. In addition, stem cells, which can be cultured in a dish, resemble the early cells of the embryo. As such, understanding the mechanisms that drive different cell identities in the embryo is also crucial for expanding our knowledge of how to direct stem cells to develop into the different cell types of the body. This will be critical to develop future approaches for regrowing, repairing, or replacing damaged or diseased cells, organs or tissues.

What outputs do you think you will see at the end of this project?

This project aims to answer outstanding questions in developmental and stem cell biology. The Principal Investigator and her research group are well known for running cutting-edge research, which is consistently published in high-impact journals and presented at conferences.

Expected outputs:

- publications in high-impact scientific journals
- conference presentations and papers
- new information in the field
- new experimental methods and approaches that could be used by other research groups in the future
- fostering of new international collaborations that will allow new approaches to current and future scientific questions
- training of scientists in responsible use of animals in research and mammalian embryology techniques
- data to support future funding applications and potential patent applications

Who or what will benefit from these outputs, and how?

Understanding development and cell identity in the embryo has many downstream benefits. In the short term it will improve knowledge of the mechanisms the early embryo uses to become specialised and grow. This knowledge will help us improve methods for working with, regrowing, repairing, and replacing damaged or diseased cells in the early embryo, which will likely impact in vitro fertilisation techniques. It will also impact on efforts to grow embryo-like structures using stem cells, which have huge potential to contribute to our understanding of development and to reduce the use of animals in research.

The immediate beneficiaries of these outputs will be the scientific community. Publications from this project will be published throughout the period of the project and scientists studying development, stem cell biology, reproduction, regenerative medicine and related fields will be the predominant beneficiaries of these publications.

In the medium to long-term, this project will expand our knowledge of how and why pregnancies fail. This will likely lead to improved methods for embryo culture, fertilisation,

transfer and success in reproductive technologies, including fertilisation in the dish. We also expect that improvement of embryo-like structures development from stem cells will replace the use of animals in many areas, e.g. drugs and other chemical compounds testing or assessment of gene function during the development. Data obtained will also improve knowledge of the stem cell-based therapies.

How will you look to maximise the outputs of this work?

- The Principal Investigator and the research group have several established national and international collaborations and are setting up new collaborations on an ongoing basis to maximise impact and dissemination.
- The outputs of this project will be presented at scientific conferences and published in high impact scientific journals to aid in knowledge dissemination. All publications will be open access.
- Dissemination of any approaches (successful or unsuccessful) and/or data (significant or insignificant) we may encounter in the duration of the project.
- The Principal Investigator will continue to recruit undergraduate and postgraduate students, as well as postdoctoral scientist to work on this project. These lab members will receive extensive training in mammalian embryology and the respectful use of animals in research. This knowledge and experience will be disseminated further as these scientists progress in their career and move between different laboratories and groups both academic and industrial.

Species and numbers of animals expected to be used

- Mice: 43 675

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our group is investigating the mechanisms of mammalian development, from fertilization until the formation of the recognisable body after implantation in the womb. Mouse embryos are crucial in developmental biology research and are an excellent model to study events occurring during mammalian development, including many aspects of human development. Methods for mice breeding and maintenance, mouse embryo production, recovery and culture are well established and optimised, ensuring refinement and reduction in animal use. Our group has extensive experience with mouse embryology at pre- and early post-implantation stages.

Ultimately, we are interested in understanding early human development and disease. However, the use of human embryos is technically and ethically challenging. Therefore, the mouse embryo, which undergoes a similar developmental trajectory and allows for

experimental manipulation is an excellent organism with which to carry out this research to investigate aspects of human development. The mouse represents an excellent balance between similarity to the human, size, experimental ability and cost. Our laboratory has a successful track-record of utilising mouse research to investigate and understand aspects of human embryo development.

It is important to add that, part of our scientific focus is the optimization of methods to create mouse embryo-like structures from mouse stem cells. Our success has led to a partial replacement of mouse embryos. However, these models do not yet fully capture the complexity of the mouse embryo, and therefore, it is, as yet, impossible to replace the use of mice in our current research.

Typically, what will be done to an animal used in your project?

Mice are used to generate embryonic tissue in our project. To obtain embryos, female mice will be administered two hormone injections (around 48 hours apart) to stimulate egg production and release. Hormones will be injected intraperitoneally (i.e. into the body cavity) or subcutaneously (i.e under the skin). This procedure, called superovulation, increases the yield of released oocytes, decreasing the number of mice needed to generate a set number of embryos for research. Subsequently, female mice will be placed with male mice for mating to fertilise the released oocytes. Following successful mating, embryos are obtained after humanely culling the dam and dissecting out the developing embryo.

We also plan to produce novel genetically altered mouse lines (without harmful effects), which help us understand the effect and role of specific genes. This procedure involves surgical or non-surgical transfer of genetically altered embryos into the womb of a female mouse, which in turn develop as normal pregnancies. Non-surgical embryo transfer will be used whenever possible as more refined method. However, in cases where it is not possible (e.g. transfer of embryos at very early stages, repetitive problems with non-surgical transfer efficiency that would not result in positive outcome), surgical transfer will be used. Surgical embryo transfer involves a minor surgical procedure performed under anaesthesia to transfer genetically altered embryos into the womb. During surgical embryo transfer mice are unconscious throughout the procedure and will experience short-lived post-operative pain and discomfort. The procedure will be performed in aseptic conditions to reduce risk of infection. To minimise any pain or distress, a range of available analgesia methods will be used. During non- surgical embryo transfer, embryos will be inserted directly into the uterus with a special device without any surgical intervention. Animals experience mild transient discomfort and no lasting harm. For embryo transfer (non-surgical and surgical), female mice are mated with sterile males to induce a pseudo-pregnant state, which is essential for creating a womb that allows the transferred embryo to develop. It is planned to use naturally sterile males (genetically altered) by default as more refined solution. However, we predict that due to unexpected events (e.g. problems with availability), we may need to use sterile males generated by performing a vasectomy, where the tube carrying sperm is cut. We expect that this would be not more than 10% of

sterile males used. These mice will experience minor post-operative pain and discomfort. This procedure will be also completed under general anaesthesia so that the animal will remain unconscious, and in aseptic conditions, to reduce risk of infection. To minimise any pain or distress a range of available analgesia methods will be used.

Following birth, the mice with the genetic alteration are maintained and bred in order to keep the new genetic alteration and establish a mouse colony. Subsequently, the new mouse line would be used to obtain embryos for the experiments as described above.

What are the expected impacts and/or adverse effects for the animals during your project?

For the hormone injections, the doses and routes used are well validated and are not anticipated to produce any adverse effects, beyond transient discomfort due to the injections, which will be intraperitoneal (i.e. into the body cavity) or subcutaneous (i.e under the skin).

Breeding and maintenance of genetically altered animals will have only minor or no effects that are more than minor or transient - animals are not expected to experience harmful phenotypes due to the genetic alteration, i.e. effects that would result in pain, distress, suffering or lasting harm equivalent to, or higher than that caused by the introduction of a needle in accordance with good veterinary practice (for example hair loss, swelling under skin, body deformations). For any new mouse line generated or received, welfare assessment with increased frequency of observation and monitoring will be performed to ensure that the alteration does not harmfully impact the animals.

Animals undergoing surgical embryo transfer will experience short-lived post-operative pain and discomfort. This procedure will be completed under general anaesthesia so that the animal will remain unconscious, and in aseptic conditions, to reduce risk of infection. To minimise any pain or distress a range of available analgesia methods will be used. Animals undergoing non-surgical embryo transfer will experience no more than mild transient discomfort and no lasting harm.

Male mice undergoing surgery for vasectomy (i.e. male sterilisation, a surgical procedure to cut or seal the tubes that carry sperm to permanently prevent pregnancy) will experience short-lived post-operative pain and discomfort. This procedure will be also completed under general anaesthesia so that the animal will remain unconscious, and in aseptic conditions, to reduce risk of infection. To minimise any pain or distress a range of available analgesia methods will be used.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severity: Hormone injections

Breeding and Maintenance of Genetically Altered Animals

Embryo Transfer

Vasectomy (male sterilization procedure)

Mild 100% 100% 80% 0%

Moderate0% 0% 20%* 100%

Severe 0% 0% 0% 0%

*Moderate severity will be experienced by animals undergoing surgical embryo transfer. Every effort will be made to maximize number of non-surgical embryo transfers, which will result in mild severity.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to understand mammalian development, from fertilisation of the egg through to implantation in the womb and formation of the body up to day 10 post-fertilization. Many features of development are shared between mice and humans, including gene changes, embryo shape, cell identities and failures. Due to the significant ethical considerations of using human tissue for research, as well as the limited access to this resource, an alternative model is required. Mouse embryos represent the gold standard of mammalian development research as they resemble the human embryo in several key criteria. It has been shown that similar (homologous) genes, gene networks and mechanisms play role in early developmental of the mouse and human embryo.

Mouse embryos are also readily genetically manipulable, allowing for investigation of specific gene and cell functions in a way that cannot be done in the human embryo mainly due to ethical constraints.

Special facilities, designed to keep and breed mice in the most ethical conditions are also present and will be used in this project.

Development at these stages involves the interaction of different cell types, including the embryo itself, the placenta, the yolk sac and the maternal womb. Simple model systems, including stem cells (i.e. cultures of cells with the ability to develop into many cell types of the body) and/or embryo-like organoids (three-dimensional tissues derived from stem cells) do not capture this complexity and, therefore, are unsuitable for the research outlined in this project. However, it should be noted that our group seeks, wherever possible, to answer questions in a system not requiring the use of animals.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of multiple non-animal alternatives:

1. Stem cell-derived embryo-like models (i.e. tissues based on structures derived from aggregates of different stem cell types) have been successfully developed by our group and others. These structures can partially replace or complement experiments utilising natural embryos when studying some developmental processes.
2. 2D stem cell cultures are widely used in our laboratory, not only for generating embryo-like structures but also as a preliminary model to study selected phenomena occurring during early mouse development.
3. Computer modelling to understand early development. Computational models can be used to make and validate experimental predictions without the use of animals.

Why were they not suitable?

1. Stem cell-derived embryo-like structures are being used to complement our research on mouse embryos. However, these embryo-like structures do not undergo normal development (i.e. do not develop from a single fertilised cell), do not contain all of the correct cell types, arrangement or genes of the natural embryo. Additionally, extraembryonic tissues that are also indispensable for proper embryo development (e.g. yolk sac) are not fully developed and functional according to our current knowledge.
2. Simple stem cell models, including 2D cultures, are useful to probe very specific questions (e.g. gene function in one cell type) but do not capture the complex, many cell type-nature of the natural embryo. Indeed, we are particularly interested in the interaction between the embryo and the surrounding tissues (placenta and yolk sac), which cannot be modelled in 2D stem cell cultures.
3. Computer modelling currently does not capture the complexity of the embryo, including how the cell types signal to each other and change their gene expression. This data can only be generated from further experiments in the embryo.

The above stem cell and computer models are routinely used and improved to complement our animal research. Those alternatives already partially replace or complement experiments utilizing natural embryos when studying some developmental aspects. However, as mentioned above, due to complexity of the natural embryo

development and the changes in interactions between cells, which are not yet fully deciphered, it is still impossible to replace natural embryos in most cases.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The project application and research plans have been broken down to 4 separate aims. We have divided each aim into the questions we would like to answer, and the anticipated number of animals needed to get this data. With our long-term experience in breeding and maintenance of mice and embryo generation, recovery and culture, we can estimate how many mice we would need. This number takes into our project aims, as well as, our specific protocols (for example breeding and maintenance of genetically altered animals).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During experimental design we use all available published data as well as our unpublished data to ensure that the questions are valid, novel and addressed in the best possible way, based on the current knowledge.

When designing experiments, we are considering different scenarios and outcomes and potential for the future directions. Number of embryos and mice needed to obtain a significant result is revised for each experiment. Subsequent planned experiments are always revised with the most up-to-date results. The experimental plans are modified as necessary. This is continually discussed between the licence holder and group members. We also run pilot studies to reduce the number of animals and embryos used when we start a new series of experiments. This is done to validate experimental design and/or new protocols that we plan to implement, and to ensure that the results obtained are measurable and specific, allowing us to draw conclusions in the future.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Methods for mice breeding and maintenance, mouse embryo production, recovery and culture are well known and optimised to ensure refinement and reduction in animal use. Our group and animal units have long term experience in successful mating, regularly obtaining high yields of embryos. This is assured by maintaining the wellbeing of the animals (for example, through proper handling, reduction of stress and diet) as well by implementing good practices that increase the efficiency of successful mating and

superovulation. For example, there is maximum frequency of use for the males for the mating, mating is done in a 1:1 manner, males are continuously monitored, hormone injections are performed reproducibly (i.e. at the same time of day). This approach has reduced the number of failed matings (i.e. resulting in no embryos after superovulation, low embryo yields or bad quality embryos).

Embryos are placed into experimental groups randomly. This ensures experimental and control groups are similar and increases experimental success.

Additionally, we use reliable reagents from globally recognized manufacturers and suppliers. This approach decreases the number of failed experiments, ensuring that the methods used are highly efficient and reliable.

As a good practice, close oversight of the group and experiments by the Project Licence Holder is always assured. This is carried out across the breadth of the project, including by regular meetings (at least once a week) to discuss the progress of the project and future experimental plans, ensuring that the experiments are planned well and they approach the problem in the most efficient way, and by regular meetings with mouse line managers (again once a week) to discuss status, health, availability and performance of each mouse colony. Together this ensures that the mice are always bred and maintained according to best practices and with the reduction, refinement and replacement principals in mind.

Before proceeding to the actual experiment, we use available datasets whenever possible. For example, gene expression datasets, protein interaction databases and protein and gene features/functions databases. This preliminary step enables us to have additional insights regarding our experimental plans and questions and helps us to avoid redundant experiments.

We also run pilot studies to reduce number of animals and embryos used when we start a new series of experiments. This is done to validate experimental design and new approaches that we plan to implement, and to ensure that the results obtained are measurable and specific, allowing us to draw conclusions in the future. Finally, we also use computer modelling in several of our projects that use both mouse embryos and stem cells.

If there is a need coming from other groups, we are open to share animal tissues, including tissues from genetically modified mouse lines and post-mortem tissues, in order to further reduce overall mouse numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our experimental output are mouse embryos in different stages of the development. They are recovered from female mice mated with male mice. To obtain embryos for our research we use wild-type mice and genetically altered mice.

- embryo production protocol is a well-established and validated protocol. It brings only minimal suffering (i.e. mild severity) and is not anticipated to produce any adverse effects, beyond transient discomfort due to the injections, which will be intraperitoneal (i.e. into the body cavity) or subcutaneous (i.e under the skin). Transient discomfort results from restraining the mouse for the procedure for a short time (around 10-15 seconds) as well as from the injection needle.
- genetically altered mice bred and maintained for the project are not expected to experience harm due to the genetic alteration. All procedures related to the breeding and maintenance are expected to have a maximum of mild severity (and below that threshold in most cases).
- the only method currently available for allowing genetically altered embryos to develop is to implant them into the uterus of a pseudo-pregnant mouse. Thus, we cannot avoid this procedure. However, non-surgical embryo transfer methods will be used whenever possible as more refined method, where the success rate matches that of surgical embryo transfer methods or is satisfactory. However, in cases where it is not possible (e.g. transfer of embryos at very early stages, repetitive problems with non- surgical transfer efficiency that would not result in positive outcome), surgical transfer will be used.

Protocol for generation of genetically altered animals follows current standards and well-established procedures.

- we plan to use mainly genetically sterile males as an alternative to vasectomised males in generating pseudo-pregnant females.

Why can't you use animals that are less sentient?

Non-mammalian species (including Xenopus or Zebrafish) are often utilised in developmental studies and do share commonalities to both mouse and human development. However, these species diverge importantly in their developmental timing, gene expression and embryo shape in comparison to the human and therefore, are often inadequate models with which to draw conclusions on human development. The mouse embryo offers similarity to human development, while offering potential benefits.

To generate embryos, adult mice of reproductive age must be used. However, where possible, embryos are taken at the earliest point (from fertilization to day 10 post-fertilization when body plan is formed) to minimise life stage/sentience.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our group and animal facilities staff have long-term experience in maintaining wellbeing of the animals and consistently implement new training and protocols. High standards in the facilities are maintained to ensure the animals are less stressed and well cared for (e.g. by provision of an enriched environment, acclimatisation when animals are moved into the facility, placement of animals into social groups). By implementing good practices, we also increase well-being of the animals and, therefore, mating efficiency (which leads to reduction in use). For example, frequency of use for the males is limited, mating is done in a 1:1 manner, males' efficiency and behaviour are monitored, superovulation is performed in a repetitive scheme (hormones administered at a repetitive time of day). This approach reduces the number of failed matings, in turn reducing the number of animals required.

Establishment staff also have long-term experience in monitoring animal welfare and they ensure that every person involved in animal management in any way, must be first trained to the highest standards. If needed, increased monitoring and/or adequate pain management are implemented. Pain management will be achieved through the use of medicated palatable substances for voluntary treatment such as flavoured jelly, paste or milk shake liquid. We will get the animals used to the taste profile of the substances prior to the surgery so they will self-administer effective analgesia.

Humane endpoints are strictly adhered to minimise animal suffering during the project.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the guiding principles on good practice for Animal Welfare. We adhere to the new ARRIVE guidelines (2.0), where possible. We also attain to the Lasa guidelines to ensure good practice on animal work, as well as the NC3Rs published strategy for improving animal welfare (see publication details below).

- Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217
- LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. https://www.lasa.co.uk/current_publications/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are regularly updated about advances in 3Rs by our Establishment staff (e.g. by Named Animal Care & Welfare Officers).

Additionally, we refer to available resources such as NC3R's (National Centre for the Replacement, Refinement & Reduction of Animals in Research) website page and 3Rs guidelines (https://nc3rs.org.uk/resource-hubs), LASA (Laboratory Animal Science Association) website page (https://www.lasa.co.uk/), RSPCA (Royal Society for the Prevention of Cruelty to Animals) website page (https://www.rspca.org.uk/), Norecopa (https://norecopa.no/databases-guidelines) and The Jackson Laboratory resources (https://resources.jax.org/).

We also take an active role in advancement of the 3Rs – for example we pioneered development of 3D stem cell models for mouse embryo development, which has been recognised by the NC3Rs (winner of the 2019 3Rs Prize).

78. Tumour suppression and therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Cardiotoxicity, Immunotherapy, Inflammation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand mechanisms of tumour suppression, and to investigate potential methods for tumour therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a disease caused by genetic alterations or exposure to environment factors such as carcinogens, infectious agents or/and immune suppression. It has also been

considered as a disease of ageing, as the longer someone has been alive, the greater the chance of acquiring the changes that lead to cancer. Tumours arise following genetic changes that cause normal controls that regulate cell numbers to be overcome. Our understanding of these genetic changes has improved greatly over the past 30 years, but the changes that occur during cancer development are complex, and research continues so we can fully understand the nature of the genetic changes that arise in cells and how these changes ultimately result in tumour growth.

One aspect of our research is to analyse the causative mechanisms of cancers with low survival rates such as cancers of the oesophagus and pancreas. The 10-year survival rates for cancer of the stomach and oesophagus is around 12%, and for cancer of the pancreas it is as low as 5%. These two cancer types are among the 20% of cancers associated with chronic inflammation caused by lifestyle factors, and we intend to use mice to mimic these diseases with the intention of both gaining a better insight into these cancers and developing new therapies to alleviate these conditions. One consequence of a better understanding tumour development has been the advent of new treatments such as therapies that stimulate the immune system to destroy the tumour. Although there have been many successes with these therapies, the potential exists for novel applications, for example the combination of these therapies with other existing drugs to develop new treatment strategies.

The advancements in cancer therapy in recent decades has resulted in an increased life expectancy for many who receive a cancer diagnosis. As a consequence, the importance of long-term side effects of cancer therapies has become apparent. In particular, the toxic legacy of cancer therapeutics and radiotherapy upon the heart is of increasing concern, and we intend to explore the mechanisms whereby chemotherapeutics cause damage to the cardiovascular system.

What outputs do you think you will see at the end of this project?

We hope to increase our knowledge of tumour development and suppression mechanisms and use this to identify possible avenues for the development of potential novel tumour therapeutic strategies. We also aim to improve our understanding of the impacts of cancer therapies on the heart. The output will principally be the publication of our findings in peer reviewed journals.

Who or what will benefit from these outputs, and how?

The initial beneficiaries of this work will be other scientists working in the field of cancer research. Ultimately, our aim is to develop effective therapies that are of clinical benefit to cancer patients. We mainly intend to use drugs that are already used clinically either for novel purposes or in new combinations with other therapies. The starting point for deciding on the use of these novel treatments is ongoing in vitro work, which will be used to identify which agents (usually only one or two) to take forward into the mouse. The experimental

data using mice should be generated within this licence (3-4 years) but any clinical trials prompted by our work is beyond the scope and time frame of this licence.

Another aspect of our work involves some human genetic disorders, so we hope ultimately that our observations may contribute evidence towards expanding genetic testing of families with these conditions, both by determining the source of their inherited condition and the identification of potential carriers. However the final decisions on whether our work is of use in the clinic are beyond our authority.

How will you look to maximise the outputs of this work?

We intend to continue to publish our data in peer reviewed journals and present it at conferences and invited seminars. Our publications are announced on our organisation's UK and international websites.

Species and numbers of animals expected to be used

- Mice: 35750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are widely used to study development and disease, their biology and genetics are well documented and characterised. They have a relatively short life cycle, which reduces the time taken to generate data, and many reagents and experimental methodologies for use with mice are readily available. The technology to genetically alter mice is well-developed and reliable. This technology can introduce genetic alterations to the mouse to, for example, prevent the function of a particular gene, and comparison of the behaviour of a genetically altered mouse with a mouse that has not been mutated can tell us important information about the gene in question. Congenital birth defects and cancer in humans are both caused by errors in DNA, and mice can also be generated to introduce DNA mutations that copy these disease-derived mutations so that their consequences can be further investigated.

One of the major risk factors for cancer is age, so although much of our work will be undertaken using healthy young adults, some of the work will need to use aged mice (mice over 15 months) as some differences in tumour susceptibility do not become apparent until after this age.

Typically, what will be done to an animal used in your project?

Mice will be bred with genetic alterations that in some instances may mimic human disorders. These include mutations that affect the heart, which are thought to be related to

a group of inherited human heart conditions, and mutations affecting the central nervous system, which again may be related to genetic conditions causing abnormalities in humans such as epilepsy and intellectual disability. These mice will be investigated to provide more information about how these mutations cause their associated human conditions, for example by measuring the efficiency of their hearts by techniques such as MRI or ECG, or by microscopic or biochemical analysis of tissues collected post-mortem. Other mice will be bred that have mutations that are found in human cancers. Some of these mutations alone will cause tumours to grow in the mice, whereas others will predispose to tumour growth if further procedures are carried out. We will also make use of genetic technology that allows the mouse to develop normally, but enables the genetic alteration to be activated either at a specific time in the life of the mouse and/or in a specific organ or tissue by dosing the mice with the drug tamoxifen.

In this project, we aim to both examine how tumours grow and also how these tumours can be treated. Tumour growth may be caused by several methods. One method involves injecting tumour cells, either under the skin to produce subcutaneous tumours, or into the bloodstream to mimic the spread of cancer that causes secondary tumours. Another method is by exposure to cancer-causing chemicals or radiation, which may result in tumours in organs including the pancreas, colon or liver, or by infection with cancer-associated pathogens that can cause tumours in organs such as the stomach. The cancer causing agents will usually be injected into the peritoneum or may be given in the drinking water.

Irradiation of a mouse involves a brief exposure to X-rays.

Tumour type and rate of development will vary depending upon the genetic alterations of the animal and the cancer-inducing stimulus used. For some methods the experiments will only last a few months. However, cancer is a disease of old age, so for other methods the mice may need to be kept until they are over a year in age.

Tumour development will be measured by callipers if the tumour is external. In some experiments it may be possible to fluorescently label the tumour cells so that their movement can be tracked within the body using non-invasive imaging equipment, or use methods such as MRI to check for internal tumour growth. However tumour development will mainly be monitored by at least daily observation of the mice to check for signs that they may have developed a tumour. Limits are in place in this licence to preclude the growth of tumours such that they cause unnecessary suffering.

In some cases the mice will receive potential tumour therapies, which may include drugs or immune cells, to determine whether they affect tumour growth. Before these potential therapies are given to tumour-bearing mice an appropriate dose will be set using small pilot studies. In some experiments we will give some animals chemotherapeutic agents and measure the effect they have on the heart using standard techniques such as MRI or ECG.

All mice used in this work will ultimately be killed by a humane method and after the mouse has been killed tissue samples will often be kept for laboratory analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

The study of tumour biology in mice is not possible without causing some animals to develop tumours. Tumours, depending upon their location and the method of induction, may cause weight loss, laboured breathing and pain, which will usually be evident by general malaise, social withdrawal and lethargy. Regular monitoring of susceptible animals will keep any such suffering to a minimum, and where appropriate the tumour size will be measured using callipers or where available using non-invasive imaging methods.

The administration of substances will frequently be by injection, which will cause mild and transient pain. Another route is by oral gavage which, when performed competently, should cause little discomfort. To determine an effective dose of the substance under test may require a small number of animals in pilot studies to experience toxicity at the upper dose which may include weight loss, and malaise similar to that demonstrated by the tumour bearing mice.

Some of the mice we use have a cardiac abnormality which causes progressive heart failure. These mice are usually in apparent good health until around 3-6 months of age, when the effects of the heart abnormality start to become apparent. This is observed by laboured respiration (panting) and reduced activity. Once a mouse is showing these signs, it will be killed by a humane method.

In addition to developing tumours, ageing mice may also display general signs such as ulcerated dermatitis, dental abnormalities, cataracts and general decline associated with a reduction in organ function.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the mice on this licence (>50%) are only involved in breeding and carry harmless genetic alterations. When breeding genetically altered mice, it is inevitable that mice will be generated whose genotype is not experimentally useful e.g. heterozygous mice who only have one copy of the mutant gene rather than two. These mice generally suffer no adverse effects from their genetic alteration and most are not used experimentally, although some are used in breeding.

Some mice will experience a moderate severity solely as a consequence of their genetic alteration. These will constitute up to 22% of the mice bred on this licence.

Of the mice that undergo experimental procedures, 80% will experience a moderate severity. This accounts for 29% of the total number of mice on this licence.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Living organisms are intricate combinations of numerous interacting tissue types, many of which are not fully understood. Tumour development reflects this, as it is influenced by multiple factors such as the immune system, blood vessels and surrounding tissues. This cannot be replicated in vitro. For some of our work we are using cell culture techniques such as organoid culture, which grows small samples of tissue from human patients in an artificial matrix to replicate in vitro some aspects of in vivo biology, and while we do derive useful data from this method, the technology is still in its infancy and cannot yet replace the use of animals.

Part of our work involves the immune and cardiovascular systems. Although some of the genes and signalling pathways that we study are conserved in nematodes and fruit flies, these organisms lack an immune system and cardiovasculature comparable to that of humans. Mice are the lowest mammals suitable for investigating tumour growth and the interaction of this with the heart and immune system, and their genetics and anatomy are often comparable to humans.

Which non-animal alternatives did you consider for use in this project?

We have gained valuable data regarding the biochemistry and cell biology of tumour suppressors, tumour development and treatments using cell culture techniques, and all our initial experiments are performed in vitro. In our laboratory we are also developing methods using organoids, which are three- dimensional multicellular cultures derived from human patient samples that can replicate in vitro some of the spatial organisation and function of their tissue of origin. These are useful for analyses of e.g. the gastrointestinal tract and its interaction with inflammatory and tumourigenic pathogens. This technology can be used to investigate the signalling pathways that are activated in these situations.

Why were they not suitable?

Organoid culture systems lack the surrounding microenvironment found in vivo, and the use of co- culture methods using combinations of different cell types in an attempt to overcome this is not firmly established. Similarly, when using potential tumour therapies, it is not possible to account for the in vivo pharmacokinetics of the drug when using organoid

culture. Organoid culture also works better on some tissues than others: for example, organoid culture using tissue from glandular tissues such as the intestine works much better than for stratified tissues such as the skin. Also, if human patient samples are to be used as the starting material for the organoid culture, sourcing these can be inconsistent and unpredictable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on our past experience of the methods used in this licence and the breeding that was required to achieve the numbers of mice required for each study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Following consultation with statisticians, we have found that for tumour studies, around ten mice of each sex for both control and treated groups is sufficient for statistical significance. Survival curves are calculated using the log rank test with significance of $p<0.05$, and standard statistical tests such as ANOVA and t-test are used to analyse the data. This will continue to be reviewed and resources such as the NC3Rs Experimental Design Assistant will be consulted where necessary.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will follow the breeding guidance provided by our institution to optimise breeding performance, and strains of mice that are no longer required will be cryopreserved. The mice used in this work have been backcrossed onto defined background strains (e.g. C57BL/6, Balb/c) to reduce experimental variation.

Pilot studies using small numbers of mice will be undertaken, for example when using novel substances, to determine whether the experimental approach is feasible and appropriate.

Where appropriate, control cohorts may be used as reference in multiple experiments.

Similarly, for studies where tissues are harvested post-mortem e.g. paraffin-embedded tissues or frozen tissues kept for biochemical analysis, where appropriate these will be shared or used in multiple experiments or analyses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This work will only use mice. Mice are the lowest mammalian species whose anatomy, physiology and genetics are suitable for research into human disease and are the most accurate animal model available for this purpose. Techniques for the genetic manipulation of mice are well established and many mouse models are available for use in our work.

Many of the genetic alterations in the mice we will use are harmless. Where possible we will confine any disease-related genetic alterations to the organ or tissue of interest, so that most of the mouse is functionally normal. Sometimes these genetic alterations will cause disease states like tumour growth, but we will avoid this where possible. We will sometimes allow the mice to age, which reflects the increased risk to health that comes with old age in humans, and some of these mice will experience a physiological decline as a result. For some of our work we will use mice with impaired immune systems. Although these mice can be subject to opportunistic infections, when housed under clean conditions they remain healthy.

We will use various methods of inducing tumour growth in mice. One such method is the introduction of human tumour cells into mice with impaired immune systems - this prevents the rejection of the human cells by the immune system of the mouse. This will enable measurement of the speed of tumour growth and is also the model that will be used to test potential novel tumour therapies. These cells are introduced under the skin so tumour growth is superficial and will not interfere with the internal organs. Therapies will, in many instances, be those already in clinical use. Any tumour therapies whose behaviour in the mouse is unknown will initially be tested in pilot experiments in small (2-3) groups of mice.

Many tumours in humans arise as a result of chronic inflammation, in particular tumours of the gastrointestinal tract and digestive system. In humans these conditions, e.g. pancreatitis, can often be painful and unfortunately this will sometimes be replicated in the mouse, although in the model used here the inflammation is transient and reversible. Other methods of inducing inflammation are minimally or non-invasive, and any adverse effects are reversible.

Some tumour therapies used in the clinic have unwanted side-effects on the heart. To investigate this, genetically altered mice will be given tumour therapies that are in clinical

use, and their heart function measured using methods such as MRI that are also used on patients. The agents will be given at the lowest dose possible. Some of the mice bred on this licence have cardiac abnormalities when they have two altered copies of our gene of interest. Although we may have to use a small number of these mice to collect information about the tumour therapies, the majority of this study will be carried out on mice with one altered copy of the gene that are less susceptible to heart complications. These mice should be better able to withstand the treatments they are given, and are more representative of the situation in the clinic.

Unfortunately when studying tumour biology it will be on occasion necessary for some mice to develop tumours. This will have a long latency, e.g. where the mice are aged, and the majority of the life of the mouse will be spent in good health. Other methods of inducing tumours, such as chemical carcinogens, are relatively quick, but again the mice will live most of their lives in good health. The radiation dose typically used in this licence to induce tumours has few if any short term effects. As this is a quick and non-invasive means of exposing the mouse to DNA damage, this will be used in preference to the chemical methods for an initial assessment of the tumour susceptibility of a novel genetically altered strain or cross.

Why can't you use animals that are less sentient?

Mice are the least sentient animals that have anatomy and physiology similar to that of humans. Although some of the some of the genes that we are interested in have equivalents in nematode worms and fruit flies, these less sentient animals lack the ability to grow tumours and not have sufficiently complex immune systems to be able to make meaningful comparisons with humans. The development of tumours and their interplay with the immune and cardiovascular systems are dynamic processes that requires a living animal. Age is an important contributory factor to tumour development, so the use of aged animals is required to accurately reflect this.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are routinely housed in individually ventilated cages to minimise the risk of infection, and supplied with environmental enrichment.

When administering agents to the mice we will use the least invasive route possible, for example administration of viscous substances by gavage rather than injection.

Observed outcomes of the tumour studies carried out on this licence will be used to revise endpoints in future studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will make use of the resources available at the NC3Rs website (www.nc3rs.org.uk), including the NC3R's Experimental Design Assistant where relevant, and follow the ARRIVE guidelines (https://arriveguidelines.org) when undertaking and publishing this work.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All staff who carry out work under this licence attend local good practice and welfare meetings, and we are in receipt of regular e-mails from the Named Information Officer at our establishment.

Attendance at the local annual NC3Rs day will be encouraged. We will consult the NC3Rs website for the latest updates.

When undertaking a procedure for the first time, we will consult the Named Information Officer, vets and NACWO beforehand so that any recent 3Rs updates can be implemented.

79. The effects of aging and prior injury on tissue regeneration and fibrosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Aging, Fibrosis, Senescence, Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will explore the mechanisms by which aging and tissue injury impact on the ability of the body to repair fully after injury, and its propensity to develop harmful scarring. By understanding these mechanisms, we hope to be able to manipulate them to prevent organ fibrosis and promote complete repair after injury

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Organ fibrosis becomes more common with age and after injury – and accounts for up to 45% of deaths in the developed world. There is an urgent, unmet need for new therapies to prevent progressive fibrosis – and in turn this requires a better understanding of the underlying processes driving the accumulation of scarring with aging and after injury.

What outputs do you think you will see at the end of this project?

A key goal of this project is to identify factors accounting for the sensitivity of the aged kidney to acute kidney injury (AKI) and inadequate repair.

In the short term (within the first two years) the aim is to identify changes in the behaviour of cells and the expression of genes and circulating proteins (known as biomarkers) which may be associated with the development of AKI.

The aim is to then generate new therapeutic interventions after the end of this 5 year PPL to

limit AKI and promote renal recovery in the elderly,

Reduce mortality via the development of new treatments.

Reduce morbidity and cost to the NHS (and hence to the public).

Given the annual incidence of AKI, its high mortality and the increased risk of chronic kidney disease and premature cardiovascular death in survivors there is the potential to save lives and to significantly reduce the excess costs to the NHS associated with AKI diagnosis and treatment. The current costs for this were recently estimated at several hundred million pounds annually.

This study is designed to generate information for clinical translation, but will do this by increasing our understanding of the basic biological processes of aging and how they can be manipulated. By the end of the project we should understand more about the basic biology accounting for renal aging. We will investigate how aging impacts on the function of the immune system and whether the age of the injured organ contributes to the behaviour of immune cells which are present in the aftermath of injury

In addition, we will seek to identify proteins which promote scarring in aged kidneys. As renal fibrosis is a major pathological and prognosis feature of human kidney disease, strategies that retard progression or accelerate regression of fibrosis are likely to be beneficial.

Furthermore, as fibrosis is a common end-point shared by diseases of many organ systems, anti-fibrotic therapies are likely to have broad translational potential. The longer term goal will be to translate any positive findings to the clinic to minimise the numbers of patients progressing to end stage renal disease or failure of other organ systems. If successful, in the longer term (beyond the end of this PPL) this could generate major population health and economic benefits.

Who or what will benefit from these outputs, and how?

The stated objectives have common potential short and long-term benefits and losses if not achieved; Short-term benefits will be:

- A greater understanding of the cell biology of organ fibrosis and repair, especially with regard to the identification of the major cell populations promoting fibrogenesis and tissue regeneration. This will benefit scientists in the near term (years 1-2 of PPL) as this will allow us to focus on the major fibrosis- promoting subpopulations of cells within the kidney, allowing in depth characterisation of these key sub-populations, with the goal of developing novel treatments. We will disseminate our findings widely via publications / lectures / conferences.

- The development of effective inhibitors (small molecule or antibody based) that limit organ injury, accelerate tissue regeneration and limit fibrosis in animals. Taking the therapeutic targets identified in 1 above, we will then assess small molecule inhibitors/antibody-based therapeutic approaches to inhibit fibrosis production by this subpopulation of pro-fibrotic cells in pre- clinical models in vivo (years 2-3 of PPL). We will disseminate our findings widely via publications / lectures / conferences.

- Increasing our experience and further refining the use of cutting-edge imaging techniques (e.g. MRI, ultrasound, optical imaging, fluorescent imaging via abdominal imaging window [AIW]) in the diagnosis and monitoring of organ injury and fibrosis in preclinical models of kidney fibrosis will also reduce the numbers of animals used for biomedical research, which if adopted more widely in research institutes around the world will have a major impact on reducing the numbers of animals used in biomedical research. We will disseminate our findings widely via publications / lectures / conferences (years 1-5 of PPL).

Longer term benefits might be:

- The use of small molecule inhibitors or antibody-based therapies to modulate organ injury and regeneration in patients with organ injury and fibrosis, including the development of both anti-fibrotic and pro-regenerative medicines. There is a huge unmet clinical need in organ fibrosis, so if we can identify potent new anti-fibrotic therapies this could have a massive impact on human health.

- The effects on organ transplantation are potentially far reaching. Effective therapies for acute kidney injury and the subsequent fibrotic responses to this has the potential to both minimise new cases of progressive chronic kidney disease (CKD), and to extend the functional life of each kidney transplant performed. Additionally, developing treatments to retard the progression of organ fibrosis once injury has taken place could reduce the need for transplantation (and/or dialysis in the case of chronic kidney disease) and therefore reduce the burden of morbidity and mortality associated with these therapies.New treatments which can reduce or completely avoid the need for transplantation would be of benefit to the massive number of patients with chronic kidney disease worldwide.

- Identification of other therapeutic targets that may modulate kidney injury and scarring or accelerate renal epithelial regeneration, this may be clinically relevant for the treatment of patients undergoing procedures such as cardiac bypass grafting or aortic aneurysm repair which carry high risks of acute kidney injury.

- Identification of non-invasive biomarkers of fibrotic disease and response to therapy in fibrosis of the kidney. Successful identification of non-invasive biomarkers for fibrotic disease would reduce the need for invasive tests such as a kidney biopsy, which is currently the gold standard for diagnosis of human kidney fibrosis, but can result in significant morbidity and even mortality.

How will you look to maximise the outputs of this work?

Scientific Community

The work undertaken during this project licence will be relevant across diverse specialties and disciplines. We are committed to publishing our findings in journals with an open access policy; maximising access to our work across the wider scientific community: including basic scientific researchers in fields including ageing, senescence, bioinformatics and fibrosis, clinicians and pharmaceutical researchers. We will present at local, national and international meetings and we expect these will span diverse areas including nephrology, transplantation, aging and senescence. As a group we strongly believe in developing, maintaining and learning from the sharing of knowledge and information. A component of this fellowship will dissect senescent cell heterogeneity including significant amounts of RNA sequencing; the results of which will be will be uploaded to open access repositories.

Patients and public

Despite high incidence and serious morbidity and mortality, CKD does not have a prominent public profile. The work undertaken during this project licence focuses on an area of basic science with clear relevance to progressive fibrotic CKD, and we will seek opportunities where possible to involve ourselves in initiatives which might change this. We anticipate these including public lectures and fundraising functions organised by the MRC. Our unit has a strong tradition in public engagement and employs a Public Engagement and Communications officer. This staff member can assist with summarising published scientific papers in easily lay-accessible overviews, providing a direct, accessible voice (independent of external media interpretations) to open up our published research to interested adults, patients trying to find information about their diseases and new treatments, patient interest groups, funders, lay members on science-related Committees, and senior school groups conducting their curriculum section on current and local science research.

We are also keen to enlist their help to maximise opportunities to inform patients and the wider public about our scientific work. Opportunities include 1) Science Festival workshops and Drop-in events and School workshops, presentations, career and mentoring opportunities.

Charities

We believe that there is ample evidence implicating senescence as relevant to fibrotic disease processes in multiple organ systems. By publishing our results in open-access,

high impact journals, and liaising with the public as detailed above we will engage charities to fund further clinical studies to translate our work 'from bench to bedside'.

Government departments

CKD is a source of major morbidity, premature mortality and a major source of NHS expenditure in the UK (estimated as 1.3% of total NHS budget in 2010). It is our goal via the publication and engagement plans above that results generated by this PPL will reach a broad audience, and in the medium to long term lead to clinical trials (funded by government departments, industry or medical charities) and novel therapies to reduce patient morbidity, mortality and NHS expenditure.

Nephrology is now well represented in social media; often with hugely valuable outcomes and, where appropriate and of value, we expect to be active in this respect as well.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Experiments will all be undertaken in adult mice, aged up to 2 years old.

The mouse has been selected for these experiments due to its short lifespan (aiding the study of all stages of the life cycle), its comparable mammalian renal anatomy, and the wide availability of transgenically modified animals allowing refined experiments to be designed to probe the importance of specific genes in the initiation and progression of renal fibrosis.

We will hold animals for up to 2 years, as aging is a well recognised risk factor in humans for kidney fibrosis. By studying animals aged 18-24 months old and comparing these to young animals, we maximise the chances of identifying physiological changes predisposing to fibrosis which will be relevant to human disease.

Typically, what will be done to an animal used in your project?

A typical animal used in this project will be bred in house under protocol 1.

At some point between the age of 8 weeks and 24 months of age, the animal will transfer onto another experimental protocol and undergo baseline observations, optionally including a small volume blood sample via the tail vein, and optionally including a 6 hour timed urine collection to allow detailed measurement of baseline kidney function.

The animal will then undergo a procedure to induce kidney injury, such as unilateral renal ischemia – followed by close post-operative monitoring, daily weights and analgesia.

The animals will be allowed to recover and followed for typically up to 10 weeks post surgery, with optional blood and urine collection within Establishment Guidelines, prior to cull under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Overall adverse effects

- Pain. Mild severity pain may result from ear notch sampling to permit identification and genotyping of transgenic animals, however this should be transient and no healing problems would be expected. Several of the surgical and non-surgical models used to explore the impact of various interventions on the duration and recovery of acute renal failure may cause wound pain, which whilst often only mild, may be of moderate severity. This will be actively looked for, and medication in the form of painkillers will be given to reduce its effects on the animals. Duration would generally be 48 hours or less.

5. Weight Loss. Animals may experience weight loss in the aftermath of a surgical or non-surgical intervention. This will be actively looked for, and animals will be treated with painkillers to minimise the impact of pain on food and drink intake. From our experience with these techniques, any weight loss has ceased by 48 hours post intervention, and any animal approaching 10% weight loss will be reviewed and will be culled to ensure their weight loss does not exceed permitted levels.

6. Malaise due to symptomatic renal impairment. We have designed our experiments to minimise the chances of animals experiencing symptomatic renal failure. In a small proportion (<5%) of the minority of animals undergoing a renal injury to both kidneys, the animals may become symptomatic, with hunching, reduced activity and weight loss. Should any of these symptoms be thought to be present the animal in question will be reviewed promptly and if indicated by their condition, culled to prevent severity limits being breached.

7. Transient sickness and diarrhoea. Sickness and diarrhoea can be a symptom of animals undergoing total body irradiation (TBI). This should be mild in nature, and will be controlled by regular inspection and if there are signs or symptoms such as weight loss of 20% of pre TBI weight, persistent diarrhoea, reluctance to move or feed (persisting despite adequate analgesia being administered for 48h); animals will be humanely killed. Antibiotics will be used according to the advice of the named veterinary surgeon. Animals will be housed in individually vented cages for 8 weeks post TBI to reduce the potential for infections but if infections or other health problems occur, the named veterinary surgeon will be consulted, and if possible measures will be taken to modify the intervention or make other changes that will minimise the risk of the problem recurring before the experiment is repeated. Animals showing signs of continuing disease or distress (as described above) will be humanely killed. Long- term effects are not expected in this protocol.

8. Complications of aging. Animals of greater than one year of age will be subject to additional weekly review to ensure there are no signs of unexpected weight loss,

hunching, piloerection, or altered behaviours indicative of mouse illness. Any animals exhibiting moderate or sustained features of illness such as unexpected weight loss of >10%, hunching, piloerection, or altered behaviours persisting for 48hrs will be humanely culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse - Protocols are either (mild) or (moderate) - with approximately 50% expected to be (mild) and 50% (moderate)

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Kidney failure is a complex and poorly understood disease encompassing both systemic effects and injury to multiple cell types. We will use carefully selected in vitro assays of renal cell behaviour to add value to the animal studies performed, and to minimise the need for in vivo experimentation as much as possible, but there is no alternative approach which is currently capable of replacing in vivo studies.

Which non-animal alternatives did you consider for use in this project?

We considered the use of computer based simulation in place of in vivo work, but determined that no suitable computer simulation exists for the studies planned. We will use in vitro studies in place of in vivo work whenever feasible - such as testing the behaviour of senescent renal epithelial cells using in vitro culture conditions to minimise animal use.

Why were they not suitable?

No computer based simulation is available which adequately recapitulates the function of the injured and/or aging mammalian kidney.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based the numbers above on our extensive experience in the chosen disease models, the anticipated group sizes and timepoints, and the necessary levels of cross-breeding and maintainance of the transgenic strains required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

At all stages we have planned our experiments to ensure that we are using the minimum numbers of mice necessary to answer our experimental questions, using tools including nQuery and NC3R's Experimental Design Assistant. Where possible, we will use refinements to allow multiple readings to be obtained from a single animal rather than multiple experimental repetitions, leading to less overall animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our extensive published experience in this field allows us to design experiments using the minimal number of animals necessary to answer the experimental question. Rational breeding strategies will be employed to ensure that the maximum number of animals are usable in experiments to minimise waste. We stay abreast of the latest research in the field, and will be open to sharing our own tissue stocks, or using existing stocks from other researchers to prevent unnecessary duplication of any in vivo work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used in light of the ready availability of genetically modified mice available for study of disease pathways and processes.

We have selected surgical and non-surgical models of acute kidney injury and progressive kidney fibrosis that equate to human disease. We will use a short-term kidney blood flow restriction model (IRI) and a urine flow restriction model (UUO) both of which are good models for acute kidney injury in people. We are familiar with these models and have refined them to use the minimum required kidney damage by reducing the time of blood flow restriction, limiting the degree of suffering experienced by the animals. As an example, in the large majority of experiments only one kidney will be injured, removing the risk of the animal developing symptomatic renal failure, due to the presence of a functioning kidney. We will always seek veterinary input in the event of any concerns about the condition of mice under this protocol, to ensure that signs of distress are not missed. Pain killers are always administered before and after surgery to limit discomfort experienced by the mice. Humane endpoints will always be implemented for all experiments. Additional models including nephrotoxin induced renal injury allow induction of renal injury without any surgery – again with the goal of minimising post-surgical pain and distress to the animals. The use of the newly developed model of heterochronic blood exchange allows the effects of mixed old and young serum on kidney injury, fibrosis and repair to be assessed for the first time without a major, permanent skin connection being formed between two mice – a significant refinement over conventional heterochronic parabiosis.

Additionally, this will often permit both paired mice to be used in the subsequent analysis of the experiment, which halves the numbers of animals required compared to conventional parabiosis surgery.

Why can't you use animals that are less sentient?

There are no less sentient animals available with a mammalian kidney. Due to the periods of time (weeks) required for overt and quantifiable fibrosis to develop after injury performing the entire experiment under terminal anaesthesia is not possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will be proactive in implementing any new monitoring and welfare refinements as they become available. Our goal is to maximise the research impact of each mouse whilst minimising the harm associated with this. As part of this, we ensure that all animals undergoing procedures receive heat pad support followed by overnight housing in a warmed box to minimise risks of hypothermia. Food softened with water is always placed on the flooring of cages to ensure it is easy for all animals to access fluids and nutrition. We have comprehensive in house protocols to ensure animal weights, activity and condition are documented pre/post all procedures. In the course of the last 5 years we have increased our use of models where only one of two kidneys is injured, with the goal of minimising the risk of symptomatic renal failure as a potential side effect of our kidney injury studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will make use of the ARRIVE guidelines from the NC3Rs to maximise the quality and reliability of our research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend institutional and national events and webinars organised by the National Centre for the Replacement, Refinement and Reduction of Animals in Research – and the project licence holder already subscribes to the NC3Rs newsletter. Any advances relevant to our project will be implemented via revision during the period of this PPL.

80. Zebrafish models to identify determinants of outcome in immune-mediated disease

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Tuberculosis, Immune response, Zebrafish, Inflammation

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To improve current understanding of protective and damaging effects caused by our immune system's response during tuberculosis (TB) infection and other immune-mediated diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tuberculosis (TB) is caused by mycobacterial infection. Knowing how to induce a beneficial immune response to this infection that does not injure the body's tissues would allow us to design better treatments for TB and new vaccines that induce effective immune defences so that TB disease never develops. In a broader context, understanding how to harness the immune system to control noxious agents without detrimental consequences offers opportunities to develop new and more effective therapies for diverse inflammatory and immune-mediated conditions.

What outputs do you think you will see at the end of this project?

This project will generate new information on protective and damaging effects of the immune system during tuberculosis and other inflammatory conditions, which I will publish in scientific journals.

Who or what will benefit from these outputs, and how?

By the end of this project, I hope to gain new insights that help to develop novel interventions that will significantly shorten the length of anti-TB treatment, which will be important to reduce spread of TB and minimise development of drug resistance. I anticipate that in the longer term, this work may also lead to design of new vaccines that prevent TB disease altogether.

New knowledge generated as a result of this work may also be applicable more widely, to aid design of new therapeutic strategies across a range of immune-mediated diseases for which current treatment options are limited, such as coronavirus disease 2019 (COVID-19) and other inflammatory and scarring lung diseases.

How will you look to maximise the outputs of this work?

I will publish my findings in scientific journals and make them available, where possible, before formal scientific review via public repositories such as bioRxiv. I will highlight new knowledge using Twitter and by presenting my data at scientific conferences and in seminar programmes at my own institution and those of my collaborator's institutions. Gene expression data from the work will be made available via suitable platforms such as Gene Expression Omnibus (GEO) and ArrayExpress, to allow other interested investigators to access this information for the purposes of their own research.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The zebrafish Mycobacterium marinum infection model leads to a type of inflammation that is an excellent model for human TB. The zebrafish is an accurate model of the mammalian immune system, in which levels of genes that influence the immune response can be genetically manipulated to assess their function. In addition, immature (larval) zebrafish are transparent, allowing bacterial growth and cellular responses to infection or injury to be viewed.

Adult zebrafish will be used to generate zebrafish larvae required for experiments but all experiments will be performed on larvae less than 5 days post-fertilisation (dpf), which are not considered protected by the Animals (Scientific Procedures) Act '1986'.

Typically, what will be done to an animal used in your project?

Adult zebrafish will be bred to maintain stocks required to generate embryos/larvae for experiments. These fish will live a normal, healthy life as any aquarium fish. A small biopsy of the tail fin will be taken from some fish in order to determine certain genetic characteristics, typically only once in an animal's life time.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no expected adverse effects. However, rare adverse effects (less than 1%) may include abnormal swimming, infection and abnormal development or phenotypes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected level of severity is mild for all animals.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal use is necessary for the proposed work to study dynamic interactions between the immune system and inflammatory stimuli (TB bacteria or sterile injury) in a living host and to genetically modify components of the experimental system (knocking out or over-

expressing genes), which is not possible using human subjects or laboratory cell culture techniques.

Which non-animal alternatives did you consider for use in this project?

I considered using laboratory cell culture techniques to assess interactions between immune cells (macrophages) and bacteria or other immune stimuli.

Why were they not suitable?

These models cannot replicate the complexity of the immune system in a living organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This project continues the work conducted over a period of 5 years under my current project license and uses similar experimental designs. The estimated number of animals used for the proposed work is based on the numbers used during my current project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Genes will be screened for effects on immune responses by generating knockout zebrafish embryos using a novel CRISPR genome editing technique. All screening experiments will be performed on embryos before the onset of independent feeding, which are not considered protected by the Animals (Scientific Procedures) Act. Adult zebrafish carrying germline mutations for genes to be tested will only be generated where CRISPant (knockout embryos) show differences in immune responses.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animals will be raised according to a protocol that has a high survival rate, reducing the number of animals generated overall. Sperm harvesting and freezing (cryopreservation) will help minimise the number of animals produced as unused lines can be archived and regenerated when required, with no need to continuously maintain lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project uses immature (larval) zebrafish models of inflammation. The zebrafish is an accurate model of the mammalian immune system, in which levels of factors that influence the immune response can be genetically manipulated to assess their function. In addition, larval zebrafish are transparent, allowing bacterial growth and cellular responses to infection or injury to be visualised. The zebrafish larval Mycobacterium marinum infection model provides a natural host-pathogen pairing which leads to inflammation that is an excellent model for human tuberculosis (TB).

All experiments will be performed on larvae before the onset of independent feeding; these larvae are not considered protected by the Animals (Scientific Procedures) Act. Adult zebrafish will be used to generate the larvae required for experimentation. These fish will live a normal, healthy life as any aquarium fish.

Why can't you use animals that are less sentient?

In choosing the zebrafish and focussing my experimental work on zebrafish larvae, I have selected the organism with the lowest neurophysiological sensitivity possible for work which evaluates the immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be raised according to a protocol that has a high survival rate, reducing the number of animals generated, as well as unnecessary suffering and fatality. Fish will be closely monitored by highly skilled staff to ensure that animals are bred at safe intervals and when it is beneficial to their health (preventing egg-bound females).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow guidance set out in the Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE) guidelines when planning my experiments and adhere to the standards set out by the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines when reporting my findings. In line with the ARRIVE guidelines, once experiments have been performed using a required fish line, sperm will be frozen and stocks will not be maintained further. Sperm harvesting and

storage minimises numbers of live fish generated/maintained but does require use of anaesthetic and handling, which may be stressors. However, current techniques do not require death of the fish, and are performed by highly skilled staff trained in these procedures, minimising stress to the animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will keep up to date with the latest developments in the 3Rs via the news feed from my institution's Biological Services Unit, monthly newsletters from the NC3Rs and the NC3Rs Twitter account. I will aim to incorporate any relevant advances within my work as soon as possible.

81. Antibody production for clinical and research applications

Project duration

5 years 0 months

Project purpose

- Basic research
  - Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Antibodies, Antigens, Peptides, Immunogens, Animals

Animal types	Life stages
Mice	adult
Rats	adult
Guinea pigs	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The production of animal-derived antibodies to order, to be used to address multivarious biological and biomedical questions posed by the scientific (basic, preclinical and clinical/diagnostic) and pharma communities.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The production of high quality validated animal-derived antibodies are critical tools to study biological systems (in all kingdoms) and are vital to identify for example, new biomedical targets for therapeutic benefit. They are also essential for diagnostic kits for swift patient/animal diagnosis.

What outputs do you think you will see at the end of this project?

The output will be a product ie the animal-derived antibodies. Their production will contribute to novel and crucial basic science information to further our knowledge. The new knowledge will be published in the appropriate journals by the end user of the product. The new knowledge as well as the antibody can be used in preclinical and clinical settings to treat disease as well as be used as diagnostics.

Who or what will benefit from these outputs, and how?

The animal-derived antibodies will benefit the scientific community by purchase from commercial sources or through availability from the academic research community. The antibodies are critical tools to the biological/chemistry and biomedical sector for advancing basic research, as well as for therapeutic and diagnostic use.

How will you look to maximise the outputs of this work?

Outputs maximised by constant dialogue with the customer about immunising agent preparation for the best animal-derived antibody production outcome. Sharing and receiving best practice with relevant stake holders and contributing to researcher outputs and publicising the framework we work within.

Species and numbers of animals expected to be used

- Mice: 1100
- Rats: 200
- Guinea pigs: 150
- Rabbits: 2050

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rabbit, rat, mouse and guinea pig will be used. At this life stage the animals have reached maturity, a stage of development, that will contribute to a strong immunological response.

For maximial outcome success the end-user of the animal-derived antibody will need to use multiple unique target specified antibodies from a range of species and be able to identify them in their application (tissue/diagnostic test). Raising each unique target specified antibody in the same species for use in an individual application makes it impossible to then identify the antibody with a marker tag. The marker tag uses species as its recognition feature. Unique antibodies from the same species will be identified by the same marker tag making it impossible to differentiate between each antibody and specific target. Therefore, access to target specified antibodies from different species allows marker tags recognising each species and thus differentiation between each antibody and specific target.

Typically, what will be done to an animal used in your project?

For the production of an appropriate animal-derived antibody for multiple research purposes, the animals will receive an immunisation with the required immunising agent. After an appropriate interval (2-6 weeks following the primary immunisation) the animals receive "booster" immunisation of the immunising agent. Up to 18 booster immunisation may be administered again every 2-6 weeks.

Following this, to obtain polyclonal antibodies, the animal is terminally anaesthetised and bled by cardiac puncture, blood collected then humanley killed. Further processing (by client) is required to extract the relevant antibodies. For monoclonal antibodies, animals with a strong immune response will receive either an intrasplenic or intravenous immunisation with the immunising agent. Three- seven days later, again animals wil be terminally anaesthetised and bled by cardiac puncture, blood collected and the spleen may be removed. Following this the animal will be humanely killed. Further processing (by client) is required to extract the monoclonal antibodies.

What are the expected impacts and/or adverse effects for the animals during your project?

Immediately following immunisation no adverse effects are expected. However, transient discomfort may be felt at the immunisation site (similar to that experience after vaccination-eg Covid-19). If this is the case then pain relief can be adminsitered. Occassionally within the animal following the immunisation, as the immune response develops they may appear lethargic. These effects should be transient with resolution within a few days. At the immunisation site a "clump" of immune response cells (white blood cells in response to the procedure) called a granuloma may form. The "clump" will gradualy disappear within a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Monoclonal antibodies - Moderate -100%
- Mice 100%,
- Rats 100%,
- Guinea pigs 100%,
- Rabbits 100%
- Polyclonal antibodies- Mild -100%
- Mice 100%,
- Rats 100%,
- Guinea pigs 100%,
- Rabbits 100%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

ECVAM recommendations (May 2020 doi.org/10.2760/091625) urges an adoption of technologies for the generation of non-animal-derived antibodies if available and scientifically justified. This is currently aspirational.

Animals are still necessary for the generation of antibodies. For novel antibodies the ability to recapitulate as recombinant antibodies using universal genetic sequence libraries does not exist. Universal (non-animal-derived) antibody libraries contain an extensive array of diverse antibody genes, but you cannot use the library unless you know the sequence of the antibody. The antibody sequence cannot be determined from the immunising agent sequence alone. When the mammalian immune system is exposed to the immunising agent a myriad of diversification processes leads to specific B cell production. The B cells undergo further consolidation using the innate biological immune system to establish an antibody that is selective for binding affinity, specificity and protein stability. The immunising agent presented to a universal library cannot do this. The resultant animal-derived antibody can be sequenced then presented to the library and recombinant (non-animal-derived) antibody generated that is selective for binding affinity, specificity and protein stability. Only at this stage is the animal derived route unnecessary. This situation has not been arrived at.

Where a novel target (basic research/therapeutic/clinical) or an existing antibody source is near depletion/depleted and no antibody sequence is available then the antibody must be raised in an animal. Once the antibody has been produced it then must be sequenced and future production can then be derived from recombinant technologies.

We will not be progressing towards alternative ways to generate antibodies and thus replace the use of animals. We will refuse to use an animal if a non-animal alternative is available. We have in place a robust ethical process for accepting/rejecting requests with the final decision resting with the Animal Welfare Ethical Review Board (AWERB). Decision outcomes could be 1) Accept, 2) Request more information before decison or 3) Reject. AWERB will review annually the decision making process to ensure it is still fit for purpose to meet compliance with the Act and conditions of the licence. Our role is as as service provider and not a manufacturer of antibodies. Our ethical review process makes the client take responsibility to demonstrate non-animal alternatives are unsuitable/unavailable and where they are to move to non-animal-derived antibody production where applicable. We can help with this transition in the long-term.

Moving from animal to non-animal-derived antibodies requires a transition period. A complete move now risks halting our fundamental (basic research), clinical and therapeutic capabilities and removing an important research tool that benefits society in its widest context.

Which non-animal alternatives did you consider for use in this project?

We have not considered non-animal alternatives. We are a service provider and not a manufacturer of antibodies. It is the responsibility of the commercial antibody manufacturer to determine the suitibility of any non-animal alternatives (display and aptamer technologies, non-animal derived antibody libraries). If they are suitable we would not use an animal.

Why were they not suitable?

An expert body recommends adoption of technologies for the generation of non-animal-derived antibodies if available and scientifically justified. This is currently aspirational.

The purpose of antibody generation is to produce antibodies that recognise novel targets that allow fundamental, clinical and therapeutic activities that benefit society as a whole. Technologies to generate non-animal derived antibodies still fall short in achieving this when compared to animal- derived antibodies.

The technologies might be available, but utilisation as replacements cannot be fully realised until the molecular basis of the starting component (antibody protein sequence) is known and therefore now are scientifically unjustified.

In order to determine the antibody sequence, you need the antibody and the animal is that source. The antibody sequence cannot be determined from the immunising agent alone. Once the antibody sequence is determined then display technologies can be used to produce animal free reagents as an infinite resource. The science is not yet in place for full realisation.

Even where the novel antibody sequence is known the display technologies have problems recapitulating antibody structures especially if related to viruses. This is important in vaccine development because valuable detailed knowledge about how the animal immune system reacts to the immunising agent is determined. This crucial information is lost when using display technologies. Therefore, animal-derived-antibody for certain applications will always be the only viable means.

The antibody derived from a mammalian immune reaction replicates an almost infinite number of ways the immune system has adapted to the immunising agent. The resultant antibody has a much higher affinity and specificity for its target. The technologies at the moment cannot achieve this, so the resultant antibody does not function as well in its end application.

To improve the quality of the non-animal-derived antibodies requires substantial experimentation, experience, time and resources. This needs to be worked towards but in the interim animals are still central to antibody production.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on 10+ years experience on providing the service and the demand generated by external and internal customer requests.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The selection of an immunisation regime (volume/concentration) to initiate an appropriate immune reaction combined with the number of repeat immunisations enables production of a high quality animal-derived antibody . Application of this procedure in no more than 6 animals ensures an individual project can produce the maximum amount of antibody negating the need to repeat the protocol to produce more antibody in this way. Also, the regime enables the spleen to create and store the cells primed to produce the antibody. At the end of the project when collecting the antibody, the spleen is also removed and processed to give a cell culture that can produce the antibody indefinitely. Also, the antibody can have its protein sequence determined to go on to be produced by display technologies so future production would not require an animal.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The approach of immunisation (including boosters max 18) of between 2-6 animals with the same immunising agent using a volume/concentration that initiates an appropriate immune reaction provides a robust mechanism to achieve an optimal outcome. As each immunising agent is novel the standard approach has flexibility to prevent additional animals having to be used and achieve the best from the animals in project. For example, if the immunising agent is a small molecule these can be less successful at stimulating an immune response, taking longer to reach an acceptable antibody concentration within the standard protocol time frame. Options are available to avoid increased animal use including additional boosters with longer time interval between booster allowing the animal the maximum time to respond and/or double dose (increase antigen concentration in same starting volume) for the booster immunisations. It must be recognised as each immunising agent is unique it is hard to determine the factor that causes a low response. The standard protocol with flexibility ensures the best outcome for the minimum of animals used to avoid recruitment of additional animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The adult life stage for each species (rabbit, rat, mouse and guinea-pig) will be used because their immune system is considered to have reached maturity ensuring a complete biological response will be achieved when exposed to immunising agents.

The methodology comprises a series of injections of the immunising agent with experience of transient discomfort akin to a human /animal receiving a therapeutic injection eg Covid-19 vaccination.

Why can’t you use animals that are less sentient?

The adult life stage for each species (rabbit, rat, mouse and guinea-pig) will be used because their immune system is considered to have reached maturity ensuring a complete biological response will be achieved when exposed to the immunising agents.

Animal-derived antibody generation requires an interaction between the immunising agent and the immune system so a living system is required. Adult animals will allow the generation of large volumes of antibody.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All involved staff are already trained to a high standard to carry out the immunisation procedures, welfare and husbandry of the animals. New staff will receive training to maintain the high standards we work to. Good communication among individuals results in quick response and resolution to emerging issues. All these will be maintained. Continuation of the single use needle policy that was introduced in 2019.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R -https://www.nc3rs.org.uk/experimental-design NC3R -https://nc3rs.org.uk/reuse-of-needles

NC3R -https://nc3rs.org.uk/grimacescales

LASA Good Practice Guidelines -
https://www.lasa.co.uk/PDF/AWERB_Guiding_Principles_2015_final.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Dialogue with colleagues and forum networks undertaking similar work. Engage with NC3R website and webinars (Moving to the Use of animal-free antibodies, July 2020).

Within the frame work of relevant advances in relation to the production of animal-derived antibodies, these will be tried alongside existing practices and compared to evolve the best approach to produce high specificity and affinity antibodies.

As already stated novel antibodies still require animal immunisation. Once the novel antibody is produced its sequence can be determined and any future production can take advantage of non- animal-derived technologies (EURAL ECVAM recommendations, May 2020, EU Directive 2010/63/EU).

82. Immune signalling in infection and cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immune system, Signalling, Infection, Cancer, Ageing

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To define the role of Hedgehog (Hh) signalling in lymphocytes, Natural Killer (NK) and other lymphoid cells. To characterize the pathway molecularly, and to develop techniques and reagents to modulate signalling pathways to improve lymphocyte/NK function during an immune response against cancer, infection, and inflammation. As part of this, the effect of ageing on the Hh signalling pathway will be examined and the lymphoid response of the aged immune system to tumour and infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lymphocytes and Natural Killer (NK) cells are critical to our body's defence against infection and cancer, due to their ability to specifically orchestrate the immune response and effectively kill infected and cancer cells. There are two main types of lymphocytes: B cells, which produce antibodies, and T cells. T cells can be divided into two main classes depending on their function. These are helper T cell (Th or CD4 T cells) which direct the immune response, and cytotoxic T cells (CD8 T cells) which kill targeted cells. The Hedgehog (Hh) signalling pathway has been shown to be important in the development of T cells, the maturation of helper T cells and in cytotoxic T cells for target cell killing. The role of Hh signalling in NK cells and other immune cells is unknown. This work will allow us to gain a greater understanding of the role of Hh signalling and how it functions within the immune system.

Age is one of the greatest risk factors for cancer and the highest cancer incident rates are in older people. Recently there has been much interest in the link between cancer and disease incidence and the ageing of the immune system. By investigating changes that occur to the immune system as individual's age we can gain better understanding of how immune function declines, and more specifically in the role of Hh signalling in these changes.

A comprehensive understanding of the Hh pathway and ageing may suggest new treatment or treatment regimes based on modification of the lymphoid immune response, such as amplifying Hh signalling and potentially increasing the killing potential of cytotoxic T cells in patients with cancer or infections. Such an approach would have the advantage to be applicable to all such patients, since it is independent of the makeup of the tumour or type of infection.

What outputs do you think you will see at the end of this project?

1. A better understanding of the cellular and molecular basis of Hedgehog signalling in immune cells

2. Characterisation of the functional relevance of Hedgehog signalling in immune cells throughout the response to infection, inflammation and tumour challenge.

3. Novel strategies for improving immunotherapy in cancer, infections, and autoimmunity

Who or what will benefit from these outputs, and how?

The outputs from point 1 and 2 will, in the short term, benefit our research group and will help to inform future experiments and build on our knowledge base. In the mid term, the outputs of point 1 and 2 will benefit the wider scientific community through research publications and dissemination of scientific discoveries via conferences. Our research might be of potential use to the pharmaceutical industry. In the long term the outputs of

point 3, and methods for increasing the effector functions of the immune system, may be beneficial for cancer patients. The strategy is not focussed on a specific tumour type or tissue and may also prove beneficial to patients suffering from chronic infection and autoimmunity and may improve vaccination.

How will you look to maximise the outputs of this work?

We aim to publish all our research findings in open-access journals and disseminate our research to the wider scientific community via national and international conferences and lectures. A specific effort will be made to publish novel methods to benefit scientists in the field and also publish data showing a non-significant role of Hedgehog signalling in aspects of the immune system in order to avoid unnecessary duplication of animal experiments.

Species and numbers of animals expected to be used

- Mice: 26500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The immune response is complex and requires a coordinated response from a large number of immune cell types. Many aspects of the immune response cannot be studied in vitro and require in vivo mouse models, for example, the interaction between a tumour and the immune system or the immune response to infection. These involve complex communications between cell types in many organs that cannot be accurately re-constituted in vitro. The mouse immune system is well understood and can be thoroughly investigated since (i) many reagents are available and optimised for its study and (ii) robust mouse models of both malignancy and infectious diseases have been established. The murine and human immune systems are very similar and thus results obtained using mouse models will be directly relevant to human.

We will breed genetically altered animals (GAAs) for use in our studies that will be mainly on a particular mouse background strain (C57BL/6 strain), since most immunological models have been optimised using this strain. The immune system of the mouse does not become fully mature until 6 weeks of age and we intend to study only the mature adult immune response in our experimental mouse models. We therefore do not intent to study embryonic, neonatal or juvenile mice and will only use mice over 6 weeks of age, except in exceptional circumstances. For studies examining the effect of ageing on the immune system we intend to keep healthy aged mice up to approximately 21 months of age. Aged mice will also be on the C57BL/6 mouse strain which has been shown to be long-lived and generally in good health well into old age.

Typically, what will be done to an animal used in your project?

The majority of mice (approximately 60%) used on this licence will be genetically manipulated and used for the purpose of breeding or for tissue collection without any further procedure. Most GAA will be healthy and show no deleterious effects. The mice are maintained in individually ventilated cages in a barrier environment to protect them and ensure any effect of the genetic manipulation on the immune system does not compromise the health of the animal. Approximately 15% of the mice on this licence will undergo regulated procedures that result in the experience of mild distress – such as a single injection or blood sampling procedure. This means that the mice will experience no more than transient discomfort and no lasting harm. The remaining 25% of mice will be used for a short term disease models (usually up to 5 weeks), either a model of infection, inflammation or cancer which may involve multiple procedures - such as multiple injections, blood sampling, imaging and may experience irradiation, intestinal inflammation or tumour burden. These mice may experience a higher level of distress, but in these cases the health of mice will be closely monitored and any mouse showing defined signs of distress and/or poor health will be immediately killed. All animals will be killed by an appropriate humane method at the end of the study.

What are the expected impacts and/or adverse effects for the animals during your project?

GAA for breeding or tissue collection (approximately 60%) and mice undergoing mild procedures (approximately 15%) are not expected to experience any adverse effects, other than transient discomfort, and no lasting harm. The remaining 25% of mice will include animals experiencing irradiation, tumour challenge, infection or inflammation. These animals will be closely monitored and we do not expect them to experience any pain or long-term lasting harm since our disease models are short-term with clearly defined endpoints. Adverse effects will include transient weight loss, and tumour burden which we do not expect to impact on the welfare of the animal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the majority of our mice (approx 60%) to experience subthreshold severity - used for breeding and maintenance of colonies and tissue harvesting after schedule 1 for phenotyping and in vitro analysis. We estimate 15% of mice may experience mild severity following procedures that produce no more than transient discomfort and no lasting harm. The remaining estimated 25% are expected to experience moderate severity, either a cumulative effect of multiple mild procedures or following a disease model procedure. No animals are expected to experience severe severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune response to antigen, either foreign or self, is complex and requires a coordinated response from a large number of immune cell types and therefore necessitates the need of animal models. The parallels between the human and mouse immune systems are well understood and there are robust mouse models of both tumour biology and infectious disease which can be utilised, with results being directly relevant to human.

Which non-animal alternatives did you consider for use in this project?

To minimise the number of mice used, we intend to carry out as much preliminary work in vitro (culture experiments not requiring living mice) and ex vivo (experiments done in or on tissue removed from the mouse). This will include using established tissue culture cells lines, assessing responses of individual cell types to various stimuli and assessing the signalling pathways in more depth. In addition, we have established a clinical research study using immune cells of human patients and healthy controls. These studies will run in parallel with the mouse studies and will inform and direct the mouse work as well as leading to a reduction in animal use.

Why were they not suitable?

In vitro approaches will allow us to optimise and focus our experiments. However, many aspects of the immune response cannot be studied in vitro and require a mouse model. For example, the interaction between a tumour and the immune system, or the immune response to infection. These involve complex communications between cell types in multiple organs that cannot be accurately re-constituted in vitro and are only sensibly assessed in vivo (within a mouse).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The majority of the lines in the colony will be maintained on the C57BL/6 mouse strain background which is optimised for immunological studies. This has been used as the basis for our breeding strategies. An assessment of the reproductive performance of the C57BL/6 strain has been detailed in the Laboratory resource: 'Breeding Strategies for Maintaining Colonies of Laboratory Mice' produced by The Jackson Laboratory **(Table 1).**

Table 1: Reproductive information of Jax C57BL/6 strain

Mean Weaning age (weeks)	Optimum Reproductive Lifespan (weeks)	Mean no. of litters born	Mean litter size (born)	Wean:born ratio	Mean litter size (weaned)
4	30	5.4	6.09	0.92	5.60

As standard, our breeding stock will be maintained at minimal levels with 1-2 breeding pairs of different ages at any one time. Breeding pairs are mated typically at 6-8 weeks old and allowed to have 5-6 litters (approx. 30 week breeding period). Replacement breeders will be taken from the stock mice produced or bought in from commercial breeders (for inbred wildtype strains). We try to avoid sibling mating where possible. During the course of the proposed work we estimate we will breed a combination of approximately 18 mouse strains carrying modified immune genes at any time, split between our Mild and Moderate Breeding Protocols **(Protocols 1 and 2).** When colonies are expanded for experimental purposes, breeding trios tend to be used to maximise pup numbers of similar age and provide appropriate littermate controls. However some of our lines give a reduced frequency of GAAs born (approx. 10% compared to 25% expected) and may require additional breeding groups. The majority of mice bred from the expanded colonies will be used for tissue collection for ex vivo work or in subsequent protocols, however there will be the production of unwanted experimental mice which may be used for replacement breeders or culled unused as excess. We currently have 9 mouse lines on each of our mild and moderate breeding protocols - some lines are for breeding purposes only and some lines are expanded for experimental mice. An estimation of the number of breeding females at any one time is given in **Table 2.**

Table 2: Estimated Breeding Females for Mild and Moderate Breeding Protocols

Mild Breeding Protocol 1		Moderate Breeding Protocol 2	
Breeding only (Continuation of line/breeders for experimental crosses) - Breeding Pairs	5	Breeding only (continuation of line/breeders for experimental crosses)	3
Experimental Crosses (Hom x Hom) - Breeding Pairs	4	Experimental Crosses (Hom x Hom)	2
Experimental Crosses (Het x Het) - Breeding Trios	12	Experimental Crosses (Het x Het)	27
Total Breeding Females	21	Total breeding Females	32

From these numbers, we have estimated the number of mice which will be produced from our breeding strategy over the next five years, taking into account that breeding females will be replaced every 30 weeks (a replacement factor of 1.73 a year). This has given us estimated mice numbers for Protocol 1 6500/5 years and Protocol 2 10000/5 years shown in Table 3, allowing an additional 10% for variations in breeding numbers over the five years.

Table 3: Estimated mouse numbers produced on Mild and Moderate Breeding protocols over 5 years.

	Mild Breeding Protocol 1	Moderate Breeding Protocol 2
Active breeding Females	21	32
Replacement Factor (per year)	1.73	1.73
Breeding Females per year	36	55
No. of litters per Female	5.4	5.4
Average litter size	6.09 (born), 5.60 (weaned)	6.09 (born), 5.60 (weaned)
No. pups born per year	1184 (born), 1089 (weaned)	1809 (born), 1663 (weaned)
No. mice born over 5 years	5919	9045
Protocol No (+10%)	6500	10000

For many of our experimental models our initial calculation, in consultation with our Statistician, have suggested we require 7-9 mice per group per experiment. Depending on the controls required for individual experiments, this means the use of an average of 20 mice per experiment, 10 mice per group (control and test) allowing an additional 10-20% per group for experimental losses (such as from tumour engraftment problems or technical dosing issues etc). This will be amended as we gain more information from our experiments and will also vary depending on the number of test groups required per experiment (we may, for example, have a control and 2 test groups in some instances). Most of our proposed disease models are well established and robust, however for some cancer studies, for example, there may be a more variable onset and this may necessitate larger cohorts to demonstrate significant differences. Estimated number of experiments to be performed on each experimental protocol are detailed in Table 4 below.

Table 4: Estimated number of experiments and mice used on experimental protocols.

	experiment	year	year	years
Protocol 4 - Phenotyping	20 mice	4	80	400

Protocol 5 - Immune mice	20	16	320	1600
Protocol 6 - Influenza mice	20	10	200	1000
Protocol 7 - Intestinal mice Inflammations	20	5	100	500
Protocol 8 - Subcutaneous	20 mice	25	500	2500
Protocol 9 - Blood Cancer	20 mice	15	300	1500
Protocol 11 - Cell Labelling	20 mice	1	20	100
Protocol 12 - Skin	20 mice	4	80	400

Protocol 3 involves the production of bone marrow chimeric mice which would be used to address more specific questions and create experimental cohorts of mice from more fragile breeding lines (the chimeric procedure involves the replacement of the immune system with an alternative genotype, by irradiation and subsequent bone marrow transplantation). Mice from this protocol would be directly analysed and we currently estimate creating 10 experimental cohorts on this protocol a year (1000/5 years). Chimeric mice will also be produced to form experimental cohorts as an additional step on other end protocols **(Protocols 5-9 and 12)** within this licence.

We plan to have a continuous staggered ageing mouse colony on Protocol 10. This colony management strategy will allow us to collect samples at varying ages and is also an effective way to manage experiments that require a significant investment in time. It is proposed to initially assign 20 male or female mice in each cohort, based on the number of animals required for an experiment and on the potential loss of animals in a cohort as they age (based on the experience from the current ageing colony which has been running for the past 7 years). We would have ageing colonies for both C57BL/6 wildtype mice and non-harmful genetically altered lines (with matching control mice if necessary) and plan to age approximately 10 cohorts in total a year. We anticipate carrying out the ageing project over the period of the licence, so the total estimated number of mice required on Protocol 10 is 200 mice a year **(1000/5 years).** These healthy aged mice will be used for direct ex vivo analysis. We will also produce healthy aged mice as an additional step on a limited number of other end protocols **(Protocols 5, 6, 8 or 12).**

These are our current estimates for the project licence over the next five years, but will be adapted and refined as we increase our understanding of the field and our breeding and experimental requirements.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing experiments we will initially perform pilot studies to determine the observed effect sizes to ensure that we use the minimum number of mice per group that will be informative. In addition, we will consult with statisticians before starting the experiments and throughout when required to ensure statistical confidence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We intend to run the administration of our mouse strains centrally, using the Laboratory Manager as a central communication point between all users working under the licence and the animal unit staff where the mice are housed. This ensures we can optimise strain breeding to support multiple studies. Should excess mice arise, these can be shared with other researchers who have the authority on their licence to receive them. Collaborating in this way avoids mice being bred and not used, and also avoids duplication of breeding strains within the same facility. The strict control of mouse stock ensures excess breeding is avoided and all mice bred are used as productively as possible.

All mouse lines not in current use are kept on minimal breeding. Where possible, the mice are bred as homozygous lines (providing they do not have a harmful phenotype) and when breeding heterozygotes, littermates are used as controls for experimental work. We have the facility and expertise at the Transgenic Unit to freeze embryos/sperm, and this is will allow us to store those lines needed for future studies but where no research work is planned in the immediate future. On occasion it will be more efficient to study the cell-specific function using bone marrow chimeras. This allows reconstitution of mice with immune cells of a desired genotype and obviates the need to generate new mouse models, to perform complex breeding crosses or try to produce experimental cohorts from lines which produce more fragile genotypes (such as mouse lines where the expression of Hh components have been deleted).

Every opportunity will be taken to decrease the number of animals used for each experiment, whilst still maintaining the statistical significance of the subsequent data. We would undertake pilot studies when using procedures and models new in our hands, to ensure they are optimised before large scale experiments are carried out. To maximise information, multiple body sites will be examined from each animal and multiple analysis types will be conducted on each sample, where possible. Samples can also be archived, e.g. we have optimised cryopreservation of immune cells and created a bank of peripheral immune cells and bone marrow, which can be retrieved and used for future in vitro functional studies, adoptive transfer for in vivo disease models and for production of chimeric mice. RNA and protein samples can also be stored, allowing us to revisit a previous study to perform further analysis without the need to repeat the experiment. This is most important for the healthy ageing colony which represents a large investment in time. We propose to prepare a bank of tissue samples from these mice and collaborate with other researchers interested in ageing to ensure the maximum usage of these scarce mouse populations.

We have setup a clinical research study and have optimised protocols to phenotype and analyse various immune functions in various human immune cells. This will reduce our need for some animal models since work can be accomplished in human immune cells obtained from blood.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen to use mouse models for this project because the murine immune system is well studied and this will allow us to examine our findings in the context of the wealth of information and reagents which are already available and utilise the expertise of other researchers in the field.

Additionally, many murine models of immune cell development and function have been developed and optimised, including tumour biology, intestinal inflammation and influenza. Mice are inbred, relatively small and the mammalian species that is most easily genetically manipulated. They have been shown to yield reproducible results in studies of the immune system. The majority of the GAA we use are designed to be conditional and/or inducible in nature, which will allow us to precisely control phenotype presentation until the candidate gene expression or deletion is induced. This is particularly important since we are interested in the Hedgehog signalling pathway which has important roles during embryonic development.

Why can’t you use animals that are less sentient?

The immune system takes time to establish, develop, and mature in young animals and becomes fully mature only in the mouse from 6 weeks of age. We therefore require the mice to be over 6 weeks of age to study the adult immune system.

Our research is geared towards basic and translational science. In order to be able to translate our findings into the clinic we require an animal species with an immune system very similar to the one of humans. The mouse is an excellent, cost-effective choice in this regard with a wealth of research tools for this species available.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Using ex vivo studies allows us to examine the immune system using tissues isolated from mice without the need for further procedures. This will include assays to measure T cell subsets, growth and function, as well as analysis of mRNA and protein expression. The use of in vivo tumour and infection models will initially be refined using these studies. This will allow us, for example, to optimise our experiments and focus on a particular immune cell type or tumour cell line to reduce the number of animals used. Combining the results from the in vitro data and the specific in vivo analysis will allow us to estimate the number of animals required to generate meaningful data, for example analysis of the lung response to respiratory infection will typically require more animals due to the increased variability of the immune response in this tissue compared to lymph nodes.

We have made several refinements to the healthy ageing colony. Originally, only male mice were used, and due to fighting issues, they can end up singly-housed. We have introduced female mice to the colony which can be co-housed at any point to provide company. This will also ensure that any sex- related differences are addressed in our studies. The colony was fed on a high fat diet and C57BL/6 strain mice are susceptible to diet-induced obesity. We are interested in the effect of ageing, and not obesity, on the immune system and have changed the diet of new mice being recruited to the colony to the lower fat diet currently used to maintain our GAA colony as well as the young control mice. This will ensure we are examining only the effect of healthy ageing on the immune system (especially in cancer studies, where obesity has been shown to be a strong risk factor). We will also investigate the option of buying in aged mice from a commercial supplier rather than ageing the mice ourselves. Until now the commercial supply of aged mice has been erratic, but as interest in the effect of ageing increases this has become a viable alternative.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Unless otherwise specified, the work in this project will be undertaken in accordance with the principles set out in the Guidelines for the Welfare and Use of Animals in Cancer Research: British Journal of Cancer (2010) 102:1555-1577 (referred to subsequently as the 'NCRI Guidelines') and in the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery (2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are an active member of our AWERB committee and in constant contact with our NACWOs and animal staff in the animal facility who all have an active role in communicating and advancing the 3Rs throughout the facility.

In addition, we receive regular communications from our Regulatory Compliance Advisor about advances in the 3Rs and relevant conferences and meetings. In addition, we seek advice from the national 3Rs website.

83. Cancer and the microenvironment

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cancer, stem cells, tumour environment, leukaemia, infection

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The projects overarching aim is to better understand cancer development in the context of the tissue which supports its growth and provides chemotherapy resistance.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer causes more than one in four of all deaths in the UK. Despite current therapies many patients diagnosed with cancer die of their disease. Work by our lab and others shows clearly that cancer is highly dependent on non-cancerous cells for their growth, proliferation and chemotherapy resistance. Cancer development is therefore a complex, multi-step process that involves interaction of the tumour cells with the local environment and the immune system and cannot currently be recreated by culture methods. Animal models become necessary because the nature of these pathways and drug treatments require the presence of the cancer and its microenvironment in the setting of a whole animal. These models allow us to study the interaction within the bone marrow microenvironment both in normal physiological processes and in the presence of cancer.

What outputs do you think you will see at the end of this project?

The likely output from this work is to disseminate new information through publication of data in high impact peer reviewed scientific journals. Specifically, the information is expected to subsequently inform the design of clinical trials of new treatment strategies in patients with cancer.

Who or what will benefit from these outputs, and how?

Our research has an established track record in publishing new information in high impact journals.. Moreover, we have also established a track record of bringing our published data to inform new clinical trials. For example, our published work has led to early phased clinical trials and proves biologic rationale for the re-purposing of existing anti-cancer drugs for the use in other types of cancer.

We therefore believe the short term (project year 1-3) benefit from these outputs would be the scientific community as they would benefit from our development and discovery of additional new information regarding the physiology of cancer progression, in support of therapeutic developments.

Medium term (project year 3-5) benefits from these outputs would include the scientific community as described for short term benefits but would also include the pharmaceutical industry who could develop new or existing chemotherapeutic drugs against cancer targets which we identify during this project.

In the long term (post project completion) the ultimate aim would be to improve patient care. We have experience of developing our findings through existing industrial partnerships into clinical trials which may ultimately benefit the patient.

How will you look to maximise the outputs of this work?

Our project team will engage with pre-clinical teams within pharmaceutical and biotechnology industries. Through networking and the presentation of the data at international meetings, we aim to engage with at least two new industrial partners with

drug development expertise. Teleconferencing between partners will be used to communicate our findings.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the most appropriate and a widely used model for cancer research. We will use and refine established reagents and protocols to induce cancer. We will look to develop inducible gene expression or deletion of novel candidate genes to study the impact on cancer development with in the context of its environment. Experiments will be conducted on adult mice, including aged mice.

Typically, what will be done to an animal used in your project?

Animals will be given cancer or control cells, with or without non-malignant cells from the tumour microenvironment, through intravenous, subcutaneous or intraosseous injections. These will be usually given only once and the experiment lasts until the animal show symptoms of cancer development.

These experiments will last approximately 30 days.

Before we inject cancer into the animals we need to suppress their immune system. This will be done by using a chemotherapy agent and via intraperitoneal injection. This will be given daily for up to 3 times before injection of cancer.

Once the animals have cancer we will use live in vivo imaging to monitor the cancer development - this will require intraperitoneal injection followed by anaesthesia followed by imaging. This usually takes 5- 10 minutes and the animals are then recovered.

Animals will be mated to establish and maintain colonies for use in cancer studies.

During cancer experiments animals may also be given chemotherapy or other substances by oral gavage, addition to diet or drinking water or intraperitoneal injection. This can be given daily for up to 60 days.

Embryos will be implanted surgically or non-surgically into the reproductive tract to generate to generate offspring for breeding.

Animals will be given microbes or there components to generate an immune response this will usually be given by oral gavage or intraperitoneal injection. The microbes will be given once. The microbe components can be given biweekly for up to 12 weeks.

In some cases blood sampling will be used to withdraw blood for analysis. 10% of blood will be withdrawn and only every 14 days.

What are the expected impacts and/or adverse effects for the animals during your project?

Immunosuppression - moderate weight loss for up to 2 weeks post injection of immunosuppressive agent

Transient pain when performing intraperitoneal, intravenous or subcutaneous injections

Tumour engraftment - Weight loss when tumour is advanced for up to 20% over 72h. If animals show any of the following clinical signs they will be immediately euthanased. These symptoms include rapid weight loss (10% over 24 h), anaemia, laboured respiration, hind leg paralysis, hunched posture or piloerection. Failure to eat or drink over a 24 h period.

Immune activation - transient ill health including piloerection and weight loss. Animals fail to recover over a 24h period will be immediately euthanised

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mating and addition to diet or drinking water will be mild

All animals that develop cancer are expected to have a moderate phenotype It is unlikely that any of these procedures will result in a severe adverse effect

What will happen to animals at the end of this project?

Killed

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer is complex, multi-step processes involving interaction of the tumour and blood cells with the local tissue environment and the immune system, that is set in the context of the immune system, metabolism and physiology of the entire animal. This complex interplay between cancer and the host cannot currently be recreated by culture methods.

Which non-animal alternatives did you consider for use in this project?

We have used in vitro co-culture assays and were possible will continue to use in-vitro experiments as the first proof of principle experiment. Then move the experiments into animals to study the complex interactions of the tumour microenvironment

Why were they not suitable?

These assays are suitable for the first step in identifying interactions that may be important in tumour- host development. However, they don't mimic the complexity of the tumour microenvironment and therefore are of limited use.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have an internationally recognized in-vitro research program from which we have generated as much informative data as we can to limit the necessary in-vivo assays. Together, with our published work describing complex in-vivo experiments have informed us on the number of animals required to answer the objectives of this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The total number of animals to be used in this proposal is primarily based on the use of these established protocols in our previous PPL. These have produced scientifically robust data published in high impact peer reviewed journals. We have combined this with using the NC3R's Experimental Design Assistant which has allowed us to minimise the number of animals required to provide scientifically robust data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to adopt our existing lab approach to minimise animal usage and use appropriate control experiments to answer the experimental question in the most efficient way possible. This will include careful management of colony sizes, the use of surplus

tissue for other purposes where possible. We will optimise cohort size based on scientific evaluation of previous results including in- vitro data. We will perform pilot studies in order to improve the quality and efficiency of larger studies by informing on number of animals required for a well designed study. Other variables we will assess is operator bias and try were possible to use similar age, sex and animals from the same cage. We will minimise the use of mice from single cages.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most appropriate and a widely used model for cancer research. For transplantation of (+/- manipulated) cells into host animals we will aim to use the least invasive method the experiment allows to deliver the cells (intravenous before sub-cutaneous/ intraperitoneal before intra-osseous) with a view to minimize the suffering as a consequence effect of the procedure.

For the infection models we propose to study the mammalian response to infection using various bacterial and virial mimics. This reduces the need to use entire infectious agents in the experimental design and allows quantification of the immune stimulant which improves the experimental reproducibility and design, ultimately helping to improve the overall quality of the work and reduce the number of animals needed.

With each batch of infection agent we will assess how dose effects the bone marrow and blood response to these immune system stimulants allowing us to identify quantities necessary to test future hypotheses and ultimately allow us to use doses that minimize suffering.

Why can’t you use animals that are less sentient?

Cancer is an aging disease and thus using animals that are less sentient to study tumour-host interactions would not reproduce the complex biological systems required for simulating these mechanisms.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Injection of cancer cells IV - cannula will be small (26 or 27g) and only used once. Monitoring of mice for swelling or hemorrhage.

Blood sampling- cannula will be small (26 or 27g) and flushed with heparin before use to prevent clotting. Monitoring of mice for swelling or hemorrhage.

Choice of agent for mimicking infection - where the outcome is unknown, dosage will be carefully titrated to identify smallest dose that can be used to cause clinical signs of infection.

Animals will be carefully monitored and will be killed by schedule 1 method before they suffer undue effects from the cancer.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs website (https://www.nc3rs.org.uk/experimental-design) will be used for experimental design and the ARRIVE guidelines will be followed to ensure correct reporting of animals research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Review the NC3Rs website (https://www.nc3rs.org.uk)for updates every 3 months. Resources on common procedures will be assessed and advances will be tested in pilot studies to determine their effectiveness in our disease models. Moreover, new advances published regarding experiment design of in-vivo experiments will be analysed in pilot studies to then be applied to setup and experimental disease.

84. Vascular regulation of fibrotic disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Endothelial cells, Liver Disease, Fibrosis, Immune response

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.What's the aim of this project?

Understand the role of vascular inflammation in driving early-stage tissue fibrosis
Determine the contribution of endothelial cells to tissue fibrosis
Assess the regulation of immune cells by the endothelium during fibrosis

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic inflammatory disease is strongly associated with the development of fibrotic disease and ultimately tissue failure in multiple diseases such as hepatitis, arthritis, myocarditis, and atherosclerosis to name just a few. Fibrosis, or tissue scarring, is the most debilitating outcome of chronic disease but currently, transplantation is often the only option for many patients. There are very few if any clinically effective treatments available to combat established tissue fibrosis. The rapid rise in obesity and metabolic disease globally, the most commonly associated conditions leading to chronic liver disease, has led to an unsustainable demand healthy tissue donor for liver transplantation. Currently it is estimated that Non-alcoholic fatty liver disease (NAFLD) affects 13 million people in the

UK alone (~20% of population). Therefore, it is paramount that we develop new strategies to evaluate, diagnose and target tissue fibrosis.
The cells that line all blood vessels, endothelial cells, are one of the first cell-types to sense and respond to tissue injury. Endothelial cells not only sense injury and insult to the body but are also fundamental to wound healing, tissue repair and re-establishing the perfusion of blood by their ability to grow new blood vessel into damaged tissue. Recent studies have revealed that during chronic disease endothelial cells change their behaviour from helping tissue repair to actively contribute to fibrosis. Our work has revealed that a process termed Endothelial-to-Mesenchymal Transition (EndMT) is a key mechanism by which endothelial cells lose their cellular identity and acquire pro-fibrotic characteristics. This work defined new genetic and protein markers for EndMT that were shown to be strongly associated with end-stage liver disease. Single cell RNA sequencing of patients has not only confirmed key EndMT genes are elevated in cirrhotic liver tissue but also highlighted the development of unique disease-associated endothelial populations during the progression of disease.

This licence will focus on understanding how inflammation and metabolic changes, such as high-fat diet, influence changes in endothelial identity. Together the protocols detailed will model different aspects of the complex interplay between the host vascular and immune cell response and provide new approaches to reverse tissue fibrosis and promote the healing and tissue repair.

What outputs do you think you will see at the end of this project?

This project licence will generate new understanding of the role of blood vessels, and in particular endothelial cells, and their wider influence within specific organs and on the body as a whole. The pathways and processes that underlie how endothelial cells change their behaviour following tissuedamage are novel and describing new mediators and signalling pathways involved will of great interest to numerous research fields beyond liver fibrosis. To date endothelial-to-mesenchymal transition (EndMT) has been described to play an important role in a wide range of chronic pathologies including pulmonary hypertension, renal, cardiac fibrosis and tumour progression. The broad appeal of this research will aid in its dissemination through publication in international scientific journals and conferences.

To achieve the objectives of this project we will also generate novel tools and methodologies applicable in the lab, in animal models and potentially in the clinic. To this end we will use the most refined models that can best represent human disease such as inducing chronic inflammation and providing mice with imbalanced diets similar to the high-fat and nutrient-poor aspects of our Western food. By taking these approaches and developing new scientific tools we will enhance our studies application to both basic research and clinical science, forging collaborations and driving the spread of the research.

Furthermore, by understanding the impact on specific tissues, such as the liver, we aim to develop new approaches to identify and treat patients with fibrotic diseases. In parallel with this project licence, we have established collaborative projects that gives us access to clinical samples to validate key pathways identified within these mouse models and develop new ways to assess these processes using human cells in the lab. This will both improve diagnostic and drug screening tests and reduce the burden on animal research.

Who or what will benefit from these outputs, and how?

Steps towards developing new therapies to tackle chronic and fibrotic diseases will bring huge benefits to a huge demographic of patients. However, we clearly have a gap in both knowledge and application before we can attain this long-term goal. This programme of research details a new approach to understand the central and fundamental role that blood vessels play in directing tissue to heal or result in tissue scarring and ultimately fibrosis. Early diagnosis of patients at risk of progressive fibrotic disease is a major challenge facing the clinical management of patients. By characterising the roles endothelial cells during different models of acute and chronic inflammation, imbalanced diet and liver injury, described within this licence, we aim to identify new vascular targets that can be used to diagnosis and potential treat tissue fibrosis. In the time frame of this licence, we intend to understand the key interactions that occur between endothelial cells and the surrounding tissue during the progression of fibrosis with the express hope of mimicking this environment in a dish, such as the Organ-on-a-chip. This will enable us to reduce and ultimately replace animals for screening and validating anti-fibrotic drug targets.

How will you look to maximise the outputs of this work?

This work will be undertaken with a broad range of expert collaborators from both basic and molecular biology to clinical practice. Each step will be validated to ensure that only targets that are applicable to both mouse and human fibrosis are investigated. New knowledge gained from these projects will be presented at national and international conferences while completed studies, irrespective of success, will be published in open-access journals. In accordance with the Concordat on Open Research Data, outputs from publicly funded research will be made freely accessible to maximise use of all data acquired, broaden the research benefits and allow transparent scrutiny of research findings.

We are also keen to disseminate knowledge to lay audiences through public engagement including festivals, imaging competitions and talks to allow public debate about the use of animals in medical research.

Species and numbers of animals expected to be used

- Mice: 3600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This work will be carried out exclusively on mice due to the substantial existing data that describes the extensive similarity in inflammatory and fibrotic mechanisms with humans. The majority of protocols will focus on adult mice to reflect the demographic of patients who develop and present with chronic disease and tissue fibrosis.

To maximise the specificity of studies proposed we will apply inducible genetic manipulation immediately prior to induction of each protocol and enable us to make the most of the wide and valuable array of genetically altered (GA) strains available.

Typically, what will be done to an animal used in your project?

This project will generate genetically altered mice to target and visualise key aspects of blood vessel biology and assess the dynamic changes that occur during models of inflammation, vascular growth, and fibrosis.
In this project we will use some animals in a breeding programme to develop new strains of mice that incorporate fluorescence proteins with specific vascular and fibrotic genes associated with EndMT. These mice will be used in study protocols designed to enhance our understanding of EndMT, provide robust, reproducible, and quantitative measurements of vascular changes, and track cells in real time with both non-invasive and invasive fluorescence imaging. Mice used for breeding will be housed in appropriate living environment that allows them to perform their natural behaviours and maintains their welfare. All genetic modifications will be previously established to minimise any impact on health and wellbeing. Any genetic changes that are known to impact development will be bred with additional 'conditional controls' whereby the gene/s can only be activated or deleted in the presence of additional dietary or drug supplements. Mice assigned to the breeding protocol will not be expected to experience more than transient or mild discomfort.

The four study protocols detailed in this project will assess four key characteristics of fibrotic liver disease, namely inflammation, vascular growth (angiogenesis), nutritional imbalance and fibrosis. To this end, most animals under study protocols will undergo an injection or series of injections of substances inducing inflammatory, angiogenic and liver fibrosis. Study protocols focusing on inflammation and angiogenesis will be conducted for short periods of time with the majority of mice not predicted to suffer more than transient and mild distress. A small proportion of these protocols will also be conducted with short term dietary modifications to understand the influence of these factors on the onset of tissue fibrogenesis. Liver fibrosis models require more prolonged exposure to hepatoxic substances or dietary changes (e.g methionine/choline deficient or high fat) which have the potential to induce clinically assessable adverse outcomes with some mice displaying moderate signs of distress. The vast majority (>90%) of mice in this project will be humanely culled prior to displaying any clinical signs of distress with quantitative data derived following the collection of tissues, blood and bodily fluids.

Approximately 25% of all animals under study protocols will undergo non-invasive imaging to increase the data acquired, refine the monitoring of processes being investigated and reduce the mice required for each procedure. In acute models (up to 2 weeks) animals are likely to undergo the optional steps of having blood taken and undergo 1-2 imaging sessions under 1 hour in length under recovery anaesthesia. For the relatively few mice who undergo procedures longer than 2 weeks; they will be subject to single, weekly anaesthesia to acquire blood samples and undertake imaging sessions of less than 1 hour.

Grouping will be determined by ensuring experiments are designed with comparable control groups that account for genetic background and environmental factors. We will use matched mouse strains to minimise variation between experimental groups and maximise reproducibility. Where applicable we will constrain groups to age, weight, and sex matched animals. This does not restrict groups to single sex animals but makes sure that equal composition of groups is maintained.

Animals that are under procedure will be subject to enhanced supervision to ensure their well-being and ensure that experiments are conducted within the parameters detailed in the licence.

What are the expected impacts and/or adverse effects for the animals during your project?

Almost half of the mice used within this project will be assigned to the breeding programme and will not experience any more than mild and transient distress. By breeding already established genetic altered strains with fluorescent reporter mice and using ‘conditional’ controls of gene deletion/activation we will mitigate any unforeseen impacts that genetic modification could have on normal development and behaviour.

The mice that are assigned to the study protocols will most commonly experience moderate discomfort associated with single or repeat injections of the conditional gene regulators followed by inflammatory, angiogenic or pro-fibrotic substances at doses that are well tolerated. In the unlikely event that mice display localised inflammatory reactions that such as swelling or redness, acute weight loss or abnormal behaviour for more than 24 hours in response to these procedures will be euthanised.

800 mice (22% of the total project) are assigned to receive a hepatoxic substance or high fat diet to induce liver fibrosis. These are more prolonged models lasting >4 weeks that result in clinically assessable liver dysfunction. While these models result in liver damage they are not associated with pain or abnormal behaviour and are only clinically apparent by the release of indicative proteins into the blood steam. Therefore, most mice will only experience mild and transient distress related to substance administration and blood sampling. Mice receiving high fat diet may experience some mild impact on their well-being and condition which will be closely monitor throughout. Mice be assessed by combining defined parameters such as weight loss/gain, abnormal behaviour, clinical signs of liver dysfunction to ensure mice do not experience more than moderate and transient distress. Any mice that exceed our define criteria will be euthanised.

During all study protocol approximately a quarter of these mice will be assessed by non-invasive imaging session/s conducted under short-term, inhaled anaesthesia. Short-term anaesthesia is well tolerated with mice experiencing mild and transient discomfort. To reduce the potential risk of transient respiratory distress, less than 10% of these animals will undergo longer-term anaesthesia (over 1 hour) and these longer sessions will be less frequent if repeat imaging is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the 3600 detailed in this project, 1500 (42%) of animals in this project are assigned to breeding. 2100 mice are assigned to study protocols: 800 (22%) to the study inflammatory models, 500 (14%) angiogenesis models and 800 (22%) for the induction of fibrosis. All animals under used within these protocols will experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

The development of tissue fibrosis is multi-factorial and complex involving both local and systemic interactions between blood vessels, surrounding tissue and circulating immune cells occurring at different times. To fully understand and assess how these different features of biology work together we must apply integrated approaches including assessing cells in the lab, producing computational models and determining how whole tissue responds during the progression of fibrosis. While lab and computational approaches have made great strides in recent years, they are unable to accurately simulate the environmental and cellular changes that occur in living organisms which still provide the most meaningful method of assessing all aspects of tissue fibrosis.

Which non-animal alternatives did you consider for use in this project?

We will be utilising laboratory-based methods such as culturing cells to reduce and replace our use of animal models. Specifically, we will be investigating how organ-on-chip platforms, which can recreate some characteristics of living tissue, can be used to undertake pilot studies of cell-cell interactions, genetic manipulation and pharmacological screening prior to assessing factors in animals.

Why were they not suitable?

One of the biggest challenges is that fibrosis involves numerous processes including different cell types and environmental changes that occur over a prolonged period of time, in patients fibrosis can progress undetected for many years. While we can model key elements of disease in the lab these are only possible for short periods of time. Animal models are the only available method where we can measure the development and impact of fibrosis over a number of weeks to months, making them the most applicable way to model and understand human disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimated number is due to the inclusion of genetically altered animals, which are extremely useful to clarify the role of specific endothelial cells and endothelial-specific molecules in the regulation of tissue fibrosis. These mice need to be bred for several generation before they are suitable for experimentation with 57% of the mice bred projected to undergo a procedure. All possible efforts to reduce, refine, replace the animal use have been and will be made as stated in the 3Rs section below.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This project will use genetically altered, fluorescently labelled, mice to allow us to readily visualise how different cells behave during fibrosis. This approach is a very well-established method that enables us to target selected cells, in this case those of our blood vessels, and image them using non-invasive microscopy. The application of non-invasive imaging will greatly increase both the amount and quality of data obtained from each individual mouse thereby reducing the number of mice required for each protocol. In addition, tissues from the same animal will be used in as many analyses as possible to minimise the number of animals required. Where possible will minimise the number of control mice (those used to compare specific biological response in genetically altered or drug treated mice) by performing internal, comparative controls within the same mice (e.g before and after treatment) thereby reducing the number of mice required per group.

To ensure reproducible and veracity of our experiments we will include randomisation of treatment or control groups, allocation concealment, and blinded assessment to prevent bias analysis of the data obtained. These approaches will reduce the number of experimental groups required and the impact of biological variation between animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The breeding strategy will mainly focus on crossing existing genetically altered (GA) mice with fluorescently labelled, vascular reporter animals. If the existing GA mice are associated with any adverse phenotypes, such as developmental abnormalities, we will utilise inducible gene deletion or over-expression only induce genetic modification in adult animals thereby preventing adverse developmental effect. We will continue to utilise literature searches to confirm we are using the most up- to-date methodologies for the project. This will also ensure there is no duplication with previous reports. Ongoing statistically assessment of quantitative experiments will also enable us to re-assess animal numbers by improving our power analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will exclusively use mouse models of inflammation, angiogenesis and fibrosis in this project. These three study protocols have been chosen as they represent three central roles for blood vessels, and particularly endothelial cells, during the progression of chronic disease. Inflammation is a common process that occurs at the initiation and during active disease, while angiogenesis (the growth of new blood vessels) is a requirement for efficient wound healing and recovery of damaged tissue. The dysregulation of both inflammation and angiogenesis is a characteristic of tissue fibrosis. By assessing them individually, and in combination with clinically relevant metabolic changes such as high-fat

diet, we aim to build a comprehensive picture of how vascular changes can influence liver disease and the progression of tissue fibrosis

Most mice will experience moderate discomfort due to cumulative intervention such as gene depletion and inflammation or fibrosis in order for us to precisely investigate the role of vascular dysfunction. The generation of genetically altered fluorescently labelled mice through our breeding programme will refine our methodologies to allow non-invasive imaging and maximise the data obtained from each mouse.

Why can't you use animals that are less sentient?

This work will be carried out exclusively on mice due to the substantial existing data that describes the extensive similarity in inflammatory and fibrotic mechanisms with humans. There is also a wide and valuable array of genetically modified strains that are being constantly refined to improve the qualityand breadth of data that can used to translate finding to clinical care. Less sentient animals can provide important developmental data endothelial biology however cannot illuminate post-natal vascular response as creatures such as zebrafish and xenopus lack complex immune and fibrotic response restricted to mammals.

The use of mice also provided comparison with this large-scale basic and translational study and extensively studies tools (e.g drugs and antibodies) and pathologic mechanisms that have strong association with developing translational human studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures detail continued monitoring for all animals to ensure that animals requiring post- procedural care, pain management or improved environment stimulation will be addressed. The majority of work will routinely involve brief anaesthesia to minimise the distress associated with the initiation of each protocol. Clear criteria are set to assess animal welfare before and during all procedures for signs of discomfort, weight change and condition will be routinely monitored. The any appearance of these will lead to the animals being considered for early humane endpoints to ensure that no animals suffer unnecessarily.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We describe protocols that we have been at the forefront of developing within our research field. We will continue to review our methodologies with other experts within the fields of inflammation, fibrosis and endothelial biology while also seeking the advice and guidance of the animal care staff and veterinary support provided within the establishment. All procedures will follow best practice guidelines laid out by NC3R and LASA guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All methodologies will be continually reviewed through contemporary literature and by attending national and international conferences to ensure best practice. The applicant and all researchers who work within the protocols described will stay up to date with advances in 3Rs by engaging with expert staff within the establishment and also the wider community via the N3CR website.

85. Environmental adaptation in fish

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Natural selection, Evolution, Adaptation, Environmental change, Population genomics

Animal types	Life stages
Fish	adult, gravid, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To quantify adaptive variation and understand its genomic basis in a model fish species.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The natural world is changing rapidly and animals, including vertebrates, will have to move or adapt if they are to avoid extinction. It is critical to humanity that we understand these processes, both for basic, scientific reasons and to manage the consequences of environmental change. The genomic revolution, which has taken place in biology in the last two decades and which allows us to 'read' the 'letters' of an individual organism's genetic code, has massively increased our ability to understand how animals adapt to environmental variation and change. Studies like ours will have significant benefits for our understanding of the way all animals function, including humans.

What outputs do you think you will see at the end of this project?

This project will result in benefits of at least three kinds: publications, information and data.

Evolutionary biology is currently undergoing a revolution in our understanding of the genomic basis of phenotypic variation, as a result of developments in DNA sequencing technology. Simultaneously the Earth's environments are changing rapidly and organisms will have to adapt to these changes. Thus a knowledge of the adaptive potential of organisms is critical to our ability to predict and manage the consequences of environmental change. Hitherto research on the genomic basis of traits in wild organisms has focused on conspicuous morphological differences, but many of the traits required for adaptation to environmental change are physiological, and knowledge of these is in its infancy.

Characterisation of intraspecific variation in physiology is generally poor, and how this is determined genomically is hardly understood. Many important physiological traits have strong linkages to organismal energy usage. There is abundant variation between wild organisms in mitochondrial genetics, but the consequences of this for mitochondrial function are virtually unknown.

We hope to characterise within species variation in critical adaptive phenotypes in a wild vertebrate and to discern the genomic architecture of this variation. Specifically: (i) we will quantify gene expression variation that arises from being reared in salt- versus freshwater, and investigate the genomic loci that contribute to variation in salinity tolerance; (ii) we will quantify intraspecific variation in upper and lower critical temperatures in both wild-caught and lab-raised fish from across our species geographical range; (iii) we will investigate the consequences for e.g. growth and gene expression of rearing fish at different temperatures and assess whether nutritional supplementation can offset these; (iv) we will quantify intraspecific variation in swimming performance;
(v) we will use respirometry to quantify mitochondrial function in fish from different populations and environments. These discoveries will improve our fundamental understanding or organismal function and its genomic basis, especially in vertebrates.

Who or what will benefit from these outputs, and how?

We believe that our outputs will benefit anybody interested in adaptation to environment, and in predicting or managing the consequences of global environmental change, especially evolutionary and fish biologists, aquaculturalists and conservationists.

We will produce outputs of the following kinds:

Publications. We will continue to publish our results in high-quality, international journals, normally at the rate of at least one publication every year. This will begin as soon as results become available and continue throughout the project, likely continuing after the project is complete.

Information. We will disseminate our findings through talks and presentations to the public and scientific audiences on a regular basis: annually at national conferences and biennially at international meetings. This will begin as soon as results become available and continue throughout the project.

Data. All data gathered during this project will be made available on open-access, public databases. Data will be published alongside papers.

How will you look to maximise the outputs of this work?

We will collaborate widely, both within the UK and internationally. We have an established track record of publishing in high impact international journals and presenting our work at national and international conferences. We will continue to do so. We will teach British and international early career researchers, including students, as we have done previously.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our fish, are one of the best models for understanding the genomic basis of adaptation to environmental variation in wild vertebrates. The many novel insights into the genomic basis of adaptation already gained from their study have proven of broad relevance to other species, not least humans. Our fish have a small, well-annotated, high quality genome and well-characterised, genome-wide recombination rates. They are common, easy to catch and easy to rear in aquaria in the lab. They have well-characterised behaviour and occur across a broad array of environmental conditions, e.g. from salt to freshwater and from warm to cold climates. As fish they are the vertebrates with the lowest neurophysiological sensitivity. We are most interested in the phenotypes of fully-developed juvenile and adult fish, hence most work pertains to those life stages.

Typically, what will be done to an animal used in your project?

Typically fish will be exposed to environmental conditions that are within the normal range naturally encountered by the species. Examples include salinities equivalent to freshwater and seawater, elevated and reduced temperatures, high and low calorie diets, high and low current speeds and infection by naturally occurring parasites. In such procedures, exposure to less benign conditions would generally be for short periods (hours to days), but fish might also be reared in more benign conditions for weeks to months. Examples of less benign procedures include exposure to gradually higher or lower temperature, to measure critical temperatures, or to gradually increasing current speed to measure energetic capabilities. Fish may also be housed singly for periods of time from weeks to months.

What are the expected impacts and/or adverse effects for the animals during your project?

The most likely effects on the animals are reduced (or increased) growth rates, increased breathing rates and other chronic, low level stress. These could persist for the duration of experiments. In the case of more serious procedures (critical temperature measurement, energetic capabilities), fish may experience more stress, fatigue and positional disorders.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum expected severity is Moderate, but the proportion of fish experiencing Moderate severity is likely to be less than 25%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are explicitly interested in discovering the genomic variation that underlies the phenotypic variation that gives whole animals the ability to adapt to environmental change. Replacement does not apply easily where the animals themselves are the object of study. Nevertheless, within the lifetime of this project licence we may begin to explore cloning and cellular models for the basic characterisation of certain types of genomic variation. These are unlikely to replace the need to understand the whole organism context and consequences of such variation.

Which non-animal alternatives did you consider for use in this project?

In mammalian work, the first steps in characterising the consequences of some types of genetic variation (e.g. coding mutations) can be performed by cloning into appropriate cell lines and investigating relevant cellular phenotypes. We have recently been made aware that this approach might also be possible for preliminary physiological characterisation of genetic mutations in fish. This has been done in some commercial fish species for certain types of mutations, but relies on access to specialised skills and cell lines, and has not yet been done, to our knowledge, in our fish species. Nevertheless, we hope to begin to explore the possibilities within the lifetime of this project.

Why were they not suitable?

The possibility of these techniques requires substantial technological development, and remains speculative. They could not, in any case, replace whole organism phenotypic assays in attaining a complete understanding of environmental adaptation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we will use has been estimated as the sum of the animals that will be used in the formal experiments that we are likely to do over the course of the licence, plus a small allowance for pilot studies that allow formal experiments to be as efficient as possible. The number of animals used in each experiment has been estimated according to standard principles of experimental design and previous experience.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are an established research laboratory, with abundant experience in experimental design and statistical analysis. We are also open to receiving advice from others. We always choose to use methods that reduce the number of animals used, while still obtaining scientifically valid results.

These websites may be utilised to provide additional information on statistics and experimental design: The NC3Rs experimental design assistant https://eda.nc3rs.org.uk/; The 3Rs – Reduction.co.uk site at http://www.3rs-reduction.co.uk/

In order to ensure that high quality, reliable and valid data is produced from the minimum number of experiments, the ARRIVE guidelines (Kilkenny et al., 2010) will be followed when reporting the results obtained from this project.
http://www.nc3rs.org.uk/page.asp?id=1357

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use efficient breeding techniques including, for example, storage of sperm from males when relevant. Small pilot studies will be used when necessary to check experimental protocols and to get an indication of likely results, especially in situations where experimental designs are novel in some way.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Fish are the vertebrates with the lowest neurophysiological sensitivity. The evolutionary response of vertebrates to environmental variations are likely to be qualitatively different from invertebrates because vertebrates possess more sophisticated physiological systems. Humans are also more interested in and attach greater significance to an understanding of vertebrates, partly because of their closer relatedness to us, and partly because we often have a greater interest in the management of their populations.

Fish are the most appropriate species for our work because: (i) they are tractable for fieldwork and common. (ii) They are straightforward to keep and rear in the lab. (iii) Their

population structure facilitates the evolution of local adaptations (iv) They have a fully sequenced and annotated, small genome and outstanding genetic resources. This is highly unusual for a ‘non-model’ organism, but central to much of our research.

In general our project involves exposing fish to either chronic or acute environmental stress (e.g. variation in temperature, salinity, current speed and nutrition). An important refinement is that these stresses will not exceed those normally experienced by the species in its natural habitats. Following exposure animals will be euthanised or returned to optimal conditions facilitating rapid recovery.

Why can’t you use animals that are less sentient?

Our research explicitly investigates the ability of mature animals to deal with environmental variations, and employs assays that require conscious whole organisms, to measure e.g. long-term growth rates or short-term swimming speeds.

It is possible to investigate the fundamentals of adaptation to environmental variation e.g. in insects such as Drosophila that occupy broad environmental niches and have good genomic resources, but extrapolating this to an understanding of adaptation in fish populations of commercial or conservation interest would be difficult.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We use a number of specific refinements in our work in commonly used protocol steps. Marking methods (all protocols): we usually mark individuals using elastomer dye, which is a refinement over fin or spine clipping. It is less stressful to the fish (involving only insertion of a hypodermic needle, and therefore is at the lower threshold), and allows more reliable identification over longer time periods. We always use the finest possible needles (e.g. 30G) for such marking. We are always alert to the development of more sophisticated marking methods. For example, in recent years a number of micro tags (including RFID ‘PIT’ tags) have been developed for small fish, and are now suitable for fish as small as fish. We will consider some of these methods during the lifetime of this project. Any marking methods (including those involving needle insertion) will be practised on dead fish, by anyone without recent experience.

For phenotypic assays (e.g. estimation of critical temperatures and maximum/sustained swimming speeds) we will follow published guidance of best practice. For example, for temperature tolerance estimation we will employ critical thermal methodology, which is a refinement over incipient lethal temperature estimation since the latter involves lethal endpoints and the former does not. In tests of swimming speed, we will test fish in small groups and we will train them first with e.g. slower increments in water speed than used in standard tests.

During normal husbandry, fish will be provided with appropriate environmental enrichment, for example pieces of pipe, where this does not compromise the need to maintain water quality, remembering that many fish naturally occur in water bodies that are often devoid of significant structure although it is also recognised that fish will take advantage of hiding places when alarmed.

Aquarium rooms have artificial lighting with appropriate photoperiod. The temperature of inside aquaria will be maintained between 4 ^{o}C and 20 ^{o}C (depending on season) which substantial experience in other labs has shown to be comfortable for our fish.

Fish caught in the wild will not be housed in tanks with laboratory reared fish, in order to avoid cross infection. Fish will be fed daily on a diet consisting primarily of commercially supplied fresh or frozen invertebrates or appropriately constituted flake. Handling will be minimised, but where necessary fish will be handled mainly using aquarist soft nets. Nets will be chemically sterilised (iodine) between use in different aquaria. Where appropriate fish will be anaesthised after capture, before handling. Abrupt changes of water temperature, pH or oxygen concentration will be avoided.

Water quality is the most important factor in maintaining the well-being of fish and good filtration is the most important tool in maintaining water quality in aquaria. All aquaria have individual, high quality external power filtration systems (except tanks containing fry, where this would be inappropriate).

Power filters ensure good mechanical and biological filtration. Fish are maintained at long-term densities generally not exceeding 30 adult fish per 100 litres. Substantial experience in our lab has shown that these densities allow maintenance of fish health and good growth rates over long periods (months). Ammonia, nitrite and nitrate levels will be appropriately monitored with test kits or meters. Chlorine and chloramine will be removed from water or neutralised before it is used in aquaria. Appropriate amounts of common salt and Sodium thiosulphate will be added to aquaria when they are first established to ensure water quality suitable for fish.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In recent years there has been a surge of new guidance for scientific experiments involving fishes. We will follow general NORECOPA, American Fisheries Society and other guidance (for example the PREPARE guidelines, Smith et al. 2018, guidelines for severity reporting, Hawkins et al 2011, 'Guidelines for the Use of Fishes in Research', Jenkins et al 2014, and ethical considerations, Sloman et al. 2018). We will also continue to follow recommendations in technical publications for best practice in particular procedures. We will develop a monitoring form to facilitate consistent assessment of fish when they are exposed to extreme environments, including signs and behaviours that should be used as endpoints.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading relevant papers as they are published, consulting the 3Rs website and attending relevant training courses and workshops (e.g. run by the RSPCA). We will keep in touch with developments in alternatives to in vivo experiments (e.g. Schaeck et al 2013) and with societal considerations about the use of fishes in research (e.g. Message & Greenhough 2019).

86. Dna double-strand break repair, immunity & cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

DNA double stranded break repair, Genome Stability, Immune System, Cancer

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Primary aims of this project are: (1) to develop a mechanistic understanding of the DNA repair machinery that is typically used by mammalian immune systems to generate different classes of antibody; (2) to better understand the pathological role this same machinery plays in cancer development, and (3) to define its function during cellular responses to important classes of anti-cancer drug.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

DNA repair defects in humans can in some cases lead to immune system failure and in other cases an increased susceptibility to develop cancer. This project builds on our previous results that demonstrated that the same DNA repair mechanism that is used to

generate genetic diversity in the cells of our immune system (lymphocytes) is additionally responsible for generating the chromosomal damage and mutations that triggers tumourigenesis in common hereditary breast and ovarian cancer. To date, the cellular mechanisms and DNA repair proteins involved in immune responses and cancer development remain poorly understood, and our research aims to address this unmet need and help scientists and clinicians understand the links between normal immune function and cancer.

What outputs do you think you will see at the end of this project?

The proposed work tackles basic biological questions that are relevant for a number of research fields. This work will define the inner working and principal components of DNA repair pathways that are essential for genetic diversity in immune repertoire, while also describing a molecular process that drives the genomic instability that triggers malignant transformation in the most common forms of hereditary breast cancer. Thus the benefit of this work to the research community will be two-fold: firstly, it will provide new insight into normal immune function, aiding the understanding of human immunodeficiency disorders; secondly, it will reveal the molecular basis of common human cancers, also yielding insight into potential mechanisms of drug resistance that face modern anticancer treatment regimes being used in the clinic. The new insights obtained from this work will also be documented in publications to advance the research field.

Who or what will benefit from these outputs, and how?

This work will benefit patients and the health service. Breast cancer is by far the most common cancer among women in the UK (2010), accounting for 31% of all new cases of cancer in females. It affects over 55,000 people/year in the UK and is responsible for more than 11,500 deaths/year. Commercial beneficiaries such as the pharmaceutical industry may also benefit.

How will you look to maximise the outputs of this work?

We will disseminate our knowledge through scientific publications, and by presenting the data at conferences. We will look to maximize the outputs through collaboration with experts in related and applicable areas. If we find a protein target with therapeutic value we will engage with institute-specific technology transfer department/s and/or the pharmaceutical industry.

Species and numbers of animals expected to be used

- Mice: 18 000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The laboratory mouse is the species of choice for studying immunology, organism level mechanisms of cancer prevention and deriving primary tissues, and the ideal mammal for genetic studies where animals need to be generated rapidly. Using mice provides us with an opportunity to study the role of genes during immune responses, tumour prevention and/or predisposition, and examine their role in genome regulation in well-defined primary tissues, which is not possible in higher organisms. The similarity of human and murine immune systems is reflected in homology at a genetic and protein level, making mice a good model for understanding the equivalent biological processes in humans. For example, one protein we seek to study, REV7 is highly conserved between man and mouse, sharing 98.5% sequence identity.

We make use of adult mice in our experiments due to their developed immune systems. In our development, ageing and cancer predisposition investigations, we will study phenotypes in experimental cohorts of juvenile, adult and aged adult mice, depending on when phenotypes present.

Typically, what will be done to an animal used in your project?

Mice will be bred to produce animals that have genetic mutations that are linked to homologous recombination and non-homologous end joining, or in genes involved in DNA damage signalling responses. These mice will be culled to harvest tissue and obtain primary cells for ex vivo experiments. Some mice will be given immunization challenges which will typically be done by a single injection.

Blood samples will be taken at regular intervals before the mice are humanely killed.

Some of the above mice will possess genetic alterations that are predicted to lead to the development of solid tumours. We will age these mice to monitor for the occurrence of cancers.

What are the expected impacts and/or adverse effects for the animals during your project?

Our breeding programme does not expect to have any impact on the animals.

Our immunization challenges are expected to have minimal adverse effect on the animals due to our use of only well-established foreign antigens and weak adjuvants.

We are breeding and aging some mice that may age prematurely or show predisposition for developing cancer. The main adverse effects will be the occurrence of solid and internal tumours, or a general loss of condition. In both cases, suffering will be limited by humanely killing the animals when appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

75% mild, 25% moderate.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune response involves multiple, complex systems interacting in a physiological environment, which cannot be replicated in tissue culture, and so there is no adequate alternative but to employ animals in these studies.

In this project, the majority of experiments will be performed using primary cell isolates following purification from the primary tissues of experimental mice. Such experiments will therefore replace the use of live animals in experiments.

Which non-animal alternatives did you consider for use in this project?

Transformed cell lines. Cell culture systems will replace animal tissue in our experiments to characterize the biochemical effects of mutations.

Why were they not suitable?

Transformed cell lines do not accurately recapitulate the properties of primary immune cells in vivo or those harvested from tissues and cultured ex vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We conducted similar experiments on our past project license enabling us to accurately estimate the number of animals we need to use. In conjunction, we have used literature searches, and conversations with collaborators to estimate the number of animals we will use.

We have also used statistics to ensure that we use the minimum number of animals to obtain scientifically meaningful data. Data in the form of various quantitative parameters are assessed by simple statistics or by ANOVA to allow for variable numbers of controls and mice of different age and sex. We are not normally in pursuit of low penetrance phenotypes and therefore do not normally need to examine large numbers of animals.

In breeding experiments, genetic crosses will be carefully designed to obtain the maximum number of useful animals with the minimize wastage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our lab has experience conducting similar experiments on our previous project license which has enabled us to carefully design experiments to reduce the number of animals being used. Experimental procedures are reviewed within our group, and where necessary, consultation on statistics will be sought from our establishment’s genetic statistics service to minimize any factors which could lead to too much spread and a need for more animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To ensure we produce the minimum number of animals to reach our experimental aims, good colony management rules are applied to our colonies using data gathered from a mouse tracking database that is available. We have also previously conducted experiment's with a similar design enabling us to accurately estimate the number of animals we need to answer our research question. Where possible the data from each individual animal will be maximized through the use of tissue for several different experimental aims. E.g. the bone marrow, spleen, and terminal blood samples will typically be collected simultaneously from experimental animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The laboratory mouse is the species of choice for studying immunology, organism level mechanisms of cancer prevention and deriving primary tissues, and the ideal mammal for genetic studies where animals need to be generated rapidly.

Our immunisation method only uses well-established foreign antigens and weak adjuvants, and as a consequence is expected to have mild adverse effects. A single injection and blood sampling is also the most refined and least invasive method for obtaining samples from the mice.

In strains predisposed to developing tumours, a maximum tumour burden limit will ensure that tumours grow sufficiently to obtain scientifically important information, yet not enough to cause distress or suffering. Tailored monitoring regimens in ageing mice will ensure indicators of adverse effects are recognised early to minimise animal suffering.

Why can’t you use animals that are less sentient?

Using mice provides us with an opportunity to study the role of genes during immune responses, tumour prevention and/or predisposition, and examine their role in genome regulation in well-defined primary tissues, which is not possible in higher or less sentient organisms. The similarity of human and murine immune systems is reflected in homology at a genetic and protein level, making mice a good model for understanding the equivalent biological processes in humans. For example, one protein we seek to study, Rev7 is highly conserved between man and mouse, sharing 98.5% sequence identity.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During the immunisation blood sampling regimen, care will be taken to ensure that the animal has stopped bleeding before being placed back in the cage. The mice will be monitored daily for 5 days following immunisation to ensure any adverse reaction is rapidly detected and the mouse killed immediately.

In the case of the aging, development and cancer pre-disposition study, mice will be monitored up to three days a week to ensure early detection of weight loss, loss of condition and/or tumour development. In this way, we will ensure that all humane endpoints are adhered to.

The risk of adverse phenotypes in transgenic mouse strains will also be reduced through use of conditional-knockout alleles in strains harbouring secondary alleles to direct tissue specific Cre- expression. By enabling tissue-specific gene inactivation, such as our proposed use of the Mb1-cre strain to conditionally inactivate DNA repair genes such as Rev7 in early B-cell precursor cells, we will minimize the potential of harmful phenotypes that might occur as a result of gene inactivation in other tissues.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the best practice guidance published by the NC3Rs, LASA and ARRIVE.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will periodically check whether new guidance's have been published by the NC3Rs or ASPA, and attend any meetings held on the 3R's that take place at our establishment.

Useful websites include: www.nc3rs.org.uk https://science.rspca.org.uk

87. Mechanism of action of vaccines and adjuvants

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Vaccines, Adjuvants, Innate immunity, Adaptive immunity

Animal types	Life stages
Mice	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To improve the design and formulation of new vaccines and vaccine adjuvants through the understanding of their immune mechanisms of action.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines are the most valuable tool against infectious diseases as demonstrated in the most recent pandemic. However, we do not yet have sufficiently effective vaccines against many complex diseases, including malaria. The proposed work will increase our knowledge of how vaccines and adjuvants work. This improved understanding will help inform further development of new formulations to achieve good safety and efficacy.

What outputs do you think you will see at the end of this project?

We anticipate to gain new mechanistic information on vaccines and adjuvants stimulate the immune system. We will publish these findings in peer reviewed scientific journals, and disseminate at scientific conferences.

Who or what will benefit from these outputs, and how?

Vaccine and adjuvant developers in the UK and worldwide will benefit from the knowledge on how different formulations affect the immune response in an animal model of vaccination.

This work uses malaria infection in mice as a model system for evaluating the adjuvant immunogenicity and contribution to improved efficacy. Results obtained will therefore also contribute to the malaria vaccine development efforts within the UK and internationally.

Longer term, this work could lead to the development of new vaccines for complex diseases which would benefit people globally..

How will you look to maximise the outputs of this work?

We have ongoing collaborations within the UK, Europe and the USA through which we exchange and broaden our findings.

In addition to publishing all our results in open source scientific journals, the data will be shared within our scientific networks and presented at scientific meetings and workshops nationally and internationally.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are a well established, cost- and time- effective model for studying vaccines. Mice and humans have a high genetic and physiological similarity, which allows to predict the mechanism of vaccines and adjuvants in humans using this pre-clinical model. The large amount of available data/literature allows more efficient approaches and a reduction in animal numbers. We will primarily use adult mice to establish vaccine immunogenicity, and study mode of action. Some of the work will also explore the longevity of the immune response and vaccine efficacy in aged or juvenile mice.

Typically, what will be done to an animal used in your project?

Novel vaccine formulations will be administered to mice in regimens equivalent to the human routes and dosing. Typically, mice will receive 2-3 immunisations around 2-4 weeks apart. Blood samples will be taken at regular intervals to assess cellular and humoral immune response to the vaccination. In some experiments, vaccinated and unvaccinated mice will be given a malaria challenge to assess the efficacy of the vaccine formulations against disease onset.

What are the expected impacts and/or adverse effects for the animals during your project?

In the majority of the studies the expected adverse effects (e.g. pain) will be mild and transient (maximum 48h post immunisation).

In malaria challenge experiments the severity in some mice will reach moderate. All challenged mice will be screened using blood smears for development of parasitaemia and will be killed before or at the onset of any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild 60%
- Moderate 40%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Vaccines function at a systemic (body) level. Animal models are the only option to study vaccine immunogenicity and efficacy and mechanistic effects within a whole body system.

Which non-animal alternatives did you consider for use in this project?

There are no non-animal alternatives for systemic studies of vaccine efficacy.

For the studies of vaccine and adjuvant mode of action, we will take a combined approach of using animal models in combination with different in vitro approaches.

We have a parallel project that uses human lymph node tissue which is an approach that can partially replace the use of animals.

Why were they not suitable?

Only answers to very specific mechanistic questions would be possible using experiments on cell lines.

The ex vivo derived human lymph nodes are difficult to obtain and would give limited amount of information on the vaccine and adjuvant mode of action.

The systemic effects of vaccination would remain unaddressed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each experiment will comprise the minimum number of groups necessary, with each experimental and control group containing the minimum number of animals needed to reach reliable conclusions. We have extensive (over 10 years) past experience with this type of experiments. There are also many published studies which use similar numbers of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use online tools such as the Experimental Design Assistant developed by the NC3R to help design robust experiments that can provide more reliable and reproducible results. Each experiment will be based on a power calculation to ensure the correct numbers of animals are used. This will ensure the use of a minimum number of animals consistent with the scientific objectives and reduce subjective bias (randomisation, blinding).

We will also use appropriate statistical analysis methods and consult statisticians and bioinformaticians in the experimental design and analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will perform pilot studies to inform and guide subsequent experiments addressing more focused questions.

We routinely maximise the use of tissue (e.g. multiple analyses from the same sample of blood or tissue, harvesting multiple tissues post-mortem).

We also have a parallel project that will employ human ex vivo lymph nodes to study response to adjuvants in human tissue and reduce animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most of the work will be done on inbred mice which will be vaccinated using common standard clinical immunisation routes. The majority of immunisations will be given intramuscularly as the clinically most relevant route in order to facilitate future translation of this work to the clinic. Intramuscular injection will be done under short anaesthesia, which is the least painful way to apply a vaccine via this clinical route.

For the assessment of vaccine efficacy, we will use a well-established model of pre-erythrocytic malaria challenge. Some mice might experience a moderate severity although animals will be killed before developing the disease. Killing the mice after evidence of malaria infection in the blood (parasitaemia) but before onset of disease reduces suffering and distress to the minimum that is required to assess malaria vaccine efficacy.

Some imaging work will be also be done on anaesthetised animals.

Why can't you use animals that are less sentient?

Adult mice are the least sentient model animals (small mammals) for investigating the general mechanisms of vaccine activity. Some of the work will be investigating the longevity of the immune response and will require maintenance of animals into older age.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be closely monitored for 10-15 minutes following immunisation and blood sampling procedures. Following anaesthesia, animals will be observed until their return to full alertness and normal behaviour.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines on improving Bioscience Research Reporting.

We continuously review the literature for the newest relevant research which will inform our studies. The local NVS and NACWO are available to advise in case of a new experimental design as well as our Named Information Officer. In addition, we follow updates from the following sites:

www.nc3rs.org.uk https://norecopa.no https://www.lasa.co.uk

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have a NC3R’s regional manager available for advice and discussion and attend internal 3Rs meetings.

We also regularly follow the news and updates from NC3Rs and RSPCA and keep our experimental design under regular review for potential improvements in order to increase compliance with the 3Rs. Another useful resource is Norway's National Consensus Platform for the advancement of the 3Rs, http://norecopa.no/

In addition, we continue to look for alternative methods to study vaccines and adjuvants such as human ex vivo models (e.g. secondary lymphoid tissue, fine needle aspirates) and will also consider using cell lines and in vitro systems for more specific/focused questions.

88. Impact of drugs and environment on the brain through the lifespan

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

drug addiction, early life stress, genetics, neurodegeneration, development

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this program of work is to understand how genes and the environment interact to affect mental health and brain illness through the lifespan, from early development to old age.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neuropsychiatric, neurodevelopmental and neurodegenerative disorders are widespread, and directly or indirectly impact the lives of nearly all of us. Despite this, most treatments are palliative at best, and in many cases, completely ineffective. It is therefore one of the most critical challenges facing scientists to understand the biology of brain conditions that affect us throughout the lifespan, in order that in the future we are better equipped to treat or even cure them. This project licence will build on work carried out under our previous licence to help to better understand the biology of neuropsychiatric, neurodevelopmental and neurodegenerative disorders.

What outputs do you think you will see at the end of this project?

•This work is expected to provide new information about the biology underlying brain conditions throughout the lifespan, and how this is impacted by genetics and environmental challenge.

•The primary expected benefit is the publication of new scientific knowledge about how behaviours, and particular brain regions and neurotransmitter systems, are affected by the environment in at-risk individuals.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will add to the knowledge base about the biology of neuropsychiatric, neurodevelopmental and neurodegenerative disorders. We will also promote and publish any refinements or best practice we identify during this project, thus aiming to improve animal experience and welfare. For example, refinements that we make in our behavioural protocols will be shared, free of charge, to collaborators or interested parties. We have done this in the past, sharing code for our highly refined (non-invasive) working memory test to labs across the world.

In the medium term the pharmaceutical industry will be interested in potential novel therapeutic targets we identify. In addition, in the medium term, we will pass on findings to clinical colleagues, and carry out experiments that aim to translate our findings. For example, as part of a previous project licence, we found that impulsive fish showed greater stress reactivity. That led to an additional grant to my group to work with human participants, examining links between stress and addiction, and recently a grant to work with alcohol-addicted patients and our work on the NIHR research portfolio. We continue to explore this in fish (see Objective 2 and Protocol 2) and will continue to work back and forth with clinical colleagues.

The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of neuropsychiatric, neurodevelopmental and neurodegenerative disorders, both in humans, benefitting patients and clinicians by

contributing to the development of effective medications or other therapies, which will ultimately reduce the economic and health burden caused by lifelong neurological conditions.

How will you look to maximise the outputs of this work?

We have several collaborations, both within and outside the UK. These collaborations help us employ a more interdisciplinary approach to our work, and ultimately to publish our work in leading journals. I regularly appear in the media to discuss my research, and present to schools (as part of our outreach programme). This has included demonstrations of zebrafish as a research model to schools, for example. All of our work is published open access. We also release all our data on the open science framework (osf.org) for others to use freely and without limits.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 7700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use zebrafish at all ages, for our research. Zebrafish offer a unique opportunity as a research species, as they are a vertebrate that is genetically similar to mammals, and at the same time offer the offer the potential to keep in relatively species typical conditions (ie in groups, allowing social behaviour). Zebrafish have a fully sequenced, functionally annotated genome, and are extremely robust to mutations. This, in combination with their high fecundity rate (each female can produce ~200 eggs/week), makes them ideal for many questions in neuroscience and biology. Zebrafish become protected (under ASPA) at 5 days-post fertilization (dpf). Many protocols that we use in my group relate to adult behavioural protocols, but we actively work on the development of protocols for younger animals, and even for non-protected (<5dpf) - for example, we have published several studies using 5dpf larvae, and ontogeny studies examining the potential for using younger animals in our protocols.

Our aim is to understand disorders in humans that occur across the lifespan, so we use fish from birth right through to old age (24 months+).

Typically, what will be done to an animal used in your project?

The majority of fish we use are genetically altered, but carry mutations that are not harmful. A typical fish will be exposed to drugs at concentrations relevant to humans during various life stages, to examine the effects on their behaviour (eg learning/memory,

response to novelty, or anxiety caused by a new environment), or on alterations in their neurological responses. Some fish will be grown into old age.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the fish we use will not exhibit adverse effects as a result of any of procedures, or their genetic alterations. Some fish (<1 %) will experience mild behavioural effects such as increased respiration and agitation as a result of the drugs used.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All of the protocols that we carry out are mild. Approx 50% of our animals are exposed to mild protocols, and 50% exclusively to sub-threshold procedures.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to determine whether life experiences, such as stress or exposure to drugs, alter the coordinated functioning of specific brain areas, resulting in changes in the behaviour of the animal.

The research questions necessitate the use of animals since the influence of stress on the anatomy, physiology and neurochemistry of different parts of the brain and on behaviour can only be elucidated by studying the intact animal itself. To investigate the changes that occur in brain function due to stressors or drugs, it is necessary to expose animals to such conditions and then determine the consequent effects on the brain itself.

Which non-animal alternatives did you consider for use in this project?

We use humans to understand links between genotype, 'risk-taking' personality, acute stress and alcohol use/misuse. This work stems from our work with larval/adult zebrafish carried out on a previous project licence and looks for risk factors for alcohol use and misuse.

Why were they not suitable?

Despite the examples of protocols that can use humans as replacements for adult zebrafish, they are associated with several limitations. Using human participants limits the ability for us to develop detailed understanding of the causal factors relating to the biology of neuropsychiatric, neurodevelopemental and neurodegenerative disorders.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on pilot studies and our published data. We have extensive experience in using these models and can therefore accurately estimate the number of animals we will need per group to obtain statistically valid results. As we generate more results, we will continually assess group sizes to see whether the number of animals can be further reduced from those currently proposed. We will also use the latest statistical methods for data analysis to reduce sample size.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All our experiments are designed and reported using the ARRIVE guidelines, and with reference to published guidelines (eg Masca et al., 2015; DOI:10.7554/eLife.05519).

1) All our experiments use full randomization and blinding in order to reduce problems with reproducibility in biomedical research. Specifically, animals are allocated at random to all interventions by picking animals at random from several 'batches' (eg tanks of fish nested in clutches of animals) for each experiment. Randomisation is achieved by creating an excel spreadsheet with random numbers, and choosing the tanks in the order they appear. All experimenters and technical staff are blinded to treatment allocation as far as is possible, eg by giving tanks and subsequently individual fish, ID numbers which are noted elsewhere in spreadsheets and not revealed until data analysis stage.

2) We control for possible confounders (e.g., testing tanks) and randomly allocate these as testing units.

3) We account for tank effects in our statistical analysis (ie by adding as a random effect when necessary)

4) Sample sizes are calculated based on a pilot experiment to determine effect sizes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to optimise the numbers of fish that we use for our experiments, we refer to previous experiments to determine effect sizes. For any novel protocols that we are developing, or for drugs that we will use, we carry out pilot studies to determine the expected effect size. In addition, all our behavioural work is fully automated which decreases variability and allows us to be confident in our approaches. Finally, we use environmental enrichment (plants and substrate in the tank) which has been shown to reduce stress, both in our own work and in the work of others. Stress can increase variability in experiments, thus increasing the numbers of animals required (Garner, 2014, ILAR J; Voelkl et al., 2020, Nat Rev Neuro). In order to reduce required numbers of animals, we are very careful to ensure that the animals do not experience stress during their husbandry, using evidence based enrichment and handling methods.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Of all the animal models used in neuropsychiatric research, zebrafish provide a good balance between similarity to humans and limited suffering. For example, females produce many hundreds of eggs per week, which can be extracted in a completely non-invasive manner (unlike, for example, Xenopus).

Zebrafish share genome organisation closely with humans, making them excellent models for genetic research. In addition, and relevant to our work, they share all the major neurotransmitter systems.

Finally, zebrafish show complex and well-characterised behavioural responses.

Why can't you use animals that are less sentient?

It is critical to use vertebrates with a well developed central nervous system (CNS) for neuropsychiatric research. Although we use less sentient animals (zebrafish embryos <5 days post fertilization) for some of our protocols, we cannot use these animals for more complex behavioural testing.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We refine our procedures regularly, including (where possible) replacing invasive with non-invasive protocols. When we carry out any invasive protocols (eg stress-induction, minor surgical procedures) we closely monitor the animals after the procedures, and are eliminating surgery-with-recovery from procedures whenever possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We closely follow the PREPARE guidelines from the NC3Rs (UK), but also the RSPCA and LASA guidelines for animal care.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As well as being members of The International Zebrafish Neuroscience Research Consortium (ZNRC), we receive updates from the NC3Rs (UK) and from our wide network of collaborators across the world. As an example of this, we recently learnt about a less invasive method of genotyping (ID) the genetically altered zebrafish via an NC3Rs publication. We are now working with our technical team to implement the new method. Finally, we have recently purchased a non-invasive larval genotyping machine in order to avoid handling and contacting fish at all during early development.

89. Role of protein degradation in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health orabnormality, or their effects, in man, animals or plants

Key words

Immunity, Ubiquitination, Protein degradation, Infection, Disease

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Proteins are a principle etiological agent of disease. We seek to understand how mechanisms that recycle and degrade proteins prevent or cause disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By understanding protein recycling and degradation machinery we hope to find ways to inhibit, augment or duplicate these process to treat disease.

What outputs do you think you will see at the end of this project?

The main output of our work will be the dissemination of our novel findings into how protein degradation contributes to disease, its resolution and prevention. This will be in the form of peer-reviewed publications, presentations at scientific meetings and public engagement through the use of press- releases and interaction with mainstream media. Large datasets that we generate will be deposited in publicly available databases, such as PRIDE the PRoteomics IDEntifications database at EMBL-EBI. Any materials or reagents that are generated during the work (for instance, mouse strains, cell lines, antiserum) will be made freely available to researchers upon requested or deposited with central vendors such as the ATCC (American Tissue Culture Collection).

Who or what will benefit from these outputs, and how?

The data we generate during our project will be made available to researchers. Thus those that benefit from these outputs will be anyone with an interest in biomedicine. Specifically, this could include those working, both in terms of research or clinically, on diseases caused by protein deposition and/or misfolding (such as tauopathies) or infections (such as viruses) or metabolic disorders caused by misfunctioning recycling pathways (such as atherosclerosis). This will provide immediate benefit (short term) and continue to impact research and development (long term). A specific longer-term and direct benefit of our outputs we hope will be knowledge that guides the development of new treatments or interventions. We will seek to contribute to this aim directly by testing molecules that have direct effect on disease; either through prevention or treatment. So another way that our outputs may have a benefit is in the development of new therapeutics.

How will you look to maximise the outputs of this work?

We will maximise the outputs of our work by seeking to publish in as high impact journals as we can, to do so frequently and to include as much data as possible. We will also actively seek to distribute our materials and know-how to other research groups, to accelerate others work. We have multiple established collaborations both within the UK and internationally and will use these to both facilitated our work and to disseminate both our successful and unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 47,250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using mice because they are the model mammalian organisms about which most is known. This is at multiple levels. In terms of biology, we know in most detail in

mice where their biological process are similar, and where the diverge, from us. We have the most experience with mice as a model organism in terms of husbandry and in terms of clinical signs when they are experiencing discomfort so that we can plan suitable and humane end points. Specifically for our research aims, we know that mice conserve the main protein recycling and degradation pathways that exist in humans and so are an excellent model specifically for our area of biology. We have experience working with mice and have been using them as a model for many years in our research.

Typically, what will be done to an animal used in your project?

Typically in our work we will be investigating how mice respond to disease. This disease may be induced by challenging the animals with an infectious agent (eg a virus) or a trigger (eg a prion or prion- like agent) or by inducing a physiological change by activating the expression or loss of a protein in specific tissues or throughout the animal or by delivering compounds or agents that induce or reduce disease. The introduction of these agents may be through injections into tissues or the bloodstream or into the airway. Our experiments are most often short-term, as they involve following the resolution of an acute infection (1-3 weeks). However, other experiments can be longer (1-3 months) in the case of neurodegeneration. The number of procedures are usually limited as we are seeking to understand the effect of a single variable.

What are the expected impacts and/or adverse effects for the animals during your project?

Our experiments involve the study of disease. By definition, this means that normal biological function is compromised. The precise loss of function, and hence adverse effects, are to some degree dependent on the nature of the disease. However, there are common impacts that we use to monitor the animals to ensure their wellbeing and to collect data on the impact of disease. These include weight loss, reduced movement and piloerection. For pathogen-induced disease we expect the duration of these effects to be short (ie < 2 weeks) and to be coincident with the resolution of the disease by the immune system. In some experiments we may use a short-term sub-cutaneous xenograft to report on immune activity but this is not expected to have adverse effects. In the case of more chronic diseases, such as neurodegeneration, the effects may be for longer but in this case we utilise a scoring system to ensure that they do not exceed specific levels.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Our research investigates the adverse effects of disease and how this can be treated. By its very nature, most animals in our experiments will experience an adverse impact. The severity of this impact depends on the specific etiological agent. For some viruses, we expect a substantial weight loss that is defined as being a severe impact. In this case we

monitor closely and, using our experience of these experiments, set limits on how long this weight loss should proceed before the animals begin to regain weight. Importantly, it is the likelihood of recovery and duration of adverse effects that we use to determine end-point as well as severity. Overall our experiments cover a range of mild to moderate severities and a wide range of proportion of animals that will reach this end-point (from 1-50%), depending on the disease in question.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The biological processes we study are multi-organ systems, meaning that they cannot be investigated either in mono-cultured cells in vitro or even using organoids. A key aspect of our work is the immune response, which requires movement of cells, antigens and pathogens between different compartments of the body. For instance, we are looking at the T and B cell response to viruses like influenza.

Influenza infects the lung but antigen presentation that leads to activation and proliferation of T cells and antibodies takes place in the spleen and peripheral lymph nodes. Context is important and the manner in which material is trafficked is crucial. Chemotactic gradients are established that are used to recruit immune cells to specific sites of infection whilst antigen enters the lymphatic system and drains through subcapsular macrophages before being presented to B cells. These processes are both multi- component and inter-related and require a level of organisational structure that is currently not possible to achieve outside a living animal.

Which non-animal alternatives did you consider for use in this project?

In vitro cultured cells and organoid models are alternatives we considered. Indeed experiments in these systems are used to complement our work in animals. Where processes can be investigated on a cell autonomous level, we study protein degradation during infection and disease within individual cells.

Why were they not suitable?

We cannot recapitulate the resolution of organ specific disease by combined degradation processes that take place in multiple distributed organs. For instance, how the activation of

T cells in the spleen by antigens that are produced in infected lung cells is impacted by protein degradation and presentation of dendritic cells in spleens and peripheral lymph nodes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies.

Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals to be used by calculating the smallest possible group size that will give statistically significant data and the number of mice needed for breeding to provide these. The information we require to make such an estimate is two-fold. First, I have held two previous PPLs and have experience in many of the experiments described in this application. We have data on the magnitude of phenotypic responses and the variation between individuals, thus when examining how parameters effect these processes we know how many animals we need to get meaningful results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have a decade of experience with many of the experiments we are performing and where we have less we draw on the published information from others. We use this experience and knowledge when designing our experiments. The key goal is to use the minimum number of animals to obtain a statistically significant answer to our research questions. This is based on accurate measurement of phenotypic magnitude and variation both experimental and biological. One way to reduce numbers is to reduce variability in the data. We do this by ensuring that all those conducting experiments are highly trained in the specific techniques to be used and undergo regularly re-training and assessment. We compare variability between researchers, mouse strains, dose volumes/concentrations, mouse age and sex and all possible variables in our experiments. Where we see a factor is substantially contributing to variation we re-design experiments accordingly. For instance, by changing route of administration of a pathogen.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We adopt a breeding strategy in which we breed animals specifically for experiments. This allows us to reduce the number of animals being bred. We combine experiments where possible so that one control group can serve as the control for multiple parameters being

tested. We take multiple tissues so that we can collect as much data on as many variables as possible within one experiment. For instance, we can monitor B and T cell responses from one experiment rather than setting up two.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our experiments are principally aimed at the study of disease, in most cases as induced by a pathogenic agent such as a virus. The models we use are therefore dictated by the type of infection we are studying. For instance, when we study influenza infection, we use an influenza virus. When we are studying the contribution of a specific aspect of immunity to the resolution of disease, we may use an animal strain in which a specific gene has been genetically deleted. The methods we use in our experiments do not, in of themselves, cause significant pain or suffering as they encompass the introduction of agents through injection or inhalation. The agents themselves, such as viruses, and the immune response they provoke (in the case of immunopathology) are what potentially cause pain and harm. The disease processes we study are those that cause harm and so we cannot avoid this. We do however take steps to minimise this by studying as mild a form of the disease as we can. We also typically undertake short-term experiments so that suffering is minimised. We provide extra husbandry to animals in experiments, such additional food or water or enrichment, to mitigate suffering. We continuously monitor the animals to ensure that the disease is falling within expected parameters and cull animals that exceed these parameters.

Why can't you use animals that are less sentient?

We study mammalian disease and mammalian immune responses, therefore we have to use mammals. Some of the diseases we study only take place in adult animals. For infection studies, we are interested in the responses in individuals with a mature immune system and in weaned animals that no longer benefit from passively transferred maternal antibodies (from in utero or from milk). Age is a parameter in many diseases and infections. Therefore to keep our data internally consistent and in-line with that produced by researchers around the world we use a specific age range of young adults. The exception being in certain neurodegeneration experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are always seeking additional measures of disease and the harm it induces and employ both quantitative and qualitative assessments of this. We seek to minimise the number of procedures, eg dosing, required to induce or treat disease. We follow the latest research to determine if new methods, strains or detection systems can be employed to reduce the time of each experiment, the number of mice and the severity of the disease itself (for instance whether a new more sensitive measure can be employed to allow a milder form of the disease to be studied).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We make use of the NC3R website to ensure we use the most refined experiments. We follow current guidance and check the NC3R website to ensure that this is up to date. We refer to ARRIVE (https://arriveguidelines.org) and PREPARE (PREPARE: guidelines for planning animal research and testing. Smith AJ et al) when planning our experiments to ensure we generate meaningful data. Surgery will be performed to best practice as laid out in the LASA guidelines (http://lasa.co.uk/PDF/LASA_Guiding_Principles_Aseptic_Surgery_2010.2.pdf). When substances are administer or blood samples taken, best practice will be followed as set out in A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Diehl et al..

When planning experiments we will refer to Norecopa (https://norecopa.no/) to identify guidelines, search for alternatives and ensure that we are following best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We consider the PPL as a living document and our approach is to regularly update it and make amendments. At an institutional level we have a system of regular updates highlighting new findings and training around the 3Rs. We encourage the sharing of best practice between animal technicians and have in place a system of close management and supervision. Our technicians are required to regularly attend formal courses (IAT) and encouraged to pass on new approaches. We analyse the results of each experiment in partnership with both animal and lab technicians. We find this is essential in determining sources of variation and in continuously improving practice and experimental design to reduce the number of mice we use and also minimise the degree and length of adverse conditions. We trial new approaches both in terms of inducing disease but also in following disease outcomes.

90. The integrated stress response in respiratory disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

integrated stress response, pulmonary hypertension

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Cells respond to a variety of stresses by triggering a protective "integrated stress response", which "integrates" different stress signals into a single protective "stress response". We aim to identify components of this "integrated stress response" that when targeted with drugs can treat lung diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

High blood pressure in the blood vessels that supply the lungs (the pulmonary arteries) is a serious condition that affects up to 26 people per million. This "Pulmonary Arterial Hypertension" (PAH) is usually diagnosed in people between the ages of 20 and 60, affecting more women than men. It is a progressive and debilitating disease that without treatment is fatal in half of patients in 2 to 3 years. With treatment, more than half of patients can survive for 7 years, but the quality of their lives can still be impaired and this disease carries a heavy economic burden for both the patient and the health service.

A subtype of PAH called Pulmonary Veno-Occlusive Disease (PVOD) is caused by mutations of a gene called EIF2AK4. PVOD has an even worse prognosis than classical PAH. With no effective treatments apart from lung transplantation, death occurs in 72% of patients within the first year after diagnosis.

Mutations of EIF2AK4 affect a process in cells called the "Integrated Stress Response" (ISR). By studying how defects of the ISR cause PAH in mice, we hope to find new ways to treat this incurable lung disease.

What outputs do you think you will see at the end of this project?

In this project we will investigate the role of the "integrated stress response" in the lungs. We will study how defects in the "integrated stress response" cause some patients to develop abnormally high blood pressure in their lungs, which is also called "pulmonary hypertension". For example, we wish to discover if there is a defect in lung blood vessels in "pulmonary hypertension" or if other cells, for example cells of the immune system, cause lung blood vessels to behave abnormally. This will help us to identify which cells should be targeted by new treatments for "pulmonary hypertension".

All new information will be presented at scientific conferences and published as peer-reviewed research articles. We do not anticipate new products being produced during this project.

Who or what will benefit from these outputs, and how?

In the short term (1-4 years), the main beneficiaries will be other scientists investigating how the "integrated stress response" controls lung blood pressure.

In the medium term, (5-10 years), beneficiaries will include scientists in the pharmaceutical industry who will be provided with new targets for drug development to treat "pulmonary hypertension".

In the long term, we hope to help patients who suffer from "pulmonary hypertension" by giving them access to new treatments that will improve survival and the quality of their lives.

How will you look to maximise the outputs of this work?

All information, including positive and negative results, will be shared with the scientific community at the earliest opportunity at scientific conferences. Once data are of a sufficient quality, peer-reviewed research papers will be published. All research articles will be made freely available via Open Access in accordance with UK funder guidance. All large datasets (including gene expression and protein levels) will be made freely available in publicly accessible online repositories.

Species and numbers of animals expected to be used

- Mice: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This research requires animals that have lungs, an immune system and blood vessels. There is still much we do not understand about how these cell types (lung, blood vessel and immune cells) interact and cause disease. Mice are the lowest creature in which these components can be found. Importantly, mice and humans share many very similar genes, and so we can use mice to understand how defective human genes cause disease. We need to use adult mice because previous studies have shown that many defective genes, including one which we will study called EIF2AK4, cause lung problems that only show up in adult mice.

Typically, what will be done to an animal used in your project?

Mice will be bred to have genetic mutations that cause mild pulmonary hypertension. Although they are unlikely to show obvious signs of disease, we will use non-invasive tests (ultrasound or MRI scans) to determine if pulmonary hypertension is present. In experiments typically up to 6-8 weeks, mice will be given drugs (either in drinking water or by injection) that will either worsen or lessen the degree of pulmonary hypertension. In some experiments, mice will be given drugs to make them unconscious and lung blood pressure will be measured by placing a fine tube into the heart. These animals will be unconscious throughout the procedure and killed immediately after the experiment without regaining consciousness.

Some patients develop pulmonary hypertension because of mutations in certain genes. One of these genes is important in a cellular process called the "integrated stress response". This "integrated stress response" normally protects cells from a wide range of stresses including infections or poisonous chemicals. It now appears likely that a normally functioning "integrated stress response" is necessary to prevent the development of pulmonary hypertension. Therefore, in some animals we will test treatments (by giving drugs in drinking water or by injection) that target the "integrated stress response" to try to

prevent pulmonary hypertension developing or to improve lung blood pressure in mice that have already developed pulmonary hypertension. In some experiments, mice will be exposed to stresses that trigger pulmonary hypertension, such as breathing reduced levels of oxygen (by placing them into a chamber that has lower levels of oxygen than are found in normal room air) or causing inflammation (by injecting them with agents like lipopolysaccharide that trigger the immune system).

These experiments may last up to 18 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts from injection of substances to promote inflammation (such as lipopolysaccharide, also known as LPS) include low-grade weight loss (less than 15% of starting weight). Although we expect some inflammation in the lungs and hearts of treated mice, and that their heart chambers may increase in size slightly, we do not anticipate this to cause the animals distress or breathlessness. We base this on previous experiments in which researchers gave inflammation-causing drugs (such as LPS) to healthy mice and mice with mutations causing mild pulmonary hypertension. No unexpected deaths were seen in either group. Rarely, animals treated with high doses of LPS showed evidence of distress (taking on a hunched posture with bristling of their fur); these were promptly humanely killed and in subsequent experiments we used lower doses of LPS that did not cause these signs of distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice
- Mild 25%
- Moderate 75%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

Mice are the lowest animal in which an interaction between the "integrated stress response" (ISR), lung blood vessels and the immune system can be studied. While insects

have been used to study the involvement of the ISR in vessel growth, insects do not have lungs and have only rudimentary immune systems that are very unlike those of mammals.

Clinical studies identified the gene EIF2AK4 to be defective in many patients with pulmonary hypertension. At present, how defects of the EIF2AK4 gene cause pulmonary hypertension remains unclear and so effective therapies cannot be developed. Mice and humans both have the EIF2AK4 gene and our ongoing studies have shown that mice lacking this gene develop mild pulmonary hypertension (unpublished work). Using such mice with defective EIF2AK4 genes allows us to examine the role of this gene in lung blood vessel function.

Previous research showed that inflammation can worsen pulmonary hypertension in mice with other gene defects (such as mutations in the BMPR2 gene). We therefore wish to test if defects of the mouse EIF2AK4 gene can also be worsened by lung inflammation. Mice are the lowest animal in which such an interaction can be examined. Although the immune systems of mice and humans share many characteristics, there are some differences. If these differences impair our experiments, we will have access to our institution's Assessment Platform, which provides expert support with "immune- reconstituted ‘humanised’ mouse models" - mice with immune systems engineered to more faithfully model that of humans.

Which non-animal alternatives did you consider for use in this project?

- **Cultured human cells.**

Patient’s smooth muscle cells and endothelial cells from lung blood vessels removed at the time of lung transplantation and donated by the patient for research can be grown in the lab. 'Blood-outgrowth endothelial cells' can be produced from blood samples donated by patients with genetic mutations that cause PAH. We have access to each of these cell models from individuals with normal EIF2AK4 genes and from patients with defective EIF2AK4 genes.

'Reprogrammed' skin or smooth muscle cells from patients can be made to behave as 'stem cells' (so-called iPSCs). These are cells that can be changed into other cell types. Blood vessel cells can therefore be made from these iPSCs. iPSCs can be genetically engineered to have the same EIF2AK4 gene defects found in patients, allowing us to study defects even if patients are unable to donate their cells.

Insects

Fruit flies, an insect model, have been used to examine the effects of ISR defects on blood vessel-like cell development

Why were they not suitable?

- These have been used to study the effects of EIF2AK4 defects on cell function, but such approaches cannot reliably predict the complex interactions between blood vessel cells and other cell types, for example those of the immune system.
- While fruit fly work was useful in pointing researchers towards an interaction between the ISR and "BMP signalling" (a signalling system shared by insects and mammals that controls tissue development), insects lack the complexity of the human BMP signalling system, have only a very rudimentary immune system, and lack lungs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous experiments have shown how a variety of genetic defects and chemical treatments cause pulmonary arterial hypertension. Similarly, previous studies have shown the degree of improvement in pulmonary hypertension that is possible in these animals. With this information we are able to calculate the number of mice needed in each experiment that will provide sufficiently robust results to answer our questions, without excessive numbers of animals being killed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments will be designed to ensure appropriate numbers of mice are used. Studies will use enough mice to generate conclusive results without being wasteful. To this end, the PREPARE guidelines will be followed to provide a framework for planning studies (see below).

Study design - each experiment will include detail of the groups of mice to be compared (gene defects and / or drug-treatments). For complex studies, a diagram is more easily interpreted. The NC3R's Experimental Design Assistant software will be used to generate plans in which experimental groups can be identified easily.

Sample size - exact numbers of mice allocated to each group will be calculated and stated for each experiment. This will be determined for each experiment depending upon: the reason for the experiment (what is the information being sought?), the size of the difference in the measured readout expected between each group (how big are differences likely to be?), and estimates of how variable any effect will be (how much "noise" will be in the information?).

Inclusion / exclusion criteria - these will typically be defined by animal age and any gene mutations they may have (stated in each experimental plan). Typically, genetic effects will be determined by comparison of mice without gene mutations (so called "wild-type") and genetically modified littermates.

When "homozygotes" (mice with two copies of a mutated gene) are required (e.g. Eif2ak4 mutant mice), heterozygote mice (mice with a single copy of the mutated gene) will be mated with other heterozygotes. When there is clear evidence that heterozygotes (mice with a single copy of the mutated gene) are no different from normal (wild-type) mice, these may be used as controls (carefully recorded) to minimise unused animals per litter. Swift and efficient genotyping (the process of determining whether a mouse has a mutated gene or not) will let us humanely kill mice of a not-needed genetic type at the earliest possible stage to minimise any suffering.

Statistical analysis - careful identification of the "experimental unit" (a mouse) in each experiment will be ensured by labelling to avoid "pseudoreplication" (accidentally remeasuring the same mouse) and "underpowered studies" (insufficient numbers of mice to make firm discoveries). This will avoid inconclusive experiments and avoid the need to excessive repetition.

Experimental animals - surplus mice will be shared between research groups, so fewer mice overall need to be bred or bought. The NC3R's breeding and colony management resources will be used to ensure best practice is followed. To locate genetically modified strains, we will make use of online tools to avoid mouse-strain duplication.

Experimental procedures - close collaboration also lets us share data and learn/use experimental techniques with minimum use of animals for the 'learning curve' – e.g. doses of agents that are known to activate the ISR have been based on preliminary data provided by collaborators in another institution.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of non-animal methods and fruit flies (Replacement) will limit the numbers of animals required for the in vivo (live) investigations by helping to pre-select the most effective drugs to test. Experiments will be performed in inbred strains to reduce experimental variability. Where appropriate, we will minimise surplus breeding by avoiding unnecessarily narrow specifications for animal sex, age and weight. We will freeze embryos or sperm when lines are not immediately required for studies. By sharing information with other researchers in this field, we will ensure that different groups are not unnecessarily duplicating similar experiments (except when this is necessary to ensure that research findings are robust). To this end, we will use genetically modified mice (with gene defects relevant to our research) made by other researchers, so that we are not wastefully recreating existing mice strains. In turn, we will ensure that our mice strains are available to other researchers in our field. We aim to use imaging techniques including

echocardiography, CT imaging, and magnetic resonance imaging (MRI) to allow the non-invasive evaluation of heart and blood vessel function. Such ongoing evaluation of the same animal reduces the numbers of animals required in total.

Our previous expertise in using mice to study human disease and the collaborations we have established with experts in related fields will allow the lowest number of animals to be used (Reduction) and sill allow robust statistical analysis. For example, one collaborator previously required 20 animals per experimental group to allow for technical failures, but now obtains sufficient data from groups of 8 animals. Previous experience shows that 10 animals in each control and experimental group provide a 90% chance of detecting a small difference in pulmonary artery pressure or right heart chamber pressure with high statistical confidence.

When there are no appropriate prior results to allow us to design experiments with the necessary statistical strength, for example when using an entirely new drug, we will perform small pilot experiments to provide estimates of the effect size.

For each and every experiment, as part of good laboratory practice, we write an experimental protocol which includes:

• a statement of the objective(s)

• a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals per group), and the experimental material

• an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated)

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The simplest animal that allows us to study the development of pulmonary arterial hypertension (PAH) is the mouse. Genetic mutations that cause PAH in humans have been shown also to cause PAH in mice. Similarly, chemicals that cause human PAH, e.g.

activators of inflammation, worsen PAH in mice. The degree of PAH experienced by the mice we study is typically too mild to cause obvious signs. We can detect evidence of PAH in living mice using ultrasound or MRI scans as would be performed on humans. If necessary, mice can be temporarily anaesthetised (made unconscious with medication) for scans to prevent movement that would prevent accurate measurements being made. For more accurate measurement of PAH, a fine tube is passed through the neck of the unconscious mouse and into the heart. This is only performed when the mouse is fully anaesthetised and the animal is then killed before it can regain consciousness.

Why can't you use animals that are less sentient?

Mice are the least sentient animal in which models of pulmonary function have been developed. The mouse genome has been mapped and so can easily be "genetically engineered" (that is, mouse genes can be altered) to mimic the genetic defects causing human diseases including pulmonary hypertension. Mice also offer the practical benefits of having short breeding times and large litters.

There are many laboratory tools, such as mouse-specific antibodies, that allow analysis of mouse tissues and so enable us to understand the processes occurring in disease and following treatments. Because pulmonary hypertension develops gradually in adult mice, it will not be efficient to perform only "terminal" experiments (experiments in which animals are killed to obtain information). Instead, repeated measurements (e.g. by ultrasound or MRI scans) in the same animals provide more information and so permit the number of animals overall to be kept to a minimum.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all instances, we will choose our models to provide robust data whilst impacting least on animal welfare. Experiments will be designed with an emphasis on animal welfare, being refined to minimise pain, suffering, distress and lasting harm as per NC3R guidance.

Bedding, nesting, enrichment - Mice will be provided with an appropriate environment, e.g. nesting material and shelter, including sufficient space and complexity to satisfy normal murine behaviours. This will be tailored to experiments as required, e.g. translucent environmental enrichment 'yellow- tubes' will be used to enable better observation of the mice while in the hypoxia chamber, removing the need to re-oxygenate them to check for altered behaviour. Additional food and water may be necessary in certain situations. For example, animals show a reduced activity when first placed into a hypoxic environment and so soft food 'mash' and or 'hydrogel' will be added to the cage.

Handling & acclimatisation - Animals will be handled by the researchers routinely performing their care and experimentation in order to minimise distress from unfamiliar experiences. When repeated or prolonged interventions are required, animals will be

acclimatised to new environments (e.g. hypoxic chambers) or procedures (see non-invasive approaches below).

Observation and monitoring - Animals will be monitored at least daily and more often following interventions as appropriate. For example, injections will be carried out in the first half of the day and animals will be monitored for signs of adverse effects for a period of 1 hour after drug administration and will be monitored regularly for signs of adverse effects within 24 hours of administration, e.g. bristling of the fur, hunched posture, subdued behaviour, reduced response to stimulation, or diarrhoea. Any animal will be immediately killed humanely if it shows evidence of suffering that is greater than that specified in the relevant protocol. When animals will be placed into a hypoxic environment, they will be monitored closely at least twice-daily for adverse reaction to the intervention. Animals will be weighed three times per week during the hypoxic period and weights recorded. The respiration rates of the animals will be monitored closely and changes noted. Pilot studies will be used for unfamiliar or novel procedures to establish experimental and humane endpoints, and we will perform post-mortem examinations as a routine part of all pilot studies to investigate any unexpected deaths, seeking advice from the named veterinary surgeon as needed.

Amelioration of pain - When procedures are performed, e.g. vasectomy, painkilling medication will be provided during and after the operation, as agreed in advance with the named veterinary surgeon.

Procedures will be performed using anaesthesia whenever appropriate. This will be regularly reviewed by a veterinarian to ensure that contemporary best practice is followed. Animals will be allowed to recover before further use, e.g. following vasectomy mice will not be used for mating until they are regaining weight and they are showing no adverse signs following surgery.

Administration of substances and removal of blood - We will follow the guidance of the European Federation of Pharmaceutical Industries Association and the European Centre for the Validation of

Alternative Methods. For injections and sampling, needles / catheters will be of the minimum width effective for each purpose. Adverse effects from administered substances will be limited by administered using the minimum effective volumes and frequencies to minimised discomfort, and using the lowest effective doses. Drugs will be dissolved in solutions that have been tested and deemed safe. Repeated administration may produce repeated mild distress. If the cumulative effects threaten to exceed that specified in the relevant protocol, the advice of the named veterinary surgeon will be sought and if necessary, the animals will be killed humanely. For blood sampling, no more than 10% of total blood volume in 24 hours and 15% of total blood volume in any 28 day period. Animals will be weighed to ensure bleed volumes are not exceeded. Lipopolysaccharide (LPS) is a chemical that triggers the immune system and will be used in some experiments to increase pulmonary hypertension. It will be administered following existing Home Office

guidance, in particular taking into account age, sex and strain differences in LPS effects (older animals, females and outbred strains being more sensitive) with dosing being adjusted accordingly.

Non-invasive approaches - We will use "non-invasive approaches" (methods that do not involve placing tubes into the mice) where-ever possible. Lung blood pressure measurement using ultrasound scanning is possible for mice just as it is performed for human patients. Ultrasound provides measurements that similar to lung blood pressures measured directly by inserting tubes into the blood vessel, but has the advantage that it allows repeated monitoring of the same animal over several weeks, thereby reducing variability in the experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

As detailed in the **Guidelines for the Welfare and Use of Animals in Cancer Research Apply (2010),** we will use all available knowledge to predict adverse effects and provide specialist care, especially for genetically modified animals.

Laboratory Animal Science Association (LASA) Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) will be used to guide aseptic technique for surgical procedures (both recovery surgery and non-recovery procedures carried out under terminal anaesthesia) to ensures surgical procedure are carried out skilfully with the minimum of risk and disturbance to the mice and without infection.

Animal Research: Reporting In Vivo Experiments (ARRIVE 2.0, 2020) guidelines checklist will be used to ensure optimal reporting of data from mouse experiments can be fully evaluated and utilised. The guidelines are aimed primarily at scientists writing up their research for publication and for those who are involved in peer review

Experimental planning will follow the guidance set out in the **Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE)** document (Smith et al 2018 Laboratory Animals, 52(2): 135-141).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs both by regular updated provided by our institute and from the NC3R's webpages e.g. resources page (https://www.nc3rs.org.uk/3rs-resources). We will make ongoing use of the NC3R's E-learning hub (https://nc3rs.org.uk/e-learning-resources). Refinement resources will also be accessed. Resources from the Laboratory Animal Science Association (LASA) will also be reviewed as updated, e.g. the guidance on dose selection in toxicology studies https://www.lasa.co.uk/PDF/LASA-NC3RsDoseLevelSelection.pdf will be useful to our programme of work.

91. Phenotypic plasticity and adaptation of cichlid fish in response to novel environments

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

Adaptive evolution, Phenotypic plasticity, Epigenetics, East African cichlid fish, Environmental perturbation

Animal types	Life stages
Haplochromine cichlid fish of the East African Great Lakes	adult, neonate, embryo, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterise the impact of dietary change in East African cichlids.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to protect global biodiversity it is essential to characterise the impact of environmental changes on a range of animals. Research in the past few decades has established that changes in diet and temperature can lead to changes in parts of the body without requiring changes in DNA. These changes are referred to as phenotypic plasticity

and can result in rapid adaptation of parts of the body and behaviour. Understanding the molecular basis for these changes is crucial to predict how animals will respond to a shifting climate.

Fluctuations in environmental conditions often lead to changes in available food sources. This can result from a range of factors including altered prey populations, vegetation dispersal, and migration patterns. In aquatic systems, changes in the quality of the water are leading to the rapid decline of microorganisms crucial in maintaining the marine food chains.

For instance, measuring the abundance of phytoplankton - a type of small aquatic plant - can indicate harmful effects of environmental change in aquatic environments. The upper water column, or shallower level, of the ocean has warmed ~0.1C per decade throughout the past 40 years. Linked to this warming, studies have measured a global decline in phytoplankton levels over the past several decades, as well as changes in their dispersal and yearly life cycles. Because phytoplankton make up much of the basis of the aquatic food chain, changes in the abundance and locations of these small organisms can impact every level of the aquatic environment, placing resource strain upon a range of animals. Currently, the effects of such a widespread change remain uncertain.

For this reason, we are simulating altered dietary conditions in a fish model to study the short-term adaptive process. In the proposed research, we will use East African cichlid fish—a fascinating system known for their rapid adaptation to novel environments—to investigate the responses to changing environments. Our research has two main aims. First, we will characterise the changes that occur in response to altered environmental inputs (e.g. diet) across multiple generations. Second, we will determine whether these changes persist in future generations after returning to the ancestral environment.

To address these two aims, a population of juvenile Astatotilapia calliptera bred from stock tanks will be randomly divided among three diet treatments: a marine diet, an algae diet, and an omnivorous commercial food that is normally fed to this species (referred to as the ‘control’ diet). Fish from generation 1 (G1) will be bred within their tanks to produce generation 2 (G2). The G2 offspring under treatment will be randomly divided and will continue on either the marine or the algae diets. Throughout subsequent generations, all fish will return to the omnivorous ‘control’ diet. Relating to objectives 1 and 2, objective 1 is fulfilled by G1 and G2, objective 2 is fulfilled by all subsequent generations.

What outputs do you think you will see at the end of this project?

The outcomes of the proposed work have the potential to result in several publications reviewed by other scientists. These publications will report findings related to the following main topics:

1) Identification of genes involved in diet adaptation across several parts of the body, including muscle and liver tissue.

2) Characterising how diet change alters body parts in the absence of genetic change and determining the molecular processes behind those changes.

3) Determination of whether non-genetic changes as a result of altered environment are inherited after returning to the original environment.

We expect the data generated in our work to be useful to other researchers and lead to collaborative work. We will deposit our data in publicly available, free repositories, so that other researchers can download it and use it to answer their own biological questions. This is also a reduction measure, as it should avoid repetition of the same work by other researchers.

Who or what will benefit from these outputs, and how?

Our work is of a fundamental nature and will build important knowledge of the impact of altered environments on the control and usage of genes. This will increase our understanding of short-term adaptation in the absence of changes in DNA. As our project touches upon so many fundamental biological aspects, we expect our results to impact several fields of the biological sciences, e.g. evolution, molecular biology, and genetics.

Given the fundamental nature of the proposed work, the research output is not likely to produce directly any product or method with commercial potential. However, the impact of altered diet on fish growth and reproductive success may be used to enhance productivity in commercial fish farming by informing the composition of fish food designed for optimal growth. For instance, as this project involves feeding a population of fish multiple different diets, one of these diets may result in a significant increase in health and growth rate. This finding would suggest that a similar nutrient composition may lead to increased commercial output in fish farming.

How will you look to maximise the outputs of this work?

We intend to present our results in local and international scientific conferences or other scientific meetings. We will attend at least one major scientific conference per year on topics related to our proposed research. These conferences will provide opportunities to broadly communicate our results. Collaborators and other persons directly involved in this work will also participate in dissemination efforts.

Our investigations have already led to several new collaborations with other researchers. We will disseminate all findings, including negative results. Our work will be published in free, public repositories online and in international scientific journals.

Species and numbers of animals expected to be used

- Fish: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using East African cichlids of the African Great Lakes due to their unique and fascinating diversity of body sizes, shapes, diets, and behaviours. These characteristics influence each other and together indicate how well prepared the fish is to deal with and explore its surrounding environment. In fact, the diet of these fishes strongly influences the shape of their skulls and jaws. The combination of these features make East African cichlid fishes, as a whole, an ideal system to identify the genes underlying the bodily changes relating to diet.

In order to understand the effects of a specific diet, these fishes will be fed the same diet throughout their entire life, from the time they initiate independent feeding.

Typically, what will be done to an animal used in your project?

The environmental variable perturbed in this experiment is diet. The diets of the animals in this project will be altered to represent the food regimes of different fish in the lake. Specially formulated fish feeds have been designed to represent the diet of algae eaters (algae-eating diet) and of fish eaters (fish- eating diet) while preventing any malnutrition in our experimental group.

Two groups of fish will be fed two distinct carefully determined diets. One group of fish will eat an algae diet, while another group of fish will eat a marine (fish-eating) diet, both in the form of pellets.

A control group of fish will eat the conventional diet of our aquaria stocks, in the form of flakes.

What are the expected impacts and/or adverse effects for the animals during your project?

We carefully defined each diet so that all the nutritional requirements are met. Thus, we expect our proposed procedures will impact the animals' health and welfare minimally and will not lead to long- lasting pain, suffering, or distress.

In the cases where the diet change produces effects at the level of the skull and jaw, the animals will be killed if their feeding, reproduction, or behaviour are impaired to a point inconsistent with a healthy and normal life. Animals whose diet strongly affects their feeding, reproduction, or behaviour, will be humanely killed immediately to prevent any pain, suffering or distress.

The conditions of the animals will be monitored daily. Weight and length will be recorded once every two weeks to ensure the animals remain at healthy levels. Tanks will be cleaned at least once a week and water parameters will be measured regularly. In the

case that tanks need to be cleaned more often to maintain optimal water parameters, for example when fed with one of the altered diets, we will incorporate this change for all tanks involved in this experiment. No adverse effects are seen from additional cleaning.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Fish: Mild severity: (less than 10%).

What will happen to animals at the end of this project?

Killed
Kept alive
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is important to understand how animals react to a changing environment, and in particular to dietary changes. To research this topic, we need to feed animals with particular controlled diets.

Which non-animal alternatives did you consider for use in this project?

We have considered computer simulations and cultures of cells.

Why were they not suitable?

At the moment there are no alternative resources capable of recreating the natural development of fish. In order to fully understand how animals react to a changing environment, we need to observe how animals develop and behave in a natural context. Other alternative systems, such as cell culture, or computer simulations, are not able to recreate the complex interactions that occur at the level of the organism and during development, between neighbouring cells and tissues. These interactions are most important for proper animal development. Thus, our aim cannot be accomplished without using animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We plan to produce four generations of fish throughout this experiment (maximum of 1500 animals):

1. In order to produce juveniles for the first generation (G1) of the experiment, we will breed our stock fish of that species. We expect to use a maximum of 30 stock animals to produce a founding population of 360 fish. We will divide the founding population across three treatments.

2. For the second generation (G2), we aim to produce 370 fish through controlled breeding of G1. We will include at least 120 animals per treatment.

3. For the third generation (G3), we aim to produce 370 fish through controlled breeding of G2. We will include at least 120 animals per treatment.

4. For the fourth generation (G4), we aim to produce 370 fish through controlled breeding of G3. We will include at least 120 animals per treatment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A pilot experiment was performed using a smaller subset of fish and commercial diets of similar types to the ones created for this experiment. The results from this pilot verified that significant gene regulatory changes can be observed within one generation of diet perturbation in this fish.

Meetings with collaborators who performed similar experiments in other fish models assisted us in determining the minimum number of fish required for significant sampling power. The diets will be meticulously defined in order to meet all the nutritional requirements of the fish. These measures ensure that the experiment will not have to be repeated in a large scale.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout the duration of the project, we will use the minimum number of animals required to acquire satisfactory data. Experiments will be designed, conducted, and reported according to published guidelines (namely the PREPARE and ARRIVE guidelines).

The pilot experiment, mentioned above, allowed us to define an adequate experimental design in terms of diet and number of animals used. The fishes from the founding

population will be randomly assigned to experimental and control groups. A range of tissues will be dissected from killed animals, and those tissues not immediately used for the purpose of this project will be available to colleagues and collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use East African cichlid fish for the proposed work plan. As these fish species are large and robust, they can be effectively bred and grown in an aquaria environment. Moreover, these animals can tolerate novel diets with no major biological consequences. Thus, these dietary experiments are expected to cause little to no pain, suffering, and distress to the animals.

Why can't you use animals that are less sentient?

The work proposed here takes advantage of the extreme diversity of shapes, sizes, colours, diets, and behaviours of East African cichlids. The diversity of these cichlid fishes is unique amongst vertebrates and even amongst the entire animal kingdom. Therefore, other less sentient, or invertebrate, animals will not allow us to answer the same biological questions.

Tissue dissection and extraction will be exclusively performed in dead animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will incorporate new recommendations on animal welfare, as soon as possible after their publication.

Fish will be checked daily for any adverse effects of the diet treatment. We will alter the level of food given to the fish on a regular basis to ensure the fish are consuming optimal levels for their life stage. Additionally, the algae and marine diets, both in pelleted form, will be ground up to smaller sizes for younger fish to ensure they are as easy to consume as possible. It is important to note that food pellets soften upon contact with the water so, at any life stage, remain easy for the fish to consume.

Lengths and weights of the fish will be measured every two weeks to ensure they remain at healthy levels. These measurements will be taken with minimal stress to the fish as they remain in water throughout the procedure. No anaesthesia will be used when weighing or measuring. The weights and lengths of fish under the algae and marine diets will be charted over time to determine growth rate.

These rates will be compared to those of fish consuming the omnivorous parental diet (referred to as the 'control' diet) and comparisons will be used for monitoring purposes, including surveys of overall condition via body mass and comparing growth rate to that expected for this species (i.e. growth rate of the omnivorous population). Body mass of the fish will be assessed relative to breeding frequency to determine optimal endpoints for each generation.

Cichlid housing will be continuously improved to faithfully mimic the sandy areas rich in vegetation and hiding places characteristic of their natural environment. This will be achieved by introducing sand, artificial plants, clay pots, and plastic tunnels in the aquaria. Fish will be housed in groups, in order to decrease stress and aggression levels. Manifestations of aggression, including chasing, fighting, and injuries will be monitored

daily by the scientific and animal care staff. These aggressive behaviours are normal to these species and not a product of captivity. If required, fish will be temporarily separated and groups redesigned to avoid further injury and aggression. Continuous monitoring of water parameters, food regimen, and breeding will ensure the wellbeing of the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the best practice guidelines available at www.nc3rs.org.uk. Experiments will be planned, documented, and reported according to published guidelines (namely the PREPARE and ARRIVE guidelines). In accordance with suggested practice for fish models, enrichment will be added to each tank and individuals will be housed in social groups to minimise stress and increase quality of life.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow the website of the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs, available at www.nc3rs.org.uk), and stay up-to-date with new information and new resources that become available. To achieve this, I have signed-up to the NC3Rs e- newsletter.In addition, named persons at my establishment (i.e. the Named Animal Care and Welfare Officer, Named Veterinary Surgeon, and Named Information Officer) will inform us of relevant new information and resources, and will advise, together with the animal care staff, on the best ways of implementation.

92. The impacts of marine engineering on wild fish

Project duration

5 years 0 months

Project purpose

- Basic research
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Marine fisheries, Telemetry, Marine engineering, Windfarms

Animal types	Life stages
Atlantic cod (Gadus morhua)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to investigate how marine offshore windfarms affect wild fish movement and habitat use and whether they have potential to enhance economically and culturally important commercial and sport fisheries.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Offshore windfarm (OWF) development is the fastest growing energy technology in Europe and is anticipated to double by 2025 with thousands of turbines constructed around the UK coastline. The foundations and scour defence structures of these turbines form artificial reefs which alter marine ecosystems and biodiversity. It is thought that these sites provide productive feeding and breeding sites for numerous fish species, some with commercial

and cultural value as food fish for human consumption and recreational angling. Therefore, these sites have potential to increase stocks of fish species and in turn benefit fisheries and economy, an effect known as ‘spill-over’. We aim to record the movement of five commercially and culturally significant fish species within and around OWFs so that we can assess spill-over and the management of fish stocks that interact with OWFs. Information on the ecology of fish, including their distribution and habitat use under a changing environment will help inform government departments and agencies and engineering companies in planning and designing marine engineering schemes, such as OWFs.

What outputs do you think you will see at the end of this project?

The project will generate fish tracking data by using acoustic telemetry devices which emit unique sounds (pings) that are picked up by receivers placed around offshore windfarms. These tracking data will be combined with sea-bed survey, GIS data and statistical modelling techniques to estimate the amount of time fish spend within the OWF and define specific areas (habitats) of high fish activity within the OWF. The movement and habitat use data will be analysed and written as original research papers for the scientific community in open-access peer reviewed journals and scientific conferences. Our analyses will also be presented to and shared openly with OWFs and government bodies to inform planning and policy with regards to OWF development. They will be shared through a workshop with key stakeholders and a short video published through the European Regional Development Fund "ECOSTRUCTURE" project webpages and social media platforms.

We will be using wild marine fish in our research. For some of these fish species there is limited knowledge on anaesthetic and analgesic process when performing regulated procedures, such as telemetry device implantation. Therefore, added value of our project is the reporting of optimal care and handling of wild fish to minimise pain distress and suffering. We intend to report these aspects of the project via standard peer-reviewed publication and the NC3Rs and Norecopa portals.

Who or what will benefit from these outputs, and how?

The building of offshore structures for harvesting energy is happening at an unprecedented rate but we don't yet fully understand the impacts of these structures on fish. Over the duration of the project (mid-to long-term) OWF developers and planning groups will benefit from our data highlighting the impacts of OWFs on fish movement and use of the artificial habitats that these developments create. This information will assist developers and planners in considering how to shape habitats when designing OWF foundations and scour defences. These impacts will extend to the longer term as data collection on the project is fully realised and relayed to government authorities, conservation bodies and the general public. Stakeholders outside of the OWFs include commercial & recreational fishing operations and national and international regulatory bodies concerned with assessing and protecting fish stocks and marine ecosystems. The

information will also contribute to the development of methods for assessing management of fisheries and the impacts of OWFs.

The scientific community will benefit from the refinements we make in the procedures on wild fish for surgical implantation of tracking devices and in-field handling of these species.

How will you look to maximise the outputs of this work?

Results of the project will be shared with stakeholders with the intention of providing an understanding of how OWFs may be important for fisheries, and how current legislative and conservation efforts may be adapted to include these effects. Furthermore, a short explanatory video will be produced and published across the European Regional Development Fund 'ECOSTRUCTURE' project social media accounts, scientific conferences and meetings with stakeholders. The video will focus on the context on the project, the technology used in the project, and the results. The outcomes of this project will also be published within open access journals and at scientific conferences and elements of it shared with the NC3Rs and Norecopa.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The fish used will all be adult wild-caught marine species. There is no alternative to using live fish because we aim to study the influence of OWFs on wild fish ecology and behaviour (i.e., movement and habitat use). We will study a range of species, including for example, cod (Gadus morhua), thornback ray (Raja clavata), bass (Dicentrarchus labrax), pollock (Pollachius pollachius) and ballan wrasse (Labrus bergylta). We will use adult fish to represent the breeding stock and to minimise harm by using individuals of a size easily capable of tolerating small tracking (acoustic telemetry) devices.

Typically, what will be done to an animal used in your project?

Fish will be caught directly from the sea using rod and line fishing techniques on a commercial angling boat and held in large on-board seawater tanks to assess their health against established condition criteria. At this point fish will be assessed for their health and suitability for inclusion in the study. We anticipate very few fish (<10%) will not meet the condition criteria for inclusion in the study because we will use angling techniques that minimise trauma and distress to the fish. Any fish caught, but that do not meet the necessary condition criteria for surgery will be recorded but not included in the study. For those fish deemed fit and suitable, we will insert small acoustic telemetry devices into the

body cavity through a small incision and under general anaesthesia and with local pain relief. For thornback rays, telemetry devices will be attached externally using special tags inserted into the 'wing' (pectoral fin) of the fish under sedation and local pain relief. At the end of each surgical procedure, fish will be assessed by appropriately trained and qualified persons to ensure that the fish are fit and their welfare protected. Tagged fish will be released into the wild for monitoring and therefore not deliberately recovered/recaptured. Each fish will be operated on only once. We anticipate tagging 50 fish of each species being studied (up to a maximum of 250 fish in total) and will record movements of the released fish for up to three years.

What are the expected impacts and/or adverse effects for the animals during your project?

Any surgical procedure on an animal has potential to cause pain and physiological disturbance as well as distress. We will minimise these possibilities as follows. Only fish deemed fit and suitable for inclusion in the study will be operated on. All fish will be handled, assessed and operated on by highly skilled individuals capable of quickly establishing fish health and recognising signs of distress.

Insertion of telemetry devices into the body cavity (peritoneal cavity) will be done through a small incision and under general anaesthesia and with local pain relief. For thornback rays, telemetry devices will be attached externally under sedation with an anaesthetic and with analgesia to minimise operative and post-operative pain. At the end of each surgical procedure, fish will be assessed by appropriately trained and qualified persons to ensure that the fish are fit and their welfare is protected. Stress to the fish will be limited at all stages and analgesics will be administered to minimise pain following the procedure. The implantation and tagging procedures are thought to cause only transient pain or discomfort. Tagged fish will be released into the wild for behaviour monitoring and therefore not recovered. As such the device will remain with the fish for life. Due to the small size of the tag and its minimal weight it is unlikely to affect the long-term fitness of the fish or their natural behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The study will use wild-caught fish: for example, cod, bass, pollack, ballan wrasse and thornback ray. All fish used will be subjected to 'Moderate' severity.

What will happen to animals at the end of this project?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of the work is to examine the ecology and behaviour of wild fish in relation to changes in their natural aquatic environment through the development of offshore windfarms. The use of wild fish is necessary because the behaviour of hatchery-origin stock may be influenced by the condition and learned behaviour of these fish. Therefore, there is no viable alternative to the use of free-living, wild fish.

Which non-animal alternatives did you consider for use in this project?

We considered the following alternative approaches to replace the use of tagged live wild fish:

1) Baited remote underwater video analysis to video record the quantity and activity of fish in the sampling area.

2) Netting surveys. Netting surveys could provide some information about the presence or absence of fish at a given time and could be conducted over an extended period.

3) Catch-Tag, Release-recapture surveys.

Why were they not suitable?

There is no viable alternative to the use of wild live fish because we wish to establish how changes to natural marine environments by offshore engineering projects affect their choice of habitat and movements.

1) Using baited cameras risks affecting the natural behaviours and distributions of the target species and would provide only a 'snapshot' of activity in time. In addition, the sampling sites will periodically experience poor water visibility that could compromise this approach.

2) Netting options, including invisible gill-nets and trawling are indiscriminate (in terms of species caught and size of fish) and would damage or kill most of the fish caught. Moreover, netting would not provide detailed and continuous tracking information that would be obtained by telemetry.

3) Catch, Tag, Release and Recapture. Here, fish would be caught, tagged with an external, minimally invasive tag and then released into the wild again. If these tagged fish are later caught by sport or commercial fishermen the tag information would instruct them to report the location and date of recapture, thus giving information on the movement of the fish. The drawback here is that it requires very large numbers of fish to be tagged

because recapture rates are extremely low and cooperation from the fishermen is not guaranteed. The approach would not yield continuous movement data.

Our preferred (optimal) strategy is therefore, acoustic telemetry because it would cause least harm and suffering whilst producing detailed, long-term and continuous data on habitat use and movement of fish in and around the study site.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We carefully consulted existing peer-reviewed literature and other experts on the use of acoustic telemetry devices to determine the appropriate minimum number of fish required to obtain robust and meaningful outcomes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The nature of this work (tracking the movement of mobile, free-ranging wild fish) is such that predictions of statistical power are not feasible. However, using the existing literature and after consultation with other experts in the field that currently use fish telemetry, we have established a minimum number of required individual fish that will be tagged to yield meaningful research outcomes. Fifty individuals of each species will be tagged and tracked (250 total). This will allow for fish lost through natural mortality, or to fisheries without compromising the project.

Our study site is an offshore windfarm (OWF) that allows us to carefully position our acoustic receiver units in a circular array, around turbine supports and with overlapping detection fields such that fish movement will be accurately pin-pointed and will not evade detection. Thus, the careful design of the receiver placement will ensure we can minimise the number of fish used. We anticipate that a number of will leave the detection site and, whilst some are likely to return, others may not.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Fish that are released into the wild with telemetry devices inside them will also be tagged with an externally visible marker ('Floy' tag) that request commercial fishing operations or sport fishers return them immediately to the water if they are incidentally caught (outside of this project). We have consulted with other experts using fish telemetry and established

that our chosen number of fish is a minimum that will yield robust and meaningful data. In addition, we will strategically place our telemetry receivers around the study site such that tagged fish within range will not evade detection.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

These species have been selected because of their economic value, behavioural characteristics, relatively large size and ease of capture. The size of the fish selected, relative to the telemetry devices implanted or attached, means that they will be minimally encumbered. Previous studies have shown that intraperitoneal devices of the kind we will use cause no adverse effects on fish including bass, provided they are sufficiently small relative to the size of the fish. We will use adult fish because of their larger size and because we wish to record data from sexually mature specimens. Using adult specimens will also ensure minimal handling due to their size during the procedure and therefore reduced stress.

Why can’t you use animals that are less sentient?

The research necessitates the use of sentient individuals because we are assessing the normal behaviour of adult fish in the wild.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Minimal fish handling at the study site and good fish husbandry and welfare techniques will minimise stress to the fish prior to and following the surgical procedure. We will assess the condition of fish and only use those deemed in good health for our study. Surgical implantation of acoustic telemetry tags into the peritoneal cavity ensures that the devices are not lost over the duration of the project. Previous studies have shown that fish recover rapidly from this implantation with no lasting harm, and we will minimise the burden on fish by using the smallest possible tags relative to the size of the fish. The use of an anaesthetic agent to sedate the fish during transmitter insertion and application of analgesia on pre and post -operatively will ensure distress, pain and suffering will be minimised. Before release back into the sea all fish operated on will be carefully assessed for recovery and condition and only those meeting or exceeding pre-operative condition will be liberated.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use online sources of information to stay informed about refinements. https://norecopa.no/ is an excellent resource for published works and best practices in animal welfare and research and contains an updated list of references relevant to a variety of species including fish.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly review our practices in consultation with peer-reviewed literature, and with reference to data sources including https://norecopa.no/ which is an excellent resource for up-to-date information on the use of fish in research and the 3R's. We will routinely monitor and utilise the NC3R's and Norecopa websites for updates and best practice aligned with the 3Rs. In addition, we will continually review our practices in consultation with the Named Veterinary Surgeon (NVS) and Named Animal Care and Welfare Officer (NACWO). These measures will be applied from the outset of the project in order to ensure any changes (reduction, replacement and refinement) can be applied in a timely manner.

93. Development of live bacterial therapeutics for the treatment of cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Microbiome, Cancer, Immunology, Therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify mixtures of beneficial, health-associated novel bacteria which have the potential to be used as bacteriotherapies to treat cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Currently around 1 in 2 people will develop cancer in their lifetime. The emergence of therapies that activate the immune system to fight cancer cells (immunotherapies) has led to increased survival for patients with many types of cancer. Unfortunately not all patients respond to these treatments. In these non-responder patients the particular bacteria within their gut has been found to impact their response.

This work will help us to understand the mechanisms whereby healthy gut bacteria species (microbiome) are able to enhance the immune response following treatment with immunotherapies. The research will aid in the development of new bacterial therapies to treat cancer.

What outputs do you think you will see at the end of this project?

The long-term output of this programme will be to identify the best bacterial therapies for the treatment of different types of cancer.

In the shorter-term this will involve making new discoveries on the types and behaviour of common gut bacteria found in people and how these interact with the immune system.

Discoveries made on new bacterial species will be published and available to other researchers.

Who or what will benefit from these outputs, and how?

The significant shorter-term output of the programme of work will be to generate data to demonstrate which bacterial cocktails can be used to progress to pre-clinical development in preparation for clinical studies in humans.

In the longer term, we expect our lead novel bacteriotherapies to increase the effectiveness of current cancer therapies such as immunotherapy in the treatment of lung cancer and types of skin cancer such as melanoma.

How will you look to maximise the outputs of this work?

The results of the research will be published in scientific journals and presented at scientific conferences. New techniques may be patented and shared with other researchers.

Publication of unsuccessful data or techniques will also be considered where possible.

Species and numbers of animals expected to be used

- Mice: 5500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use mice to grow tumours at the site where cancer cells are injected. Mice are widely used for this type of work, and have helped researchers understand how the body defence mechanisms react to tumour growth. Mice can therefore be used to predict the mechanisms of action and the effectiveness to treat disease of new medicines. Mice are also able to be bred without gut bacteria (germ-free) to enable us to measure the impact of bacterial therapies. All mice used will be adult mice as these will have a fully developed immune system.

Typically, what will be done to an animal used in your project?

The majority of mice on this project will be injected with cancer cells under the skin on the side of the animal. These cells grow as a solid tumour and are measured regularly to track lump size and mice are humanely killed before the maximum volume is reached. The gut of these mice will also be colonised with particular bacterial species either using samples obtained from human cancer patients or specific bacteria grown in the lab. Sometimes in order to help these bacteria grow we first need to give the mice antibiotics either in drinking water or by injection into the abdomen to eliminate the bacteria that already live in their digestive tract. At various times they will be treated with our candidate bacterial cocktails given by the mouth which requires putting a small tube into their throat for a very short period of time to deliver the bacteria into the stomach. We will use the least invasive way possible to administer the antibiotics, some of which can be in the food and drinking water but occasionally due to the type of antibiotic we need to do this by injection.

In general the bacterial cocktail will be administered orally under anaesthesia. A subset of these mice will be used in our therapy studies and will be administered with anti-cancer drugs by injection to the abdomen. These are treatments that are currently used in hospitals to treat cancer patients.

All these procedures will cause minimal suffering to the mice. All the mice will be check daily by qualified animal care staff.

A small number of mice who are cured of their cancer and the small lump is no longer detectable will be injected again with the same cancer cells under the skin to their opposite side. If cured of both tumours mice will be kept for observation for a maximum of 60 days. This may allow us to show that the effect on the immune system is long lasting and represents good candidates for long-term therapeutic benefit to cancer patients.

When the mice reach the endpoint of the study, defined by a humane endpoint such as tumour size or timepoint, they will be humanely killed prior to tissue collection. Some mice could have small blood samples collected while they are alive so that we can track the effect of a treatment and a further terminal blood sample under non-recovery anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice typically do not show any altered behaviour when administered cancer cells.

We select the cancer cells to be administered to be the most suitable for our experiment which give rise to tumours that are well tolerated. Very rarely the mice may scratch at their lumps causing the skin to be broken and if this is observed the mice will have their claws clipped to reduce the likelihood of damage.

Some of the immune system treatments, as they are designed to provoke the immune system, can give rise to clinical signs such as diarrhoea. This will be closely monitored (twice a day or more if necessary) and when it exceeds predefined thresholds the affected mice will be humanely killed.

Mice will be used to assess the impact of bacterial cocktails on the immune system of healthy mice without a tumour. These mice could experience some side effects from the treatments such as lethargy identified by a lack of responsiveness. All mice are carefully monitored and if they exceed pre-set observations such as weight loss, dehydration and changes to normal behaviour they will be humanely killed. We will provide extra bedding and additional support to the mice to minimise these effects.

Where mice may scratch at a tumour site, the preventative addition of trimming the claws of these mice will be implemented. This will allow them to relieve the itch but limits the damage to the site of the tumour.

Bacterial cocktails are administered orally under anaesthesia to reduce the movement of the animal and ensure all bacteria reaches the stomach. Thus reducing any likelihood of abrasion to the oesophagus and subsequent infection due to the bacteria.

The type of mice and experimental protocols that we are using are well established, widely used and designed to cause the least pain, suffering and distress to the mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice
- Mild approx. 8%
- Moderate approx. 92%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune system is extremely complex. During the development of cancer there is an interaction between the growing tumour and immune cells such as white blood cells. Immune responses directed towards growing tumours can kill tumour cells and eliminate cancer. These interactions are highly regulated and can not be replicated in experiments carried out in the laboratory.

Which non-animal alternatives did you consider for use in this project?

We are able to grow specific bacteria species from human gut within our laboratory. We then measure the basic interactions of these bacteria with immune cells, such as white blood cells, isolated from human blood samples. These non-animal alternatives allow us to determine the difference between good and bad gut bacteria without the need to use animals. We continuously consider their use and development in light of new experimental data.

Why were they not suitable?

It is not possible to replicate the full complexity of the interactions between bacteria and immune cells using laboratory experiments which do not use animals. Animals with an active immune system remain essential to understand these interactions under conditions within living tissues such as the colon and tumours.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on our extensive experience with tumour growth studies in mice, we use 8-10 mice per treatment group. This is a sufficient sample size to allow for the differences in tumour growth patterns we typically observe between individual mice. All experiments with a positive outcome are repeated at least once and a maximum of two times to ensure reproducibility.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We continuously evaluate our methods and experimental results to determine if we can further reduce the number of animals per experiment. We now believe that one of the major sources of variation is caused by the composition of the bacteria between mouse colonies and even between mice in different cages. The effect of mother-offspring proximity during the early stages of life has a strong influence of the composition of an individual's microbiota.

We will employ three measures to address this. First, we will inoculate germ-free animals with defined bacterial types (microbiota) or a purposely designed microbiota guided by our data. The second approach we will employ is to use littermates, who are genetically identical, such that the microbiota is controlled against cage to cage effects. A third approach is using wild type mice with a standard mouse microbiome that are treated to enable colonisation with human microbiome.

We believe these three approaches will lead to less variation between experiments and, as a result, the need for fewer animals to be used.

We also utilise the NC3R's experimental design tool (https://www.nc3rs.org.uk/experimental-design- assistant-eda) to aid in experimental planning and follow the most recent PREPARE Guidelines: https://norecopa.no/PREPARE to ensure all aspects are conducted to the highest standards.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be carried out on each tumour cell type to determine variability in growth. These data will aid in optimising the numbers of animals required per group to effectively determine any impact of treatment on tumour growth.

Wherever possible, multiple experiments will be performed on the tissues collected from an individual mouse, including harvesting mouse tissues for experiments or cells that can be frozen and stored. For example, the spleen can be used to isolate mouse immune cells for further assays. Tumours can be harvested for analysis of the immune cells within and DNA collected to measure changes in mouse genes with treatment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For this project our idea is that defined bacteriotherapies either alone or in combination with anti-cancer drugs can block or cure cancer. We used peer reviewed literature to guide our tumour type selection alongside in-house data.

This project will use well-defined and optimised tumour types, such as melanoma, grown in mice with no gut bacteria (germ-free) and specified known bacteria (gnotobiotic). To assess the impact of the host microbiome mice can bred and maintained germ-free allowing us to inoculate animals with defined bacterial cocktails so we can monitor the activity of the host and microbiota with sophisticated molecular approaches.

Why can’t you use animals that are less sentient?

Mice are used in this project as they share many of the same species of gut bacteria as humans. Animals with a more immature life stage stage do not contain these same bacteria and are not as easily bred and maintained in a germ-free 'bubble' within isolators.

The mice are required to carry out normal habits such as eating and drinking to enable us to measure the impact of orally ingested substances on the gut bacteria.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Germ-free mice are bred and housed in cages within 'bubbles' or large contained isolators which prevent the entry of viruses or bacteria. The cages contain environmental enrichment and mice are housed within social groups of 4/5 animals.

Mice will have two daily welfare checks which include observing that animals are healthy and can move freely in every cage, have sufficient food and water and the isolator temperature/humidity readings are appropriate. These details are recorded on observation sheets within a day book for assessment of an individual animal's health status.

Where novel agents are administered, the duration and frequency of monitoring including periods of continuous monitoring will be increased for example, following administration of novel agents. A single animal will be dosed and monitored for one hour before the other animals on study are dosed.

For mice which receive oral administration of a mammalian microbiome, this procedure is carried out under anaesthetic to reduce the likelihood of any harm due to movement of the mouse during the process and post procedure checks are carried out. We will continue to work with animal care staff to assess the requirement for anaesthetic use.

Active use of and continuous development of humane endpoints will allow us to continually refine procedures. For example in the measurement of tumour size we are considering

trialling the use of non- invasive methods such as Biovolume http://www/biovolume.com in comparison to standard calipers.

Currently once a tumour reaches 700mm3 it is flagged as yellow and will subsequently be measured daily.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure best practices we follow the updated ARRIVE guidelines [PLoS Biol 2020 18(7): e3000410]

We also follow the PREPARE guidelines to ensure all best practices are followed by researchers who use animals on this licence. [Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823.

Epub 2017 Aug 3.]

In addition, we follow updates to best practice guidelines on The Laboratory Animal Science Association, LASA and NC3Rs websites.

We will publish to ARRIVE and PREPARE guidelines and where possible data will be presented at scientific conferences.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use the NC3Rs website to gather up to date information about advances in animal research. This information will be disseminated to anyone involved with this licence including Project Licence Holder (PPLH), Personal Licence Holders (PILs), Named Animal Care and Welfare Officers (NACWOs), Named Information Officer (NIO) and Named Veterinary Surgeon (NVS) and implemented where appropriate.

94. The role of nitrite in coronary artery disease and its associated risk factors

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Coronary artery disease, Hypertension, Diabetes, Mechanisms, Therapy

Animal Types	Life Stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project investigates nitrite as a therapeutic target to improve the poor heart and blood vessel function associated with diabetes and high blood pressure, which are major contributing factors to the development of coronary artery disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work? What is the role of the heart and blood vessels?

The heart pumps blood through blood vessels, which carry the blood to and from all areas of the body. This whole network of vessels for blood circulation is called the vascular system.

The heart receives its own blood supply through blood vessels known as coronary arteries, which like all other tissues in the body, needs oxygen and nutrient-rich blood to function. If these blood vessels are damaged or diseased, this gives rise to coronary artery disease (CAD; sometimes known as coronary heart disease).

What is heart attack?

CAD is the most common type of heart disease, and the first sign of this is a heart attack (myocardial infarction). This happens when there is a narrowing or blockage of a blood vessel, which prevents blood flow to the heart. In the UK, there are approximately 63,000 deaths due to heart attacks per year.

How does diabetes and high blood pressure increase the risk of developing a heart attack and increased heart injury?

There are several chronic conditions (also termed comorbidities) that increase the risk of CAD development, including diabetes and high blood pressure (hypertension). Diabetes is caused by high blood sugar levels for a prolonged period of time, which can lead to the lining of the blood vessels becoming thicker and therefore restrict blood flow and cause serious heart complications. High blood pressure can cause significant strain to the blood vessels, which subsequently become damaged and make it harder for the blood to flow around the body.

Why is it important to undertake this research?

It is estimated in the UK that 3.9 million people are diagnosed with diabetes and 12.5 million people are diagnosed with high blood pressure, figures which are increasing both nationally and globally. Studies have revealed that patients with diabetes and/or high blood pressure are more at risk of having a heart attack. Furthermore, patients with these comorbidities tend to experience increased adverse effects by causing worsened heart cell death following heart attack. This can affect clinical outcomes profoundly by increasing mortality.

There is an urgent need for effective therapies that prevent blood vessel and heart abnormalities from these comorbidities and therefore limits heart injury when a patient has a heart attack.

Therefore, understanding the underlying mechanism of diabetes and high blood pressure is essential, and how to prevent further heart cell death following heart attack in the presence of these comorbidities is warranted.

Nitrite as a potential treatment against cardiovascular (heart & blood vessel) disease

Currently, there are very few treatments available to protect against blood vessel and heart abnormalities caused by diabetes and/or high blood pressure. Our research group is investigating a chemical called nitrite as a potential treatment strategy for improving blood vessel and heart function.

Nitrite is found in green leafy vegetables (e.g. spinach, beetroot) and work carried out under our previous licence we discovered a new mechanism in how it is able to regulate blood vessel and heart function during normal, healthy conditions. However, we do not know how nitrite functions during periods of ill-health - such as diabetes and high blood pressure - and whether use of nitrite would prevent further heart injury following a heart attack under these comorbidities.

Therefore, the work to be carried out under this licence is essential to:

• Identify key signalling pathways of nitrite in how it modulates blood vessel and heart function, which will further scientific knowledge

• Advance the understanding in how nitrite works on blood vessel and heart function during diabetes and high blood pressure

• Identify the key targets of nitrite mechanism that could lead to the development of new therapies to treat against blood vessel and heart abnormalities observed in diabetes and high blood pressure

• Assess whether nitrite has the ability to reduce heart tissue injury following a heart attack in the presence of diabetes or high blood pressure

What outputs do you think you will see at the end of this project?

The ultimate aim of this licence is to better understand the role of nitrite on blood vessel and heart function when they become diseased (e.g. diabetes or high blood pressure) and whether it can reduce heart tissue injury following a heart attack (myocardial infarction). This new information will enable us to identify potential new treatment targets that could be used to prevent or slow the progression of heart disease. These treatments could lead to the generation of new medicines with significant subsequent improvements to human health.

Our primary outputs will be in the form of publications describing these mechanisms in scientific journals and conference communications. We hope that these publications will be useful for other researchers and paves the way for new research, ultimately translating our findings to patients at risk of heart disease.

Who or what will benefit from these outputs, and how?

Short term: Gain an understanding in the underlying mechanisms of healthy and diseased blood vessel function and the development of a heart attack. Our colleagues and collaborators will benefit from the data that will inform them their experiments and approaches.

Medium term: The mechanisms and pathways identified will enable us to target specific molecules/proteins with potential to aid development of novel therapies. Our colleagues and collaborators will benefit from the data that will inform them their experiments and approaches.

Longer term: We anticipate that we will advance our understanding of the mechanisms underlying blood vessel dysfunction and heart attack. This project may identify key signalling pathways that could lead to improvements in current therapies and development of new therapeutic targets for heart disease associated with blood vessel dysfunction. All new findings will be shared with the wider scientific community, published in journals and scientific conferences.

How will you look to maximise the outputs of this work?

To maximise the output from this work, we are collaborating with chemists, biochemists, pharmacologists and clinicians nationally and internationally. The findings from this project will be presented at conferences and published in peer-reviewed original research articles. In the longer-term, we will engage with fundraising committees and patient groups to discuss our key findings for new drug treatment. To enable wider dissemination (local, national and international exhibitions) we will develop an interactive stand to illustrate the concept of our research in cardiovascular disease. A proactive media engagement strategy will be implemented to raise public awareness of cardiovascular disease.

Species and numbers of animals expected to be used

- Mice: 6500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Blood vessel dysfunction and how it progresses in the development of heart attack are complex multifactorial syndromes which involve the interaction of numerous body systems and various factors (e.g. high blood pressure, diabetes) over a prolonged period of time. As such, it is impossible to evaluate the mechanism and novel drug targets in a single cell isolated set-up.

In this project, we will use adult mice as their cardiovascular systems are fully developed and are similar to human cardiovascular function and molecular pathways.

We choose to use mice as this allows us to breed and use mice which are genetically modified, thus allowing the genome of the animal to be manipulated so that the protein product of a particular gene is not produced (or in some cases the manipulation can be so that more of the protein is produced). Using genetically altered mice will help us to better understand the human disease and identify new treatments.

Furthermore, we will be able to draw on a large body of existing knowledge for this species to allow rapid progress and large number of well-established procedures are available to model key aspects of human disease.

Typically, what will be done to an animal used in your project?

To identify the key signalling pathways of nitrite, we will use normal and genetically modified animals which lack genes specific to important pathways regulating blood vessel and heart function.

In these set of experiments, animals will undergo non-recovery terminal anaesthesia under which tissues will be removed for further analysis on specialised laboratory equipment for the assessment of blood vessel function and/or models that mimics heart attack.To evaluate the mechanism of nitrite in diabetes, we will use diabetic mice. In these set of experiments, blood sampling will be taken from the diabetic animals to monitor blood sugar levels and may be administered with nitrite or control (e.g inactive treatment control group). Similar to above, the animals will undergo non-recovery anaesthesia for the removal of tissues for analysis in the laboratory.

In this project, we will also evaluate the impact of high blood pressure on blood vessel and heart function. We will use normal and genetically modified animals which lack genes specific to important pathways related to regulating blood pressure. Some animals will be administered with pharmacological agents via previously implanted subcutaneous mini-pumps and may also receive an injection of control (vehicle) or nitrite. Mice will have their blood pressure measurements taken using standard tail cuff (non-invasive) method on several occasions before and after medication or no treatment (control). Tissues will again be taken under non-recovery anaesthesia for further analysis in the laboratory.

For all experiments, once tissues have been taken under non-recovery anaesthesia, they will be used on a specialised laboratory equipment for the assessment of blood vessel function and/or used in models that mimic a heart attack.

What are the expected impacts and/or adverse effects for the animals during your project?

The proposed mouse models of diabetes and high blood pressure models are well-established locally.

Some mice will have an osmotic pump implanted to induce high blood pressure whilst they are anaesthetised and this may cause some temporary discomfort. Mice will be monitored

daily for their general well-being and weighed on weekly basis. Should animals show signs of distress they will be killed humanely.

In some protocols, blood pressure will be measured non-invasively (like in humans with a blood pressure cuff). It is unlikely that this will result in harm or distress; all animals will be handled using non- stressful handling techniques and application of the device itself does not cause pain.

Some animals may experience mild discomfort from receiving an injection. Some mice may receive multiple drug injections or undergo repeat blood sampling (for example in diabetic animals to measure blood sugar levels). If this is required, the routes and volumes will be suitable for their age and size and will be such that animals fully recover between interventions and will not suffer more than transient pain, distress and/or long-lasting harm, and we will make every effort to minimise cumulative adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Non-recovery 50%
Mild 25%
Moderate 25%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The events that occur in the development of heart disease are complex, involving changes in blood flow, oxygen supply to tissues, and inflammation. Therefore, it is not possible to measure tissue injury in cell culture models as there is disproportionately larger extracellular space (e.g. the culture medium), that prevents the accumulation of metabolites and the profound lack of oxygen (hypoxia) and substrate deprivation that accompanies ischaemia in a whole heart model. Consequently, findings in cell-based models of simulated ischaemia always need to be replicated in an in vitro whole heart model.

Therefore, animals must be used when measuring the consequences of ischaemia on the remodelling process. This process is complex and results from changes in all the cell types within the heart, which in turn are modulated by circulating agents, such as neurohormones and inflammatory mediator, as well as circulating cells. The processes cannot, therefore, be modelled in a cell culture.

Which non-animal alternatives did you consider for use in this project?

We are using isolated organ applications for testing the blood vessel (myography) and the heart (Langendorff preparation). For the assessment of processes at molecular level we have considered using commercially available cell lines or cells from relevant mice. When feasible, we use obtain clinical samples, such as blood vessels and heart biopsies from patients undergoing heart surgery, in order to minimise and reduce the number of animals required.

Why were they not suitable?

Certain mechanisms that will be studied in this project using animals cannot be studied in cell culture due to the complexity of the cardiovascular system and uncertainties/unknowns in these diseases.

Human tissue samples are difficult to obtain and the information we can obtain from human tissue samples is limited because of the legal constraints on access of tissue, and ethical constraints on experimental interventions in patients for the treatment and diagnosis of disease. Therefore, due to these circumstances we are unable to do all our research in isolated cells and humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals to be used in this project based on past experience and relevant published work. We have performed statistical analysis to work out the number of animals we will use for this project. The proposed experimental design and methods of analysis of the results have also been reviewed by a statistician.

Importantly, when estimating total numbers, we have taken into account the fact that some animals might serve multiple purposes (e.g organs and tissues used for different objectives). Therefore, all experiments have been designed to minimise the number of mice needed to make statistically meaningful conclusions.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our breeding colonies for the genetically altered animals are tightly monitored to ensure that we have sufficient size to produce the number of animals needed without significant excess. Whenever possible, tissues from the same animal will be used for multiple purposes and will be shared amongst team members working on this project (e.g. heart, blood vessel, blood samples etc…), thus reducing the number of animals used. In addition, serial assessments (e.g blood pressure, blood sampling) to reduce experimental variability by allowing comparison at different time points in the same animal, therefore reducing number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For each and every experiment, as part of good laboratory practice, we will start experiments with a small pilot of a few animals to ensure that there will be no unexpected welfare harms and assess whether if it is needed to go on to a large experiment with more animals. We will harvest multiple organs and tissue and share them amongst the research group to perform experiments in the laboratory to minimise the number of animals is used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Currently the mouse cardiovascular system is considered a robust model for that found in humans and has the advantage of genetic manipulation. The genetically altered strains are lacking important mechanistic elements which helps us to understand the mechanisms of blood vessel and heart function. We are already breeding these genetically altered mice under a different licence and the mice do not show any clinical signs or suffering.

We have also designed this project to avoid suffering and distress in the mice:

1. We harvest the heart and associated blood vessels under non-recovery anaesthesia and use ex vivo techniques to measure blood vessel and heart function. This is a major refinement to our protocols as we are not using procedures in living animals to assess blood vessel and heart function, which minimises severity and suffering.

2. The models of high-blood pressure and diabetes we are proposing to use in this project are well- established. Therefore, we have good knowledge of the course of the pathology and so can refine our endpoints.

3. We will use non-invasive techniques to measure blood pressure, which is the most refined method available and minimises suffering to the animals.

4. Several steps will be taken to minimise stress resulting from administration of medication. For example, the use of refined handling methods to prevent distress and minimizing injection frequency to prevent lasting harm.

Why can't you use animals that are less sentient?

Species that are less sentient do not share common characteristics with humans nor are they sufficiently characterised to be reliably used as models of human disease. Animals are used at the earliest of their life stage, but the composition of the scaffold of blood vessels and heart changes, builds up over life, and we can only use mice which have fully matured blood vessels and a developed heart (e.g. at 8 weeks of age).

Control of blood pressure is significantly affected by general anaesthesia. Therefore, whenever possible, and welfare concerns can be addressed, physiological measurements will be performed in conscious animals. It is important that our scientific research is transferable, where the results have relevance to the cardiovascular disease in humans.

Tissue and blood vessel isolation is performed in mice which have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All the experiments undertaken in this project are designed to use procedures that cause the least pain, suffering and lasting harm. The major refinement to our protocols is in the area of harvesting tissues under non-recovery anaesthesia, which minimises suffering in the mice. In addition, when anaesthesia is applied, the efficacy is monitored throughout the procedure.

Some animals will be administered with a pharmacological agent and may experience mild transient discomfort from receiving an injection. If blood sampling is required, routes and volumes will be suitable for their age and size and will be such that the animals recover between interventions and will not suffer more than transient pain and distress. This will ensure there is no lasting harm and therefore we can minimise cumulative adverse effects.

Administration of pharmacological agent is performed according to the route and dose that minimises adverse effects and input will be encouraged from the animal technicians and Named Animal Care & Welfare Office (NACWO). Since stress and anxiety affect the control of blood pressure, all animals will be handled using non-stressful handling

techniques (such as tunnel handling). They will also be allowed to adapt to experimental conditions (e.g. measurements of blood pressure via tail cuff) in advance of experiments to reduce anxiety and stress. All animals will be closely monitored throughout the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We actively check for up-to-date publications relevant to the techniques used in this project to ensure that we are conducting experiments in most refined way and to maximise scientific output. Major guidance through the project is taken from the NC3Rs, whose website (https://www.nc3Rs.org.uk/3rs- resources) provides resources on the general principles underlying the experiments highlighted in this project. This includes anaesthesia, breeding strategy and numbers, and experimental design.

LASA guidelines will be used for administration of substances, volumes and frequency limits with the most up-to-date veterinary knowledge (https://www.lasa.co.uk/current_publications/)

We will publish according to ARRIVE guidelines 2.0 (https://arriveguidelines.org) to help ensure that experiments are reproducible with minimal wastage of animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular updates from organisation (e.g. newsletter) and the NC3Rs website. In addition, we have regular discussions and updates with the staff in the animal facility to ensure that we are using up-to-date information in relation to the 3Rs. Regular updates are also sourced from attending scientific conferences and publications from cardiovascular journals.

95. Modulating the immune response in cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunomodulation

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify novel mechanisms by which substances that modify immune responses (immunomodulatory substances) can initiate, enhance or maintain anti-tumour immune responses in vivo. These studies will not only provide fundamental understanding of the requirements for an efficient anti-tumour immune response, but should also provide proof of principle data for future therapeutic development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is the second leading cause of death worldwide, accounting for 9.6 million deaths every year. However, new therapies targeting pathways known to inhibit the immune system have revolutionised cancer therapy, and clearly demonstrated the importance of the immune system in tackling cancer.

Unfortunately, a large number of cancer patients are non-responsive to such immunotherapies, highlighting the incomplete understanding of the mechanisms underlying the activation and suppression of the anti-tumour immune response. Therefore, it is critical to gain a greater understanding of the processes leading to a successful immune response during cancer and to identify novel targets and immunomodulatory substances that could be used alone, or in conjunction with current therapeutics, to improve cancer treatment.

What outputs do you think you will see at the end of this project?

A central goal of this project is to identify new understanding of the mechanisms by which immunomodulatory substances can initiate, enhance or maintain anti-tumour immunity.

One of the immunomodulatory substances that we will initially focus on (IMM-101) has already been tested in phase I and II clinical trials. As part of this project, we aim to generate vital preclinical data to help this promising therapy to advance to phase III trials and, ultimately, to the clinic.

This project aims to disseminate new knowledge by publication in peer reviewed journals and presentations at conferences, seminars and workshops. We hope that in the longer-term our work will contribute to new immunology-based therapies for cancer. In the 5 years of this project, we aim to continue our high standard of publication, averaging more than 5 research papers per year in highly- respected peer-reviewed journals.

Who or what will benefit from these outputs, and how?

This project aims to answer basic scientific questions. The new knowledge generated, and the unravelling of important fundamental immune mechanisms, will be relevant to a broad range of human and animal conditions, including cancer.

In the short term, we will gain novel mechanistic insights into how the immune system can be modulated to promote tumour clearance. This new information will offer the potential of enhancing future treatment options for a broad range of disease, as the immune response is centrally involved in all cancers. Importantly, one of the immunomodulatory substances that we will initially focus on (IMM-101) has already been tested in phase I and II clinical trials, and has demonstrated safety and efficacy in advanced pancreatic cancer and melanoma, and is currently being assessed in a range of other cancers. Therefore, increased mechanistic understanding of this promising therapy is critical for its progress to phase III trials, and to patients.

In the longer term, we aim to discover novel therapeutic candidates through our fundamental research into anti-tumour immune responses. These novel candidates could be targeted individually, or combined with established therapeutics, to improve current cancer treatment strategies.

How will you look to maximise the outputs of this work?

Communication of our findings will be primarily through publication in widely-read peer-reviewed journals, but also presentation at local, national and international congresses and institute seminars. To ensure maximum dissemination, only journals that allow open access without payment by the reader will be considered. To prevent unnecessary repetition of experiments by others, we will seek to publish all data generated under this project, including negative results.

To enable rapid translation of our findings to the clinic we will exploit new and existing collaborations, and with local clinicians as part of the translational environment within our institution. We have highly effective systems in place for technology transfer. Additionally, we aim to expand our current collaborations with pharmaceutical and biotech companies by presentation at national and international forums at which industrial representatives are present.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We study adult mice because the immune system, tissue organisation and development of all mammals are similar, allowing mice to be a model for humans and other animals. We also use mice because scientists have created many genetically altered mouse lines that allow us to dissect in fine detail what happens during immune responses and in cancer. Genetically altered mice, and many of the tools designed to work with mice, allow us to define in precise detail how particular cells and molecules of the immune system work together to fight cancer. By manipulating these cells and molecules, we can identify the immune components that are most effective at preventing tumour growth, and use that information to help design future cancer therapies.

Typically, what will be done to an animal used in your project?

Typically, animals will receive a single or multiple injections containing an immunomodulatory substance (e.g. antibodies to neutralise a specific immune mediator or deplete a specific cell type, or cells to promote a particular response) and/or cancer cells.

Experiments might look at the immediate immune response in the first few days after administration of an immunomodulatory substance or tumour cells, or may last several months to allow full tumour development, or assessment of immune memory. These experiments will typically last between 1 and 28 days. For longer experiments, mice are likely to receive multiple doses of an immunomodulatory substance (e.g. once a week for 2-3 weeks). For some experiments, mice will receive an injection of tumour cells either prior to or after treatment with immunomodulatory substances. Depending on the substance, it may require multiple doses over a time period as tumours develop (typically up to 4 weeks). Experiments will end with animals being killed humanely, sometimes under terminal anaesthesia.

The cumulative experience of mice will typically be exposure to 2 or 3 procedures that may each cause short but usually separated periods of typically mild or potentially moderate degrees of suffering.

Separate from the above experiments, some genetically altered animals will be used only to breed and maintain animal lines.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of animals will experience no adverse effects or only mild adverse effects.

Tumours grown on the flank can affect walking and normal behaviour and, in rare cases, can become ulcerated. However, the tumour models we will use are generally well tolerated and will rarely reach moderate severity. Although immune modulation can trigger systemic inflammation that can cause weight loss, piloerection, hunching and reduced movement, in most cases these effects should be mild or transient.

In all experiments, animals will carefully monitored and humanely killed before they exceed moderate severity limits.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect approximately 85% of mice to experience mild severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The mammalian immune system is highly complex, relying on the co-ordinated actions of multiple different cell types and molecules that collectively provide protection. As such, the insight in vivo experiments can provide on the mechanisms necessary for tumour protection is of significant clinical relevance. Importantly, we know the importance of the tumour microenvironment and its ability to suppress immune responses, thus limiting the efficacy of immunotherapies.

Unfortunately, in vitro systems are unable to reflect the cellular and molecular complexity of the immune system and tumour microenvironment. Therefore, the use of mammals is essential for gaining a better understanding of the mechanisms underlying immune protection that could be utilised for patient benefit.

Mice will be used in these studies because their immune system closely resembles the human immune system therefore giving a better chance for translating potential therapies. Additionally, a wide array of wild type and genetically altered strains of mice are available that will allow us to better decipher the role of immune cells and molecules in anti-tumour immunity. Finally, a vast range of reagents is available for analysing murine cellular and molecular interactions during immune responses.

Which non-animal alternatives did you consider for use in this project?

1) Analysis of human biopsies.

2) Use of cell lines and in vitro systems.

Where possible, we will use in vitro assays to provide initial data on the effects of immunomodulatory substances on specific immune cells. This data will then be used to inform and complement our in vivo experiments.

Why were they not suitable?

The types of experiments required to track cell function in vivo are not possible with human tissue biopsies, nor can we experimentally manipulate humans.

Many location-specific features of cells are lost once they are removed from the tissue, which makes the use of cell lines impractical. In vitro systems typically allow for the study of one or two cell types in a highly controlled environment that is not reflective of the complex immune system in vivo. Therefore, to fully understand how different cell types and molecules co-ordinate an effective immune response we require in vivo experiments.

We will regularly review the literature regarding in vitro and zebrafish systems so that if new approaches are developed we can test them and potentially exploit them if they succeed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice has been estimated based on experience gained under my previous Home Office licenses, taking into account breeding strategies for genetically altered mice, and anticipated numbers of planned studies over the course of the license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For all of our experiments, in-bred mice are used to reduce experimental variation, which makes it possible to use fewer animals to achieve statistical significance. For the majority of our studies, mice from the same litters are used for control and experimental mice, reducing variation that can occur due to differences in the microbiota. Overall, our experiments are designed to reduce the number of variables (for example age) to as few as possible and thereby reduce the number of control groups required.

We work with the NC3Rs Regional Programme Manger to ensure all lab members are introduced to the NC3Rs experimental design assistant and encouraged to use it. Everyone in the lab is trained in statistical methods and these are regularly discussed at lab meeting, to ensure all agree the best methods are being used. This includes randomisation and blinding, whenever practically possible.

Tissue-sharing is a major tool we use to reduce animal usage.

A significant proportion of our animal use is related to breeding programmes for genetically altered lines. We follow the advice of our animal facility staff to optimise breeding, and regularly discuss numbers at lab meeting to ensure we do not overbreed. Where possible and appropriate, we use substances that can target or block immune processes in wild type mice, to reduce use of genetically altered mice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We routinely perform pilot experiments to determine the optimal number of mice to achieve statistical power. Experiments are then performed on a minimum of two separate occasions to ensure reproducibility, following which data pooled from experiments are statistically analysed to reveal less pronounced effects without increasing overall animal use.

We have many years of experience in planning animal experiments and we plan our research to ensure that all animals are used most effectively. We often combine experiments to ensure that multiple organs are used to address multiple objectives at once. Careful discussion between multiple researchers is required to avoid compromises. Due to high variability in immunological and tumour models in vivo, especially in genetically altered models that we have yet to assess, we will adjust groups sizes as required, should subsequent power calculations indicate that this is necessary.

The increased use of genetically altered animals has led to more complicated breeding strategies and, as a result, larger colonies. We reduce the numbers of these animals in our experiments by using littermates as controls wherever possible. Additionally, when a particular strain is not being used experimentally we work closely with the animal technicians to develop a breeding strategy that maintains low numbers of stock animals.

In many experiments, we will use bone marrow to carry out pilot studies in vitro, therefore only a few animals are used to initially test new hypotheses. Importantly, we continue to work closely with collaborators who can supply bone marrow samples, therefore reducing the number of genetically altered animals that have to bred to facilitate experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse models to study the immune response in cancer. Mice represent the most appropriate species for in vivo study of cancer immunity, because of the extensive knowledge of their physiology as it relates to humans, the genetic and biological tools available and the ability to be easily bred and handled.

The cancer models we will use do not cause significant pathology, and doses and timing are carefully managed such that the animals will experience minimal suffering. As our experience of these tumour models develops, we will look to refine our approaches to ensure robust experimental results whilst minimising pain, suffering or distress.

Why can't you use animals that are less sentient?

To our knowledge, no other species of lesser sentience can fulfil the requirements of this project to the same extent as the laboratory mouse. We are studying long and complex immune processes, and trying to understand how the adult immune system handles tumours, and how different cells communicate to orchestrate an appropriate response. Only adult animals would give meaningful results. To define the impact of immunomodulation on tumour growth requires mice to be monitored for several weeks, so procedures cannot be carried out on terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All procedures will be performed by trained and skilled personal licence holders, who will handle animals with care. Animals will be monitored for adverse effects using score sheets previously developed in conjunction with the NVS and NACWO. These score sheets have proven to allow for objective measurements of clinical signs associated with adverse effects to determine when humane endpoints have been reached.

In line with the establishment's policy, we will adopt the latest techniques in animal handling (e.g. cupping) to significantly reduce the stress associated with procedures. Furthermore, where possible, the least invasive methods for dosing and sampling will be applied.

Anaesthesia and analgesia will be provided where suitable (e.g. for humane restraint, during or in recovery from surgery). The best aseptic technique will be used during surgery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow LASA guidelines, and consult the recommended https://www.nc3rs.org.uk/3rs-resources on a regular basis, including watching videos of best practice techniques. For specific models, we read papers from other groups doing similar experiments, as well as consulting directly with other researchers to discuss the most refined procedures.

We will continue to use the NC3Rs Experimental Design Assistant to ensure we design experiments that will allow us to achieve statistical significance whilst minimising the number of animals we need to use.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our animal facility includes a team of dedicated veterinarians that are continually seeking to improve animal welfare and refine animal use. We consult closely with them and take full advantage of the extensive resources provided to ensure we are following current best practices. We will continue to work closely with our local NC3Rs representative to ensure we stay informed about the advances in the 3Rs. For example, we have recently attended an NC3Rs Experimental Design Assistant workshop to ensure we are using the EDA to the fullest extent in order to achieve our scientific aims with the minimal number of mice.

96. Trans-generational effects of age in birds

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Evolution of ageing, Ornithology, Trans-generational effects, Epigenetic

Animal types	Life stages
House sparrows	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to better understand how age influences how inheritance can occur via non- genetic, yet heritable, mechanisms. I will address this knowledge gap by testing the hypotheses that (1) an organisms' age does not only affect its own traits, but also those of its progeny produced at different ages. Any such non-genetic, yet heritable mechanism is called epigenetic. We also hypothesize that (2) such age-associated effects are carried over into future generations, under wild conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Trans-generational effects can influence how selection acts and traits evolve. In fact, ageing can induce change to the DNA or even change what is in an ejaculate. These changes then influence the behaviour, physiology, and ability to reproduce of future

generations. However, while we know a little about these mechanisms in laboratory animals, we do not know how often they occur, and what their significance is, in wild animal populations. Notably, we do not know how, and how much these epigenetic modifications affect the ability to reproduce. Furthermore, past experiments been unable to distinguish between the different influences of genetics, the environment, and the epigenetic effects of parental age. This is mainly due to the difficulty to conduct in-vivo fertilisations in wild animals. Yet this knowledge is crucial to understanding the role of trans-generational effects, and ageing, in evolution, ecology, biomedicine, gerontology, and other fields. My long-term data from a wild bird population, together with a cross-foster design, can overcome this problem. A better understanding of the trans- generational effects of age will significantly help explain how longevity can evolve, and may guide the way towards a healthy, long life.

What outputs do you think you will see at the end of this project?

My project involves contributions to two long-term animal studies that are going on for decades now. These so-called long-term population studies are rare due to the logistic challenges of keeping long- term projects going for so long. However, these data are also crucial, and central for our understanding of ageing and longevity in wild populations, and evolution in the wild.

As such, I anticipate that the data collected under this project license will lead to at the least 10 major publications, and several minor ones, during the duration of the project license. As this data goes into our long-term database, the likelihood of more outputs after the duration of the project license is close to 100%. Thanks to the nature of the longitudinal data, I anticipate that these data will contribute to publications throughout the next decade and beyond.

The data from the wild will give us unprecedented insight in the ageing process of natural populations the so-far elusive trans-generational effects of ageing. There is currently keen interest in each of the individual aspects of the proposed study, in particular trans-generational effects, and the epigenetic mechanism. Only a "natural laboratory" of the type I use, where we can collect data and samples over a long period of time allow these questions to be pursued in a realistic framework.

Furthermore, our work routinely now contributes to an online database that is (on request via a dedicated website) openly shared with other reserachers in the field. The data from this project will contribute to this database, and as such reduce the need for similar data to be collected in other projects.

Who or what will benefit from these outputs, and how?

The nature of this rare data on a long-term population, recent advances in statistics, theory, molecular and genetic methods, mean that I expect to answer several major, longstanding questions that are likely to be of wide interest, both to the research community and to the wider public. Among other end-users, the results will be of most

immediate significance to conservation biologists who require the tools to manage the consequences of human induced global change. Furthermore, the results will also add significantly to the body of knowledge on the house sparrows, a species that, though still numerous, has been declining rapidly and without explanation in recent years in the UK and many other European countries. The results should also contribute significantly to our understanding of the evolution and maintenance of the differences in ageing rates, which is a big question in biology, in gerontology, reproductive biology, and even in sociology and politics. This study will improve our understanding of the evolution of ageing.

How will you look to maximise the outputs of this work?

To maximize the benefits from this work I will disseminate the results both through scientific publications and presentations and, where appropriate, the media and direct contact with the public. I have a good track record of publishing my work in high impact journals, including open-access journals, and of disseminating the results more widely, especially through press releases and subsequent interactions with the international media. I will publish our results in open access journals, or in journals with the gold standard open access policies. People who will be involved on this project will present the results at conferences, seminars, and workshops. We regularly hold outreach events.

Species and numbers of animals expected to be used

- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are studying animal behaviour, ecology, and evolution in wild animals. There is no replacement for studying the live and wild animals when we want to know their behaviour, reproduction and genetics, and their response to occurring environmental changes. This is very different from medical research where one is interested in a certain disease and uses a model system to study the disease. We study wild animal behaviour and per definition thus need to study wild animal behaviour.

We study house sparrows because they are gregarious birds, that easily accept nest boxes and thus are easy to study. A similar argument is made for blue tits. Both are central model species in the fields of ecology and ornithology (maybe similar to mouse and rat models in medicine).

There is a large knowledge gap especially in our understanding of ageing and trans-generational effects of age between findings in laboratory animals, and those in the wild. For a long time, it was thought that wild animals do not show signs of old age, but among others, my past research has proven this wrong.

To understand the evolution of trans-generational age effects, it is necessary to observe wild animals age, because firstly, captive laboratory animals are typically bred to reduce variance, meaning there is a reduced genetic diversity. This reduced genetic diversity will affect how individuals age, especially as e.g., mice or rats are typically bred to only live for a short time, thus unknowingly, in such strains, any senescence effects will not have been considered during selection processes. Furthermore, to understand how much mortality comes from catastrophic and environmental effects, and how much is due to senescence requires longitudinal sampling in wild animals, as the former does not take place in captive animals. Next, due to the lack of variable selection pressures we cannot use results from the laboratory to interpolate to the wild, requiring the use of wild populations to really understand the evolution of ageing.

Yet, using wild animals in the study of ageing is difficult because it requires longitudinal data - that is data on the same individuals sampled at multiple times throughout their lives. This allows one to distinguish effects of age that change within-individuals, from those effects among individuals. For instance, imagine a population of animals where young ones that are also small die at a higher rate than young individuals that are large. Any observer who would not know of this fact, and sampled cross- sectional (meaning, measuring individual's age and size only once each) would think that older individuals are larger than younger individuals, because none of the smaller ones live long. Then one would draw the wrong conclusion that individuals grow larger as they age. To avoid this pitfall in ageing research, one must sample cross-sectionally - sampling individuals repeatedly over time - termed longitudinal sampling (Fig. 1).

However, longitudinal sampling, thus repeated capturing, is exceptionally difficult to achieve, because wild animals are often highly mobile and might enter or leave a study area unbeknownst to the researcher. This is the reason we know so little about ageing in wild populations.

In this project, I will make use of two populations of birds well suited to overcome these problems. One of these populations of birds lives on an island far enough away from the mainland, for the birds to be unable to fly across such large stretches of water. As such, we can be confident that when we do not encounter a bird repeatedly, that it has died from natural causes. Furthermore, the island population is small enough that we can monitor all broods, mark all chicks that hatched on the island, and recapture every bird repeatedly. These features make this population an outstanding one to study effects of age, because know exact ages, and can repeatedly sample individuals as if they were in the laboratory - using this study system as a "natural laboratory".

Thus, the island population overcomes most of the problems one encounters when studying ageing, and trans-generational effects of age.

Another problem occurs when studying trans-generational effects of age: To disentangle the effects of genetic, behavioural, and epigenetics, one needs to conduct a minimally invasive (and unregulated) experimental procedure called cross-fostering. This means a subset of siblings from one brood will be distributed to other broods. That means, some chicks will be raised by parents that are not their own, while others will remain in their original brood. We can then look at how the chicks grow up, and if they are more similar to their foster parents, we can conclude that they these effects are inherited through the behaviour of the foster parents, while if they are more similar to the genetic parents, it is more likely a genetic effect.

In birds where the female sometimes cheats on her partner, there is one more factor at play: a chick can have a genetic mother and father, and a social mother and father. The social and genetic mother is always one and the same bird, but the social and genetic father do not need to be the same individuals - if she cheated, the social father (the male bird tending to the brood the chick was born in) is not necessarily related to the offspring he raises - so called extra-pair offspring. We can detect such extra- pair offspring by taking a small blood sample and conducting a DNA paternity test. So, if we now cross- foster the extra-pair offspring to foster parents, this chick has three fathers: a genetic father, who only contributed his ejaculate, a social father, who took part in the incubation, and who cares for the social mother, and a foster father, who raises the young.

This allows us to make a more differentiated assessment of which effects are at play and allows us to confidently distinguish epigenetic effects of age from those introduced by parental care. Using cross- fostering and the genetic parentage, we can disentangle the effects of genetics, epigenetics, and environment in the house sparrows for most traits that are not highly variable. However, for this all to work well we need birds with large clutch sizes, to improve statistical power. The bird population on the island has a reasonably large clutch size, but it is a limiting factor. As such, I want to also use a different population of songbirds, of a species with an unusual large clutch size.

In short, I use the island population to better understand longitudinal effects of age, and the effects of parent ages on offspring. These birds need to be repeatedly sampled for their blood - as chicks for their DNA and for parentage analysis, and later repeatedly through life for a longitudinal database of biomarkers of age. I use the other songbird population to better disentangle the effects of genetics, epigenetics, and the environment. These birds only need to be sampled during breeding - chicks for parentage and biomarkers, and parents for parentage.

Typically, what will be done to an animal used in your project?

All birds will be caught in their nests before they fledge. We will measure and weigh the chicks, swab feathers and skin for microbiome samples, and then take a very small blood sample – only the blood sampling is a regulated procedure. When they are old enough, they will receive a passive-integrated transponder (PIT-tag) and rings from the British Trust for Ornithology (BTO). The BTO is a research institute combining professional and citizen

science aimed at using evidence of change in wild bird populations, to inform the public, and policymakers. The BTO is the only bird-ringing license granting institution in Britain and considered to be the strictest in welfare and ethics policies in the world.

The PITs are either embedded in their rings or implanted under the skin (99% of all birds receive this treatment). PIT-tagging is an unregulated procedure, and there is research in my study species that this does not cause lasting harm. The use of PIT-tags reduces the need to recapture birds as we know the birds are alive by detecting their presence when they feed at a feeder equipped with an antenna. The combined use of BTO rings and PIT-tags minimises identification errors, increases the amount of data collected and reduces stress to the animals.

After fledging, we attempt to re-capture birds every year, and on recapture we will register, and measure the bird, take another tissue sample for biomarkers (blood from the brachial vein under the wing), and swab again for microbiome samples. Males may be sampled for ejaculates (an unregulated procedure). The blood sample collected by using a very thin needle to pierce the vein under its wing until a very small drop of blood occurs, which we take up with a microcapillary by capillary action (no suction is involved). Then a cotton ball is gently pressed on the vein, and then wing is being held closed for a short while until the bleeding stops (typically within less than 2 minutes). The ejaculate is collected by gently stroking the bird's genital area, which typically induces ejaculation within 1 minute. The ejaculate is again taken up with a microcapillary. After this the bird is set free again.

Due to the nature of the project, some birds will be subject to repeated sampling, but there is at least 3 months' time between repeated sampling (on average 1.5 years).

All birds will be caught following the guidelines of the BTO, and all handling, ringing will be carried out by an experienced and bird ringer licenced by the BTO.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects are some handling stress during capture and handling, and potential discomfort by the needle prick and bleeding. The procedures are known to result in no more than transient discomfort and no lasting harm in wild birds.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild for both, house sparrows and blue tits.

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We study wild animal behaviour. Natural systems are extremely complex, and while population modelling is a very useful tool, one needs data from the wild to parameterize these models. We know nearly nothing about these types of trans-generational effects, this is a large knowledge gap.

Which non-animal alternatives did you consider for use in this project?

I often use population modelling in my work.

Why were they not suitable?

We have no data available for how to implement or parametrise these models. This is basic research, we do it because the parameters are unknown.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use state-of-the-art, Bayesian statistics to estimate how many individuals we need. Our study sites are chosen such that the populations are small enough that we can cover all individuals – needed for the parentage analysis and to know their exact ages.

We have estimated the number of animals as the maximal possible number of birds that may be present in the two different study sites. However, it is very likely that it will be much fewer birds than this. The nature of studying a wild population means we cannot for sure say how many birds we will catch.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use our past experience in combination with good practise in our field, and statistical power analyses, to ensure that the size of our population is sufficient to answer our research questions. Unfortunately, the NC3R's Experimental Design Assistant is not sufficient for our use as it does not allow for multiple environmental influences in data collected from the wild, nor does it include the complex genetic analyses we run. Therefore, we use specifically made software to estimate the numbers needed for the genetic analyses (e.g. pedantics package for R). We use state-of-the-art statistical models that allows us to make the best use of what data we have, thereby reducing the need to redo experiments. When working with wild animals one cannot tell beforehand which birds will be caught, and whether they will be suitable for analysis. Therefore, using advanced statistical methods that allow us to use all data drastically reduces the numbers of individuals that need to undergo the procedure.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Using already established long-term populations allows us to use a very large amount of already existing data of birds (ancestry, genotype, age, life history traits) that does not need to be collected again.

Similarly, to collect certain behavioural data we use PIT tags that allow to record presence and absence of birds without the need to recapture them, as such we have drastically reduced the number of recaptures and increased the amount of data. We currently work towards an even more efficient system that includes machine learning algorithms detecting individuals from videos, yet this is still in its infancy.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use house sparrows and blue tits. Both model species are suitable models for testing the proposed hypotheses: their basic biology is relatively well-understood, and our study population offers specific advantages. In particular, my island population is a closed population with no emigration or immigration making it an excellent “natural laboratory” in which I can study trans-generational effects of age.

We also in these species can use our accquired expertise from past studies. For instance, we now use PIT-tags and video analysis to reduce unnesseccary assessment of behaviours in captivity. This reduces the time the birds spend in captivity, and thus reduces stress significantly.

Why can't you use animals that are less sentient?

We are studying animal behaviour, ecology, and evolution in wild vertebrates. There is no less sentient replacement for studying the live and wild animals when we want to know their behaviour, reproduction and genetics, and their response to occurring environmental changes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The proposed procedures will have minimal impact and are central to our aim of understanding behaviour and genetics under the most natural conditions possible. We annually review best practices. We run an annual data workshop during which we review our data and assess whether our activity has welfare costs. From these data workshops I myself have published multiple studies showing that PIT- tagging and cross-fostering are not harmful. Studies by others have shown that the regulated procedure, handling, and ringing are not harmful. However, note that these data are reviewed regularly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We comply with the requirements of environmental regulators, the BTO. The BTO is a research institute combining professional and citizen science aimed at using evidence of change in wild bird populations, to inform the public, and policymakers. The BTO is the only bird-ringing license granting institution in Britain and considered to be the strictest in welfare and ethics policies in the world.

The procedures will be undertaken by staff employed on the project; these will include researchers, graduate students, field assistants and technical staff. Both of my current PhD students hold PILs linked with the old PPL, which encompassed the same procedures.

In addition to the relevant modular training all my staff are and will be trained by me and the BTO in field methods. All my staff that will handle, ring and sample birds will be training with our local BTO. It they do not already have one (which is often the case), they will be put forward for a BTO ringing license.

Over 2600 ringers (including myself) are trained by the BTO to catch and ring birds, a crucial quest for conservation. I and my staff are regularly assessed by BTO trainers to ensure our knowledge, skills, and handling protocol is state-of-the-art. Our BTO catching,

handling, and ringing licenses must be renewed annually, so training and assessment is reviewed annually.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I personally regularly review and revise our methods, read the respective literature, and adapt and improve where possible. I also discuss all these in my research group meetings and expect my staff to also keep up with all relevant and current research. We regularly study the impact of our observations on the wild birds on their behaviour, survival, and fitness, as this is crucial for my research to know.

97. Investigation into the inflammatory mechanisms associated with inflammatory bowel disease and intestinal cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Innate, Inflammatory bowel disease, bowel cancer, inflammation, mucosal

Animal types	Life stages
Mice	juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Inflammatory bowel disease (IBD) and gastrointestinal cancer develop through a complex interplay between host genetics, the gut microbiome and environmental factors. Over the last 15 years we have conducted a number of large genetic studies on patients with IBD, which have resulted in the identification of genes that increase an individuals risks of developing disease. The aim of this research project is to discover how these genes increase an individuals risk of developing IBD and cancer. We will focus our study on characterising alterations in the immune response, microbiome and environment, which have all been shown to be relevant to the development of human disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The cause of IBD and gastrointestinal cancers is still unknown even though we have now identified over 200 genes which increase the risk of developing the disease. We now realise that disease occurs through the complex interactions of genetics, microbiome and environmental factors. In order to determine how an IBD causally related gene influences cellular behaviour, the development of bowel inflammation, the microbiome composition and how the environment impacts on these responses requires the use of transgenic mouse models in combination with human studies and in vitro assay systems. Understanding the complex interplay between these systems will allow us to develop better screening protocols and identify new therapeutic opportunities.

What outputs do you think you will see at the end of this project?

Major outputs from this study

1. We will gain a greater understanding of mucosal immunity

2. We will gain a greater understanding of the processes involved in mucosal inflammation and how this can lead to the development of cancer.

3. We will identify drugs and microbes which can manipulate the immune response in the bowel to either regulate the development of inflammation and/or impact on cancer development.

4. All of the results that are generated will be freely available to the scientific and medical community through presentations and published scientific papers.

Who or what will benefit from these outputs, and how?

In the short term 2-5 years

The study will benefit the scientific and medical community through the generation of novel data on molecules previously unrelated or poorly characterised in the fields of mucosal immunity, inflammatory bowel disease or cancer. Investigators in similar fields could make use of the genetically modified mice, immortalised bone marrow cell lines and mini-gut organoids developed during the study.

In the medium term 4-8 years

The pharmaceutical industry will be able to use the data to help design therapeutics that would directly target the molecules we have identified or the processes which they are involved with. These studies would need to undergo testing and screening, which could make use of the genetically modified mice, immortalised bone marrow cell lines and mini-gut organoids we developed during the study.

In the long term 8-12 years

New therapeutics for the treatment of inflammatory bowel disease and gastrointestinal cancer.

How will you look to maximise the outputs of this work?

We will set up collaborations with other investigators in the field and in associated areas which could benefit from our expertise and cell lines. We will disseminate our findings both positive and negative through manuscript preparation, poster presentations and public seminars.

Species and numbers of animals expected to be used

- Mice: 2300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to study the mechanistic role of molecules identified as associated with human inflammatory bowel disease and gastrointestinal cancer you need to use appropriate animal models. These diseases involve a whole host of different cells from the local gastrointestinal tissue and the circulatory cells. It is currently not possible to study these diseases in a cell based system so we have designed the experiments in mice. Mice are the least sentient, and most understood (in terms of gene expression and gene modification and cell labelling) animals that represent mammalian biology. The models we have incorporated have been shown to be very reliable models of human disease and capable of providing mechanistic insight into how inflammatory bowel disease and colorectal develop in humans. The models use adult mice as these have a fully developed immune system and are able to develop and recover from colitis, which replicates the human condition. This makes it possible to study the induction and recovery processes in these animal models as well as test the effects of potential therapeutic compounds.

Typically, what will be done to an animal used in your project?

Typically, genetically modified mice will be bred in our facility and maintained until needed and then transferred into an experimental protocol. An animal enrolled in our experimental protocol will typically be given an agent that generates inflammation within its lower gastrointestinal tract, via their drinking water or via direct oral administration. Animals in these procedures will typically be involved for 2-3 weeks. The mice may also receive an intra peritoneal or intra venous injection of a cancer promoting or immunomodulatory drug, which will alter the development of the gastrointestinal inflammation and development of the cancer. The duration of the cancer experiments are up to 6 months as the process is relatively slow and is designed to replicate the human condition. Typically a mouse will

undergo 2 (one of which is breeding) and in some instances 3 procedures (Breeding > Bone Marrow Transplantation > Bowel/Sterile Inflammation/colorectal cancer development).

What are the expected impacts and/or adverse effects for the animals during your project?

The mice will develop a colitis like inflammation in their colon which will last for approximately a week in wild type mice and this may differ for genetically altered animals. During the colitis animals will experience moderate discomfort and will lose body weight and show signs of a loss in grooming.

These symptoms will be closely monitored and now allowed to exceed our severity limits. The colitis typically fully resolves after two weeks in wild type mice. In the case of gastrointestinal cancer development, the initial stage involves the injection of a cancer promoting agent in combination with the development of colitis. In the initial two weeks animals will experience moderate discomfort and will lose body weight and show signs of a loss in grooming. These symptoms will be closely monitored and not allowed to exceed our severity limits. The colitis typically fully resolves after two weeks in wild type mice. Over the following 18 weeks tumour will develop in the colon. The tumours will grow slowly and in most cases they will not impede the mouse and normal behaviour, such as feeding and grooming will still continue. They may experience some periods of ill health if they respond poorly to any substance we give them to study/ influence the behaviour of the cancer development. This should be transient, but some mice may experience some weight loss or digestive abnormalities, but this should not persist. Tumours should develop by the 20 weeks, but animals will be sacrificed once they start to show signs that the disease has progressed to an intolerable stage before this time point if necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect that all of the mice involved in the experimental protocols (~75%) will not exceed a moderate severity level and mice used for breeding purposes (~25%) we expect will be mild or sub- threshold levels.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We only perform experimentation on animals when there is no human equivalent or where it would be impractical to study humans. For example, where specific genetic lesions have been produced resulting in the deletion or modification of a protein that might be important in a regulatory signal transduction pathway.

Which non-animal alternatives did you consider for use in this project?

Where possible, we use cells from sources other than laboratory animals. In my laboratory we are doing many experiments in human volunteers and patients with inflammatory bowel disease. These studies have included culturing cells from peripheral blood, rectal biopsies and injection of bacteria subcutaneously. It is our preference, and greatly to our advantage, to use human rather than animal cells. They are cheaper, can be obtained in much greater quantities, and to a higher level of purity. We are also now using CRISPR/Cas9 and RNAi technologies to attempt to deplete cells of specific gene products as an alternative to animal gene targeting studies.

We have also introduced mini-gut organoids that allow us to study the immune mechanisms of the colonic epithelial cells. This approach does require a small number of mice (1-2 per strain), but the mini-guts can be maintained in culture for months greatly reducing the numbers of mice needed for our experiments.

When we acquire a new mouse strain we now generate an immortalised bone marrow cell line which can be used in place of the traditional bone marrow derived immune cells. This means we do not have to breed mice in order to generate a continual supply of these cells during the project.

Why were they not suitable?

It is not possible to substitute the colitis and inflammation derived cancer mouse models for an in vitro (organoid/cell line) alternative. Both models require the complex interplay between the tissue, immune system, circulation and the gut microbiome. We are able to conduct mechanistic studies in vitro and have set up the required systems to do these without the need for large numbers of mice.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of the mouse models and protocols are already well established in our project. We have generated a substantial amount of experience at running these types of experiments and have used this knowledge to make sure we collect the maximum amount of information and data from the minimum number of groups and animal. We have identified the most relevant time points during the models of colitis and sterile inflammation induction and this information will allow us to design experiments with the minimal number of animals needed to provide robust and statistically relevant data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In all instances we will adopt the best possible practice on the principles of experimental design whenever possible.

In circumstances where we need to investigate new substances, we will adopt the following best practices:

- The initial doses of any test substances or organisms will be determined through literature search.

- Pilot studies will be performed, starting at a low dose and then increasing doses of substances or organisms for each appropriate route of inoculation, in groups of 2 animals, to establish an effective dose for test substances or appropriate bacterial load (Colony Forming Units – CFU) for each strain of animal. Initially the mutant mice will be infected with a dose of organisms below that producing symptoms in wild type animals and the effects observed in 2 mice. Not all organisms will be tested with all therapeutic agents. In general, the response to all agents will be determined with one organism. Positive effects will be examined with the other organisms.

- Once the dose required to produce a clinically identifiable response has been established, the groups of animals will be increased to numbers which provide sufficient numbers to enable identification of any significant differences.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In close collaboration with our biological services staff we will maintain an efficient breeding programme. All of our mouse strains will be on the same genetic background, which means that wild type control mice can be shared across multiple GAA experiments. Wherever possible, we have attempted to perform multiple measurements from the same dataset (applying the appropriate corrections) and to compare multiple treatments to the same control, reducing the number of control animals required.

We based our sample sizes on estimates of effect size and variability from previous data from our laboratory. However, this is just an initial estimate, and we fully expect that our understanding of the data will increase over the project. As this happens, we will refine our

sample size calculations and either use less animals, if possible without reducing scientific significance, or seek permission to enrol more animals in the study if higher numbers are needed.

We have implemented a new research protocol that can generate an immortalised cell line from a single mouse (Nat Methods. 2006 Apr;3(4):287-93). Each mouse strain has a corresponding cell line generated and these in vitro lines are used for validation and mechanistic studies without the need for additional mice. We will also generate mini-gut organoids from a single mouse from each strain. The mini-guts can be maintained in culture for many months and can be used to study cell-cell interactions and epithelial cell immune responses. The use of mini-guts will reduce the numbers of mice we need to breed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All methods used in these studies use standard protocols which have been published and the overall severity has been determined as “moderate” for all experiments. Methods have been chosen that most closely resemble the human diseases we are interested in. They will provide results which will increase our understanding of human inflammatory disease. If the animals appear ill (hunched, depressed, lethargic, exhibit pilo-erection or become anorexic) for more than 24 hours, or loses 20% of their body weight, they will be killed by Schedule 1 method. Ill animals will be offered particular care. If deemed necessary by the NVS and NACWO, extra bedding material and soft diet may be provided to keep the animals comfortable. The levels of colitis causing drugs and bacteria have been determined through a number of pilot studies previous performed by our group. The levels chosen will produce the minimal pain, suffering and distress on the wild type mice, but importantly still permits us to study the immune response and diseased tissue. The effects in genetically modified animals will be unclear and pilot studies on groups or 2 mice will be used to ascertain the levels needed in these animals to generate the desired response.

Why can’t you use animals that are less sentient?

In order to study the development of inflammatory bowel disease and inflammation driven cancer we require an organism with a similar immune system to humans. Mice are the obvious choice as they can be genetically manipulated and have been shown to develop

colitis and colorectal cancer that closely replicates the diseases in humans. We plan to manipulate the immune system and the majority of drugs and modulators have been developed either in mice or humans. Due to these reasons the use of less sentient animals would not be appropriate in this project.

We have used zebrafish larvae in previous studies to study bacterial infection in the gut, but this model cannot be used in this instance due to a lack of a suitable model for inflammatory bowel disease and colorectal cancer. In addition, a number of genes we are looking at are only expressed in mammals making the fish and invertebrates unsuitable for the study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
