In all of our protocols we maintain a high level of monitoring during periods when the animals are at a risk of moderate levels of suffering. In addition, all of our procedures have well defined end points, which involve culling the mice with an appropriate schedule one method. This is at a specific time point or at an earlier humane endpoint based on the level of suffering.

In some instances, ill animals will be offered particular care. If deemed necessary by the NVS and NACWO, extra bedding material and soft diet may be provided to keep the animals comfortable. In the event that the diagnosis and any subsequent treatment taken on NVS and NACWO advice failed to remedy the ill-health of the animal, it will be killed by an appropriate schedule one method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our Biological service unit has a series of guidelines regulating many of the procedures routinely done to animals, for instance how often an animal can receive an injection, where, and how much, or how often it can give a blood sample. We will follow all of these, as well as other standard operating procedures that were developed by specialists at our institute for the explicit purpose of minimising animal suffering, and are periodically updated.

How will you stay informed about advances in the 3Rs, and implement these advanceseffectively, during the project?

Our university routinely circulates advances in the 3Rs and hosts seminars on experimental design and 3Rs. We will always seek to identify ways the 3Rs can be incorporated in our project, while ensuring they do not impact on the (statistical/ biologically relevant) consistency of our data.

98. Cell surface receptor functions in fertility

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

receptors, fertility, reproduction, sperm, egg

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to increase understanding of the role of cell surface and secreted proteins in fertility.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infertility affects 1 in 7 couples in the UK, and also just under half of all pregnancies in the UK are unplanned. These issues cause enormous emotional stress and result from an incomplete understanding of the biological process of fertilization and fertility.

What outputs do you think you will see at the end of this project?

We anticipate that at the end of this project, we will have identified new fertility genes that will contribute to the generation of new scientific knowledge that will be published in scientific journals. This information could also be used to diagnose infertility and thereby provide answers and guide the most appropriate fertility treatments for infertile couples.

Who or what will benefit from these outputs, and how?

Our work on surface molecules in fertility has identified two new genes (Juno and Adgrd1) that can already be used to diagnose infertility in women who are unable to conceive. Within the short term, perhaps within the lifetime of this licence and the next few years, we envisage that further work in this area will increase the number of fertility genes that can be used in these diagnosis. Over the longer term (several years) the research described here will contribute to strategies to develop new fertility treatments and contraceptives.

How will you look to maximise the outputs of this work?

All of the data from our animal experiments will be published in open access journals thereby increasing the exposure and reach of this research to other scientists across the globe. The research is regularly presented to other members of the scientific community in conference presentations and seminars. Where appropriate, upon publication of the research a press release will be made to inform the general public of the advance. We will also use some of the more recent vehicles for publication which enables the publication of negative data to maximise the dissemination of our research.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All the research outlined in this project will use mice as an animal model. Mice are a suitable model for these studies because they are mammals, and almost always contain a recognisable counterpart to any human proteins that we identify in our in vitro screens. Mice have a long history of making important contributions to the understanding of human biology and many valuable resources such as gene- deficient mice are available. Therefore they enable us to make scientific advances with an increased confidence of

correctly interpreting the outcomes of experiments designed to discover new treatments and therapeutics to improve human health. We will mainly use adult mice because they are fertile but some work on eggs and embryos will be necessary.

Typically, what will be done to an animal used in your project?

Animals will receive vaccinations with the aim of inducing an immune response to generate antibodies. Typically, individual mice will receive an initial vaccination followed by two booster immunisations. It will usually be necessary to take small amounts of blood to assess the antibody responses. These procedures are very similar to those that are given to babies and children as part of their routine vaccinations. Animals will be superovulated by the injection of hormones similar to the procedure used to superovulate women undergoing fertility treatments. In a few cases, surgery will be used to gain access to the reproductive tissues so that the mechanism of infertility can be established; for example, this will address if there a problem with sperm-egg fusion, embryo transport, or embryo transplantation.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of procedures, we expect that the animals will experience no more than mild transient discomfort during the procedures. Where surgery is required, this will be done under general anaesthesia and the latest surgical techniques.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not expect that any procedure will exceed the moderate category. The vast majority of procedures performed under this licence (>95%) will cause only mild and transient discomfort to the animal, we estimate that the remaining 5% will experience moderate levels of suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals to make antibodies because non-animal alternatives typically result in antibodies whose properties are not adequate for our work. We need to use animal models to study fertility because there are no suitable alternative models for sperm and eggs that would allow us to study fertilization nor investigate the transport of embryos in the mammalian oviduct.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of some antibody selection systems that do not require the use of animals, but these alternatives aren't adequate for our research. To study fertilization and embryo transport, there are no suitable alternatives that do not require the use of animals.

Why were they not suitable?

We have found that antibodies generated without animals often have lower binding strengths and so they are not suitable for our purposes (see Appendix 1 for a scientific justification). It is not currently possible to use non-animal alternatives to investigate fertilization or the transport of embryos through the oviduct.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Making good quality antibodies requires a significant investment in research time and we will not generate more than three antibodies per year. Each antibody would usually require immunising around five animals to ensure at least one animal has an appropriate immune response. Allowing for additional attempts, this totals ~50 mice over 5 years.

To investigate fertility, the group sizes used will be established according to effect size of the phenotype under investigation. For those genes that result in complete sterility, which are the genes of greatest interest to us, the group sizes can be kept small because they have such a strong effect size. In these instances, the group sizes are usually less than ten. We estimate that we will use no more than 250 animals for these experiments: 200 for superovulation and 50 for embryo transfers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals that we require to make antibodies, we have developed a method of making more antibodies at one time in fewer animals. This works by immunising animals with mixtures of proteins and identifying those secreting specific antibodies at the selection stage. To produce oocytes (eggs) for IVF assays, we will use superovulation to increase the number of eggs that we can obtain per mouse, which reduces the total number of animals required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where we require multiple monoclonal antibodies at once, we will consider co-immunising mice with protein mixtures to reduce the number of animals that we require. For fertility investigations, we may perform one type of experiment on one of the two oviducts. Where appropriate, we can use the other oviduct from these mice for other types of experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using adult mice to study sperm - egg interactions using in vitro fertilization. It is necessary to obtain sperm and eggs from mice to acheive this. Sperm and eggs are obtained by a terminal procedure and so there is no long-term suffering or pain. Where we need to access the female reproductive tissues using surgery, we will do this using general anaesthesia and the latest surgical techniques to minimise any suffering or pain.

Why can’t you use animals that are less sentient?

We cannot use animals that are less sentient than mice because we require the use of a mammalian species which contains an adaptive immune system to make useful antibodies. For our fertility research, it is known that mice contain orthologous proteins to humans that are involved in fertility and so the discoveries that we make in mice can be applied to humans - this would not be the case using fruit flies or nematodes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will be refined by continual improvement and discussions with the scientists and animal technicians, NACWO and NVS to create a culture where the welfare of the animals is central to experimental design. Regular training and protocol review will ensure that any refinements will be implemented promptly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The National Centres for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) web site provides a resource of up-to-date protocols, publications, guidelines, videos and other information that enables the rapid dissemination of the most up-to-date best practices.

Discussions with other scientists at conferences and within the establishment will ensure that improvements in local practices are quickly implemented. Examples of where procedures have been recently refined are the single use of needles, providing enrichment in the cages (fun tubes, mirrors, blocks, food as seeds), adopting tube handling, and use of animal body cues such as the grimace scale to observe pain.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly discuss refinements for animal experiments with the NACWO, NVS, and animal technicians. We will keep abreast of developments discussed and implemented by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) through their monthly newsletters and blogs. The animal facility holds regular forums and updates on the current best practice and latest developments.

99. Cell biological pathways in neurodegeneration

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Late-onset neurodegeneration, Cell biological pathways, Primary cultures, Genetics, Tissue analysis

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will establish cell biological function and dysfunction of biological pathways that are implicated by genetic analysis, including genome-wide association studies (GWAS), in late-onset neurodegenerative diseases such as Alzheimer's disease (AD) and Parkinson's disease (PD). A particular focus will be on changes in the movement of cellular components along cellular membranous structures and signalling function in neuronal and immune cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

AD and PD are degenerative disorders of the brain that lead to progressive physical decline and cognitive impairment. Currently there are no disease modifying treatments for either condition that stop or slow disease progression. PD and AD affect 4% and 20% of the population over the age of 80 respectively, and so represent an increasing healthcare challenge as the life expectancy of the UK and global population increases. As the disease progresses, brain dysfunction and neuronal death increases, but the reasons why this occurs are not clear. This is an important gap in our knowledge, as in order to develop new treatments that can halt or slow neurodegeneration, we need to understand the molecular events underlying pathogenesis. The ultimate goal of this project is to lay the foundations for the development of novel drugs that can slow down the rate of disease progresses and improve the quality of life for people suffering from late-onset neurodegenerative diseases.

What outputs do you think you will see at the end of this project?

We want to define how neurodegeneration risk factor proteins come together to control cell biological function, and how inherited genetic changes in these proteins causing neurodegenerative diseases such as AD and PD disrupt this. This new information will be made available to scientists, patients and carers at national and international conferences and open access publications.

Who or what will benefit from these outputs, and how?

Our ultimate goal is to use this information to lay the foundations for the development of novel drugs that can slow down the rate at which neurodegenerative diseases progress, delaying the worsening of symptoms and improving the quality of life for people with these diseases.

How will you look to maximise the outputs of this work?

My work will benefit from ongoing long-term national and international collaborations with cell biologists and electrophysiologists on Parkinson's and Alzheimer's disease respectively. In addition, recently strengthened national collaborations through shared supervision of PhD studentships with molecular neurobiologists and bioinformaticians, who have extensive experience in cell biological pathways in late-onset neurodegenerative diseases will support the research strategy of this project further.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project requires the use of juvenile and adult mice to establish the underlying mechanisms and progression of neurodegenerative diseases. Mice are the species of choice primarily because they are routinely used for laboratory investigations of genetic defects in the CNS, for which a considerable amount of experimental data on neurodegeneration has already been gathered. Mice are also the standard species for generating genetically modified animals. The genetically modified mice we use have shown no clinical signs to date. In addition, all chosen procedures cause in general no harm to the animals. In the unlikely event of any adverse effects the mice will be treated. If this fails to alleviate symptoms mice will be humanely culled. The data we generate in mice can provide more information about human disease states and can be compared to other studies using models of neurodegeneration. We will generate tissue cultures and use tissue from these animals for our experiments. This will provide a reliable and consistent source for generating data on the underlying mechanisms and progression of neurodegenerative diseases.

We have collaborations with colleagues working on PD genes in drosophila that inform our work in mice and also considered further the use of invertebrates for our aims. However, use of drosophila and C.elegans while in general useful for investigations of neurodegeneration are not suited for our investigations. For example, whereas mice and humans carry the LRRK2 PD and LRRK1 genes, drosophila and C.elegans only carry one lrk gene. In addition, cell signalling such as Wnt signalling is less complex in invertebrates in comparison to mice/humans. e.g., drosophila only carries one dsh gene, humans/mice possess DVL1, DVL2 and DVL3. The consequence is that loss of function of Wnt components in dropsophila leads to often severe developmental changes whereas phenotypes in mice can be mild e.g., DVL1 knockout mice show mild behaviour changes.

Typically, what will be done to an animal used in your project?

Typically, mice with genetic modifications (GA mice) causing neurodegeneration in patients will be bred. The offspring will be used for the generation of primary cell cultures. Some mice will be injected with lentiviral biosensors to record activation of different cell signalling pathways. The injection of lentiviral biosensors is preferred to backcrossing the animals to diverse cell signalling reporter strains as this would require the use of additional animals for every signalling pathway investigated.

Alternatively, mice will be genotyped to identify wild type and genetically modified mice. These mice will then be aged for different amounts of time and terminally anaesthetised to obtain brain tissue for further analysis. In a subset of experiments we will treat these mice with lipopolysaccharide (LPS) to mimic infection/immune stimulation and thereby

reproducing conditions considered to be important in the environmental genetic interaction leading to neurodegenerative diseases through immune modulation.

What are the expected impacts and/or adverse effects for the animals during your project?

The transgenic mice used in our experiments have not exhibited or are expected to exhibit any abnormal behaviour or show signs of distress. These mice breed and develop normally. Further, terminally anaesthetising mice to obtain the brain tissue is expected to cause minimal distress.

Some mice will have to undergo injections of biosensors to record cell signalling changes and/or LPS to induce peripherally neuroinflammation and potentially increasing neurodegeneration in our genetic models. These are standard procedures causing potentially mild discomfort at the injection side and potentially mild to moderate reactions in response to the LPS induced inflammation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding of transgenic mice and obtaining brain sections from mice is likely to cause minimal distress and is therefore likely to be at most of mild severity. This will apply to approximately 70% of the animals that we will use.

We estimate that 30% of will undergo LPS and/or biosensor injections. Injections might cause pain categorised as mild as it might result in some temporary discomfort to animals. LPS can potentially cause inflammatory reactions that could be mild or moderate. However, the C57BL mouse strain we use is resistant to this effect of LPS.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

One of my key questions is what happens when cell biological functions, including signalling cascades, are up- or down-regulated in vivo? In order to address this, we will

investigate changes in a complex cellular context e.g., innervation from different brain areas and also interaction of the brain with peripheral and CNS immune cells. In addition, PD and AD are late onset slow progressive disorders. Therefore, pathogenic changes need to be observed over longer periods of time during development and ageing. Currently, complex interactions between different components of the immune system, different cell types in the CNS and communication between peripheral and different CNS regions cannot be achieved in cell cultures. However, we will whenever possible use cell culture methods to inform in vivo treatments.

Which non-animal alternatives did you consider for use in this project?

In vitro experiments will whenever possible be conducted in immortalized cell lines including patient derived induced pluripotent stem cells (iPSCs) if applicable to inform experiments in animal models.

We also use in silico advanced computer models in particular Protein Protein Interaction (PPI) network and expression analysis including data from post-mortem human tissue to inform our animal experiments.

Why were they not suitable?

In-vitro assays cannot adequately model the complete array of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modification results in normal or abnormal processes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have taken precautions to reduce the number of animals to the minimum required for reproducibility and to obtain quantitative data from our analyses. We establish conditions for assays on wild-type mouse tissue to reduce the use of GA animals and provide preliminary data on expected variations.

This way we obtained data on 3-6 animals per group showing significant ($p<0.05$) differences in protein levels between GA and control animals.

Our work using immune modulators requires us to establish optimal conditions before any reliable statistical calculations can be attempted. Nonetheless, published literature suggests that differences between genetically modified animal models of

neurodegeneration and controls will be more pronounced under activated than under basal conditions, suggesting that required numbers will be no more and likely less than the number required to establish significant differences under basal conditions.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will be able to use several brain areas, additional organs and/or blood for immune cell isolation form the same animal reducing the total amount of animals required. We estimate that one animal is required to produce three of the required data sets e.g., in brain, spleen and bone marrow derived macrophages.

The minimum number of animals needed to achieve statistically significant results will be based on the statistical analyses. If possible, means and standard deviations from previous experiments or the literature will be taken for power calculations. However, when working with novel immunomodulatory treatments, preliminary experiments (cohort no larger than 3) will be carried out. Animals will receive a specific dose of e.g., LPS and compared with a matched control group. The optimal dose may then be adjusted, and further animals added. This will also provide information on effects and potential side effects of different components. Once repeatability is gained for components with minimum severity the dose will be applied to an experimental cohort. This will reduce total animal number and constantly refines our protocols.

If indicated we will perform power calculations using programmes such as G*Power.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Evaluation of outcomes from preliminary experiments will determine subsequent group size as defined by power calculations using standard deviations from the preliminary experiments. This will be done using recognised statistical packages using a statistical significance of at least $p<0.05$ and a power of 80%.

Experimental design will include appropriate controls to allow detection of the effect of change of individual variables.

Statistical analysis will be performed using both parametric and non-parametric methods depending on data distribution. For the use of multiple groups we typically utilise an ANOVA test, for comparisons of 2 groups we often utilise a student’s t-test.

We ensure that any tissues generated from previous experiments are archived and stored appropriately ensuring that unnecessary repetition of experiments is avoided.

As part of good laboratory practice, a protocol for each experiment including statements of the objective(s); description of the experiment, including experimental treatments, the size of the experiment, and experimental material; and an outline of the method of analysis of

the results will be obtained prior to acceptance of experimental protocols by the PPL holder.

Animals will only be bred if a user requirement has been established, and the breeding programme will be subject to regular review to optimally meet anticipated demand. Spare animals will be made available for use on other scientific projects. Breeding will be optimised, wherever possible, to produce only the genotype required e.g. Homozygous breeding pairs.

Most experiments, involve breeding transgenic mice. These are heterozygotes to generate a mixture of wildtypes, genetically modified mice and heterozygotes. We use wildtypes and genetically modified mice for our experiments. However, we cannot determine the numbers of these generated by a given breeding pair. From our experience, we need to keep at least 4 breeding pairs per colony to allow generation of the required numbers of animals for all our experiments and for the colony to be maintained. Hence, the number of mice estimated for breeding is based on our current experience of the number of mice produced using 4 breeding pairs per mouse colony.

Animals used for breeding and experiments are group housed in enriched environments. This allows animals to be relatively relaxed, thereby ensuring that we get good quality tissue from them and obtain the maximum amount of data from each animal.

For pharmacological agents that we have not used previously and for which there is no publicly available data, we will carry out pilot experiments to optimise these experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most appropriate model species for this investigation as they are the lowest animals in the evolutionary tree with suitable models of PD and AD cell biology and signalling. No use of species phylogenetically closer to humans is proposed.

We will be using genetically modified mouse models for our work. The GA mouse models of familial neurodegenerative diseases we have chosen are well documented, readily available and used as disease models by researchers worldwide. The genetic modifications have been shown to have little impact on breeding and the animals have a normal lifespan and are able to eat and drink normally.

Mice will be genotyped where possible using ear snips. Under exceptional circumstances such as genotyping of neonates where due to limitations of DNA extractions genotyping might not be possible using this method, tail snips might also be used to genotype animals if required. To reduce distress via this method, we will apply a local anaesthetic to the tail end before obtaining the snip

Other than injections the mice will not receive any surgical intervention. For example, lentiviral injection at the first day of life (P0) is a short procedure, and therefore animals recover instantly. We have used lentiviral biosensors over the last 5 years and have not observed any adverse effects.

In general, components anticipated to be used under this PPL will consist of routinely used compounds such as LPS, and compounds modified from routinely used compounds including compounds with neuroprotective potential. Therefore, administration of any compound is not expected to produce more than mild adverse effects.

We will use treatment to modify protein activity in cells. We will only do this if the agents have been shown to be safe and not cause any long-lasting harm to animals. In particular, some transgenic mice will be administered routinely used immunomodulatory substances such as LPS. Any compound previously not in routine use will be tested in a small number of animals prior to being applied to an experimental cohort to refine protocols so that repeatability is gained with minimum severity. To minimise adverse effects of injections, we have optimised procedures where necessary by using appropriate local anaesthesia, aseptic techniques and administering analgesics to reduce infection if required. We find that using these conditions, animals are not distressed.

To quantify the effects of genetic modifications or treatment, we will obtain tissue from animals. To obtain good quality tissue, we will terminally anaesthetise animals before embarking on this procedure. This will ensure that the animals experience little distress during this process.

Why can’t you use animals that are less sentient?

We will be investigating cell biological function when possible by setting up primary cultures from embryonic stages or mice at the first day of live (P0) or the following day (P1). We will be investigating effects of genetic and environmental changes on late onset neurodegeneration. Therefore, we will also require adult mice to obtain tissue after terminal anaesthesia.

We also considered the use of invertebrates. However, use of drosophila and C.elegans while in general useful for investigations of neurodegeneration are not suited for our investigations. In addition, we have collaborations with colleagues working on PD genes in drosophila that inform our work in mice.

For example, whereas mice and humans carry the LRRK2 PD and LRRK1 genes, drosophila and C.elegans only carry one lrk gene. In addition, signalling such as Wnt

signalling is less complex in invertebrates in comparison to mice/humans e.g., drosophila only carries one dsh gene, humans/mice possess DVL1, DVL2 and DVL3. The consequence is that loss of function of Wnt components in dropsophila leads to often severe developmental changes whereas phenotypes in mice can be mild e.g., DVL1 knockout mice show mild behaviour changes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Biological Services unit staff and/or research staff monitor animals housed in the Biological Service unit daily. If animals are observed to be experiencing distress, we monitor these more regularly. The NACWO and/or NVS might be consulted.

For at least 5 days post injection, animals are regularly monitored twice a day for signs of distress. Moreover, they are weighed daily to ensure that they are feeding and developing normally. They are group housed in environmentally enriched cages.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will following Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines which have been published and are available on the NC3Rs website.

In addition, we will follow the published Animal Welfare and Ethical Review Body (AWERB) guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I and researchers working with me will continue to attend seminars run by NC3Rs representatives such as regional managers. In addition, we will check blogs, internal and external webpages, and other current or new resources when they become available. We also discuss NC3Rs at our local BSU user meetings. Further, we are in regular contact with the Named Animal Care and Welfare Officer (NACWO) and Named Veterinary Surgeon (NVS) who will also provide advice on how to implement advances in 3Rs during the project.

100. Exploring the role of the cell surface molecule podoplanin in fibroblast-macrophage cross talk in arthritis

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Arthritis, Inflammation, Podoplanin, Fibroblasts, Macrophages

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to explore the role of a new family of cellular targets expressed on fibroblasts and macrophages that enhance joint inflammation or promote its resolution during arthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is now clear that the persistence of inflammation can also occur both as a result of insufficient production of anti-inflammatory mediators as well as the more traditional mechanisms of excess inflammatory mediators These observations have important implications for the way in which we treat chronic inflammatory diseases. Much like a diabetic is given insulin to replace the insulin they can no longer make, we could start giving naturally derived anti-inflammatory mediators to individuals with chronic inflammation to restore and replace the ones that they are no longer able to make enough of. In this way we would be replacing good pathways rather than just blocking bad pathways to restore healthy joints.

Biological therapies (such as anti-TNF) have transformed the lives of patients with Rheumatoid Arthritis (RA). However, their effect is transient, and relief is partial. There remains a pressing need for effective, treatments that really cure as opposed to just treat RA. Our patient partners have explained to us that while current treatments are good at reducing inflammation in their joints, they are not as effective in reducing pain and restoring joint function.

Our preliminary work has identified new molecules on the surface of cells that reside in the joint which regulate joint inflammation and help the resolution of arthritis. However more studies are needed to better understand the cellular and molecular mechanisms involved in these processes. In this way we will be able to evaluate the efficacy and safety of reagents that not only block inflammation but also promote the processes that help to resolve it. This will place us in an ideal position to develop new therapeutic strategies that permanently switch off arthritis and ultimately cure inflammatory arthritis such as Rheumatoid Arthritis.

What outputs do you think you will see at the end of this project?

The work to be carried under this licence will:

Drive a clearer understanding of how arthritis starts and develops by evaluating the role of a new family of cells and molecules by exploring the cellular mechanisms that trigger inflammation or promote its resolution.

Determine new cellular and molecular targets related to fibroblast-macrophage cross talk which will help develop new therapeutic strategies to cure RA.

Provide new scientific findings on the mechanisms that drive the resolution of inflammation in RA that we will disseminate to the scientific community through oral presentations and posters as well as high impact scientific publications.

Who or what will benefit from these outputs, and how?

- Pathways to Impact
- Short-medium term

Scientific developments and innovations leading to our enhanced understanding of the role of immune effector fibroblasts in inflammatory arthritis described in this licence will have an immediate impact on the ongoing projects at the host organisation, and further afield upon dissemination. Moreover, the project aims to improve our understanding of the processes driving pathology in chronic disease, specifically disease pathways mediating the persistence of joint inflammation that we anticipate will underpin the development of the next generation of anti-rheumatic therapies.

Medium-long term

We intend to invite external seminar speakers who have an interest in the role of fibroblasts in chronic inflammatory diseases to our organisation, with the view of fostering further collaborations based on the concepts and ideas incorporated in this proposal. We envisage that these collaborations will occur during and following the completion of this project, and therefore represent a medium to long-term impact of this work. Using these collaborations, we will develop the infrastructure needed to translate these findings into clinical trials and ultimately, clinical practice, therefore fully exploiting the translational potential of this work.

Long-term

Clinical academics, pharmaceutical companies and patients directly will benefit from advances in our understanding of disease pathology and particularly why some individuals with arthritis do not respond to currently available treatments, along with identification of novel targets, which can be taken forward to develop new therapies. We will develop collaborative networks to realise the translational potential of our findings over the subsequent 5-10 years following the completion of this project.

How will you look to maximise the outputs of this work?

Collaborations: This project builds on a strong collaboration between three leading institutions. The members of these research teams, with a strong expertise in RA pathophysiology, will provide all the necessary knowledge, skills and abilities to deliver this project and translate the scientific discoveries into patient benefit.

Dissemination of new findings: We and our collaborators are planning to use different approaches to disseminate our research findings and maximise the uptake of our research by the scientific community and clinicians.

Explanation of project aims and presentation of data at professional meetings and conferences by either oral or poster presentations. This will allow us to raise awareness of our work, exchange knowledge and receive feedback that may be helpful for additional studies.

Publications of high impact papers in a peer-reviewed journals to reach the widest possible audience and be available permanently. Negative results will be also published to avoid

repeating experiments that are inappropriate for the topic or do not support the initial hypothesis.

Public engagement: Throughout the project, we will engage and involve patients and the public in our research who will participate in the dissemination of our research and provide a powerful voice. Our group has established patient research partners group who arrange regular seminars and events attended by patients with RA to enable the dissemination of our findings into a diverse audience.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse models of arthritis recapitulate aspects of RA pathogenesis in humans and have contributed directly to the development of anti-rheumatic therapies. Mice are the lowest mammalian model for human skeletal and immune systems in which we can test the impact of gene manipulation and evaluate the efficacy of therapeutic interventions. We use adult mice as they have fully developed joints.

Typically, what will be done to an animal used in your project?

We will use two main models of arthritis; induced (90% mice) and spontaneous genetic (10 %). Within the induced arthritis the majority of animals (80%) will undergo general anaesthesia (up to 10 minutes), daily handling for scoring and calliper measurements of joints and limbs; administration of an agent or cells to determine cellular function or therapeutic efficacy and will be killed up to week 8 via schedule 1 method or non-schedule 1 for withdrawal of fluids (e.g. blood).

Each experimental model will be monitored daily following intervention and mice will be assessed for any signs of distress with supportive measures provided. Procedures will be undertaken using the most appropriate anaesthetic and analgesia will be given. The mode of substance administration will be chosen to cause the least harm and distress to the mouse. Any new substances or route of administration will be tested in a small pilot study and the mice monitored daily for signs of distress.

Humane endpoints will be strictly adhered to.

What are the expected impacts and/or adverse effects for the animals during your project?

The maximum severity limit in this licence is moderate. Possible adverse effects include irritation from local injection, pain from joint inflammation, weight loss or mobility problems. All forms of arthritis cause joint stiffness and some degree of disability for the duration of the study, but refinements will be always provided prior to the start of arthritis experiments. Pain will be also managed using opiate analgesics with advice from the NVS.

Any animal showing deviation from normal behaviour as judged by; body weight, body condition, general and coat appearance, gait or behaviour will be treated with pain relief and administered food supplements in the form of gel or mash. Before pain and inflammation exceed a moderate severity level, animals will be killed to prevent any on-going pain. All animals will be killed at the end of the protocol with the exception of protocols 1 and 2 (Breeding and maintenance of genetically modified mice).

TNF-DARE transgenic mice, the spontaneous model of arthritis used in this project, will also develop inflammatory bowel disease and may exhibit signs weight loss 10-12 weeks of age. These mice will be monitored and scored for arthritis and systemic inflammation, and we will refine our approach with self- administered analgesic gel (but not NSAID) to prevent animal suffering and with advice from the NVS. They will be humanely killed no later than 20 weeks from the first sign of arthritis.

For induced polyarthritis models, animals will be killed by week 8 after first signs of arthritis via Schedule 1 method or non-schedule 1 for blood withdrawal. Not every joint is affected at the same time so these mice will be monitored and scored for arthritis and systemic inflammation weekly and we will refine our approach with self-administered analgesic gel ((but not NSAID) to prevent animal suffering and with advice from the NVS.

Monoarthritis models which are less debilitating than the polyarthritis models affects only one joint and resolves rapidly within 5-7 days but is not as representative of RA as the polyarthritis models. There are no systemic effects expected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity to approximately 95% of animals Mild severity to approximately 5% of animals.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To study the inflammatory response, three components need to be examined: time, place and cell type. While place (organ) and cell type (leucocyte or fibroblast) can be examined relatively easily in humans, it is difficult and, in some cases, unethical to perform multiple biopsies, and adoptive transfer experiments in humans with arthritis without underpinning preclinical data that support therapeutic utility. Furthermore, as manipulating fibroblast biology has the potential to affect systemic immune function, we will need to determine whether manipulating fibroblasts as a therapeutic target affects the innate and acquired immune response and this requires testing in different mouse models and those that most closely resemble aspects of human disease. This step is essential to ensure that the translation of our findings to humans passes through the appropriate clinical regulatory stages before use in patients with arthritis. Where possible, human samples (tissues and cells) will be used to test the efficacy of test compounds using in vitro histo-culture experiments.

Which non-animal alternatives did you consider for use in this project?

Human primary cells/cell lines (isolated from human synovium biopsies) and peripheral blood mononuclear cells (PBMC) isolated from human blood samples will be used for cell isolation and co- culture (organoid) experiments in the presence and absence of an inflammatory stimulus (TNF-alpha) with or without test agents targeting PDPN and its binding proteins. After co-culture, cells and medias will be collected and analysed for genes and mediators known to stimulate or antagonize inflammation and tissue damage.

We are also planning to set-up and use organoids system; 3D spheroids made from synovial cells that are reconstituted with cells derived from synovial tissue for co-culture experiments. This system will provide a powerful tool to study the synovial cellular crosstalk between fibroblasts and macrophages driven by PDPN to test the effect of agents such as antibodies. We anticipate that this parallel approach will reduce the use of animal models.

In this project, we also aim to establish a correlation between podoplanin (PDPN) expressed on fibroblasts and macrophages and changes in disease activity and severity in patients with RA. To perform this, we are planning to use freshly isolated synovial tissue biopsies and matched blood samples from patients.

Why were they not suitable?

In addition to in-vitro models, this programme of work requires models that mimic acute and chronic arthritis that recapitulate the temporal aspects of human RA pathogenesis, allowing us to produce biologically meaningful results. This work includes pre-clinical

therapeutic (drug and/or cell) efficacy studies required prior to embarking human clinical trials. There are no other in vitro alternatives to this work.

We will also keep reviewing the scientific literature in order to identify any new emerging technologies and models that could be potentially adopted instead of in vivo models (such as the 3D organoids mentioned above) .

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal number calculations are based on data obtained from ours and our collaborators previous experiments using the same mouse models of arthritis. All experiments are designed to ensure that minimal numbers of mice are used to obtain biologically significant results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical calculations based on previous experiments will be used to ensure that minimal numbers of mice will be used in this project.

When new procedures are planned, we will use the NC3R's experimental design tool for good experimental design. Each animal will be assigned to treatment groups randomly and experiments will be performed blind with respect to the treatment and genotype in to minimise unintentional variability.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In vitro methods using human samples will be used initially in all cases to test the efficacy of new compounds and estimate the magnitude of the expected response.

Where therapeutic interventions or new procedures are planned in-vivo, small-scale pilot studies will be first established in 2-4 mice prior to full experiments to assess variability.

We also plan to use, where possible, the monoarthritis and serum transfer induced models of arthritis as opposed to the collagen induced model: both the serum transfer and monoarthritis models need fewer mice for the following main reasons:

The penetrance of disease is significantly higher.

In Monoarthritis model, only one joint is affected, allowing us to use the contralateral joint as a nonarthritic, genetically and environmentally matched control.

In the serum transfer induced model, all four limb joints are affected, allowing us to use one mouse for many readouts

We will stop our experiments at any stage where our findings fail to show any significant increase in our understanding of the mechanism by which the cells and molecules of interest function in inflammatory arthritis. In addition, the literature will be also continually reviewed to ensure that we are not repeating published work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- Mice are the best model for the study of persistent disease because:
- The main components of their immune system are shared by humans; this is essential where immune responses as opposed to the function of individual genes is being studied and thus will produce satisfactory results.
- A wide range of wild type and genetically manipulated strains of defined genetic makeup are available.
- An extensive range of reagents are available for analysis of immune responses.
- They are the most acceptable animal models that show the least degree of neurophysiological sensitivity and will suffer the least pain, suffering, distress or lasting harm.
- There are no other alternatives to this work.

We have refined and streamlined as much as possible the models of arthritis that we use. Importantly we will use a research strategy that includes the use of different models of inflammatory arthritis to recapitulate a specific phase or aspect of joint disease more accurately, depending on the scientific questions of that particular experiment. This targeted approach will limit the use of persistent models of joint inflammation to only those experiments where it is needed to model that specific aspect of the disease.

Where necessary, males carrying the mutation will be used for breeding with wild type females as this means the female does not have the burden of the effects of the mutation alongside pregnancy.

The maximum time a single mouse is likely to have arthritis is 5 weeks as the arthritis is self-limiting. We will give mice treatments that lessen pain and discomfort that might occur as part of the inflammatory response. This will include pre-emptive treatment with opiate analgesia. We have also adapted treatments used in patients with arthritis (e.g anti TNF biologic therapies) for use in mouse strains that have a genetic predisposition to develop arthritis. We have put in place mitigations as described below in the 3Rs to ensure that any suffering by an individual animal is minimized.

Why can't you use animals that are less sentient?

Less sentient animals do not recapitulate aspects of the RA pathogenesis in humans. Adult mice, to be used in this project, are the lowest mammalian model for human skeletal and immune systems in which we can test the impact of gene manipulation and evaluate the efficacy of therapeutic interventions.

We will not be able to use animals that have been terminally anaesthetised as the duration of experimentation (days) exceeds the time that animals can stay under general anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use well established reagents and protocols that have been developed under previous animal licences and in collaboration with other research centres in the UK. We will therefore be able to use the lowest and pre-optimised doses of agents that are well tolerated. Our experience with murine models of arthritis over the last decade as outlined within this project has allowed us to refine them as much as possible by minimising any adverse effects and very clearly defining humane endpoints. In doing so we have developed specific score sheets for the different polyarthritis and monoarthritis protocols in use in order to capture the specific aspects of each arthritis phenotype and ensure clear and consistent analgesia and humane endpoints. Similarly, due to prior optimisation, all mouse models will run for the shortest possible duration to minimise suffering. We have also made refinements to the housing of the animals to cater for any disability arising from arthritis. These refinements include long drinking spouts on water bottles, soft and warm flooring, non-tangling nesting material, food on the cage floor, use of the most refined route of administration, and hydrating food. All these refinement methods will be constantly reviewed to ensure best practice is followed.

The use of analgesia for these protocols will be kept under review and depend of model used and scoring sheets. For example, anti-TNF therapy will be used during the breeding of animals for the TNFΔARE model to reduce their symptoms however in some

circumstances specific analgesic drugs would not be applicable such as in monoarthritis, where the main scientific endpoint is weight-bearing so this will be affected by analgesics.

We have refined a few of our protocols over the last decade years.

● We will use established reagents and protocols that we have developed and refined over the last 5 years to treat the mice. Therefore, we will not need to perform unnecessary toxicity studies and will be able to use the lowest doses of agents that are well tolerated.

● We have refined and streamlined as much as possible the models of arthritis that we use. Importantly we have very clearly defined humane endpoints. We have refined procedures of cellular transfer, including by intra-articular injection, so the smallest volumes can be injected.

● Where necessary, males carrying the mutation will be used for breeding with wild type females as this means the female does not have the burden of the effects of the mutation alongside pregnancy.

Where necessary, male mice, transgenic for the gene of interest will be mated with wild type females in order to exclude indirect effects on the progeny derived from gene overexpression in the pregnant female.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All staff involved in this project will continuously review the literature on animal welfare provided by the local AWERB and be guided by NACWOs and NVS to ensure that all our experiments are conducted in the most refined way.

To ensure the best use of the most appropriate animal models, our experiments will be carried out according to the LASA guidelines: Laboratory Animal Science Association (https://www.lasa.co.uk/) providing guidance toward animal experimentation and welfare.

When planning for animal experiments, we will check the PREPARE: Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (https://norecopa.no/PREPARE) checklist to ensure an optimal study design and be aware of different elements to consider before and during the study.

Finally, we will follow the ARRIVE guidelines: Animal Research: Reporting of In Vivo Experiments (https://arriveguidelines.org/) for reporting and describing our in-vivo experiments when writing scientific publications to ensure a comprehensive and clear description useful for other research projects using animal models.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend local 3Rs events and sign-up to the NC3Rs e-newsletter to stay informed about the latest 3Rs advances and updates.

101. Genetic analysis of metastatic cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, metastasis, therapy, genetics, imaging

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main objective of this project is to reproduce genetic alterations observed in human cancer in a mouse system in order to better understand the basic biology of cancer and the process through which the cancer spreads from the initial site to various other organs. Specifically, we will utilise a highly refined set of genetically engineered mice to test the importance of specific pathways in driving disease progression in cancer. Ultimately, success in this work will represent a significant advancement in the field of cancer research through the analysis of tumours and new therapies in a realistic environment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

More than 1 in 3 people in the UK will develop some form of cancer during their lifetime. Fortunately, the overall survival of most cancer patients increased remarkably in the past decades through early detection, but also improved treatment protocols that include the

surgical removal of tumour tissue and conventional chemotherapy and radiotherapy. However, the majority of these approaches are associated with severe side effects. Moreover, the prognosis for patients with relapsed and/or aggressive tumours remains extremely poor. Notably, the vast majority (i.e. about 90%) of metastatic cancers that have spread to secondary sites are refractory to treatment and are therefore incurable.

Thus, there is a pressing clinical need for further research, like ours, to identify the basic mechanisms that drive cancer progression. This knowledge is essential to assist the design of future anti-cancer agents and improve the outcome of patients exhibiting aggressive clinical behaviour.

What outputs do you think you will see at the end of this project?

We anticipate that our research will advance scientific knowledge about the formation and progression of tumours. This will be achieved through observational studies of tumour development in murine models that satisfactorily reproduce the human disease. This information will be of significant interest to other scientists in academia and in industry, as the results could open up new possible avenues for the development of anticancer drugs for patients with malignant disease. To ensure the dissemination of our work, we will publish our results in scientific journals and present our findings at seminars and conferences.

Who or what will benefit from these outputs, and how?

The primary potential benefit of this proposed work relates to new knowledge about tumour growth and malignancy. This information will have a major impact in the biomedical research as the data can serve as a basis for the development of rational therapeutic strategies to combat metastatic cancer. Thus, the potential secondary benefit of this work will go beyond basic cancer research, possibly leading to the future development of novel pharmacological interventions.

How will you look to maximise the outputs of this work?

A number of avenues will be taken to explore the medical application of our results within the lifetime of this project. Specifically, we will interact with research business managers employed by the establishment to facilitate interactions with industry and translate the potential value of this project to benefit society as a whole. In addition, we will share best practice with the local and national research community using similar models. In particular, the use of imaging will allow us to define more humane refinement of end points and study parameters and we can share these protocols with other teams working in the same area to enable them to do the same.

Species and numbers of animals expected to be used

- Mice: 19500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice constitute important models for the characterisation of complex cellular processes. One advantage relies on the ability to dissect biochemical reactions in vivo by the use of targeted genetic deletions.

This type of molecular manipulations is particularly successful in mice and has contributed substantially to an increased understanding of biological processes involved in normal development and pathogenesis. In addition, the genetic conservation with humans and comparable disease aetiology make mice highly suited for cancer research studies.

Typically, what will be done to an animal used in your project?

This project will create, breed and maintain mice with appropriate genetic changes. For the majority of animals, we anticipate that these genetic alterations will have negligible adverse effects and be of mild severity. Some mice will be utilised for tumour studies. Substances which are intended to alter tumour growth may be given by a number of routes, e.g. in the diet or drinking water, by direct application onto the skin or by experienced licensees via oral gavage or by needle injection, on one or more occasions. We may also make use of special imaging techniques to view the primary tumour as well as their spread in the living animals. Careful monitoring of tumour bearing mice is crucial for our studies and we have strict criteria when animals are to be killed. In particular, tumours will only be allowed to grow to a particular size and if the animal's normal behaviour is altered they will be killed. At the end of the experiment the mice will be killed painlessly according to an appropriate procedure. Autopsies may be carried out to expose adverse effects undetected by external examination and the information used to refine future studies.

What are the expected impacts and/or adverse effects for the animals during your project?

We will do everything possible to minimise adverse effects relating to tumour growth. In particular, we will not allow mice to carry on with fully developed tumours, but we will kill them in a humane way before any signs of suffering will develop. For this reason, the most likely level of severity in most cases will be mild. However, in some cases, some animals will be moderate for their welfare impact. Any suffering will be minimised by careful monitoring to allow for the early signs detection of general lack of wellbeing. Moreover, if there are indications of ill health from gavage or skin ulceration after substances are

applied directly to the skin, then the animals will be removed from the study and humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In the majority (about 70% of mice) the severity will be mild, but never more than moderate.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to utilise mice because an important component of tumour growth is based on the interactions of tumour cells with the host organism (so called tumour microenvironment).

Which non-animal alternatives did you consider for use in this project?

We will continue to employ non-animal alternatives to complement our in vivo studies in mice. For example, we will confirm the therapeutic applicability of our discoveries using cell culture systems. Moreover, we will test the clinical significance of our results by using credible computational modelling built using publicly available data from cancer patient materials.

Why were they not suitable?

While cell cultures and computer modelling constitute alternative approaches, conclusions drawn using such systems need to be tested in murine models that can simulate the cellular complexity of tumours. Additionally, metastasis (the process of cancer spreading to other organs) happens in vivo in the whole organism and there are no experimental alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice utilised in this project will be kept to a minimum by using optimum crossing designs. The demand will be assessed before breeding and crossing. Colonies will only be maintained while there is an experimental plan and funding allocated. Moreover, the group sizes and the replications will be kept to the minimum possible to achieve statistically robust data. Importantly, we will keep consulting with statisticians as new studies begin to ensure that the optimal number of animals is used to obtain meaningful results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Every opportunity will be taken to decrease the number of animals used for each experiment whilst still maintaining the statistical relevance of the subsequent data. In particular, experiments will be designed with repetitive measurements of the tumour volumes in the same animal. This has greater statistical power and animals need only be killed at the end of experiments rather than at each time-point, thereby drastically reducing the numbers of animals being used. The use of non-invasive imaging techniques that allow tumours to be studied in the same animal will also improve our study design and reduce number of animals required to answer specific questions. Moreover, we will always aim at maximising the amount of data we get from each mouse. We may also employ national on-line design resources,

e.g. the Experimental Design Assistant (EDA) tool created by the NC3R, and consult with the NC3R team who provide periodic onsite help, to improve our approach.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

An effective means of achieving reduction will be to avoid producing unwanted mice by carefully regulating our breeding colonies. Breeding will be optimised by replacing breeders before their reproductive performance declines. Wherever possible, colonies will be organised to produce only the genotype required by our studies. Cryopreservation will avoid wastage from the need to maintain colonies by continuous breeding. We are very familiar with the tumour models included in this application. Together with considerable experience and expertise available in animal husbandry, this will ensure careful management of colonies, matching supply to demand and thus avoiding the production of surplus animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is one of the best model systems in cancer research that has greatly contributed to advance knowledge and improve treatment. This is largely due to the availability of different models that exhibit distinct cancer phenotypes consistent with the human disease. This advantage will allow us to utilise the most appropriate and refined systems for discovering clinically relevant mechanisms that drive or suppress the development of tumours.

Why can't you use animals that are less sentient?

An invertebrate model would not be appropriate since cancers do not arise in invertebrates and other differences in metabolism would greatly reduce the significance of findings for humans. The mouse is the lowest vertebrate in the evolutionary tree that can be genetically manipulated to produce the required genetically modified model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We operate within a very tightly regulated, clean and well administered facility that has an excellent track record for animal care and safety. In all cases, we will avoid pain, suffering or lasting harm to the animals by the use appropriate anaesthetics and procedures.

Frequent monitoring will be used to assess progression of tumour burden, animal health and behaviour, so humane end-points are reached well before onset of clinical adverse effects. Moreover, we will be kept inform of any potential harmful events through our online system, so that we are always aware of issues with our animals and can respond to them quickly. Overall, adverse effects associated with tumour studies will always be limited to the minimum required for a valid scientific outcome.

Administration of compounds will be carried out by appropriately trained and skilled personal licence holders who will use specifically designed gavage tubes, fine needles and aseptic techniques to minimised stress due to restraint and momentary discomfort from oral gavage or needle insertion. Re- gavaged and repeated injection will be permitted only if the animal has fully recovered from previous procedures. Importantly, cancer therapy will

be given at dose levels known to be tolerated. Any evidence of unanticipated toxicity would indicate reduction in dose and/or frequency of dosing.

Additionally, we will refine our approach by incorporating non-invasive tumour imaging where possible. This will provide opportunities to shorten our experiments, prevent potentially malignant tumours from escaping detection, and ensure that humane endpoints are adhered to, as more accurate detection and analysis of tumour growth informs decision making. Animals will have full recovery between periods of anaesthesia, rehydration and maintenance of body temperature during imaging sessions.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be guided and directed by the most up to date documents on the welfare and use of animals in cancer research. Additionally, we will follow relevant ARRIVE guidelines to ensure that our studies are reported in enough detail to add to the knowledge base.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Main sources of information include:

i) The NC3R team who provides very helpful advice;

ii) The NC3Rs and the BSF newsletters sent by email to all users of the animal facility;

iii) The National Centre for the Replacement Refinement and Reduction of Animals in Research (https://www.nc3rs.org.uk/resource-hubs); and

iv) Peer-review scientific papers, oral communications/posters in conferences and discussion amongst scientific colleagues, reporting alternative in vitro models to the use of live animals.

102. Host-pathogen interactions and vaccines

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

receptors, vaccines, pathogens, host-pathogen interactions

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the role of pathogen cell surface and secreted proteins in host interactions and develop vacccines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The interactions between receptor molecules displayed at the surface of cells are critical in the regulation of infection biology. This research is focussed on understanding the biological roles of these receptor molecules in infection and identifying vaccine targets.

What outputs do you think you will see at the end of this project?

The outputs of this project will be the functional characterisation of novel extracellular host-pathogen interactions during infection and the identification of new vaccine candidates for clinically and economically important parasites including Trypanosoma spp., Leishmania spp. and Schistosoma mansoni.

Who or what will benefit from these outputs, and how?

The short-term beneficiaries will be other scientific researchers who will gain a wider knowledge of the biology of the pathogen. In the longer term, small holders living in Africa who depend on livestock animals for their milk, food and draught power would benefit from effective vaccines to protect their livestock animals. Ultimately, vaccines for animal African trypanosomiasis would stimulate the economic growth of many African economies. For the parasitic diseases that affect humans, the development of an effective vaccine would have an enormous humanitarian benefit to those living in endemic regions. The timescales to licensure of human vaccines, however, can be as high as 20 years.

How will you look to maximise the outputs of this work?

All of the data from our animal experiments will be published in open access journals thereby increasing the exposure and reach of this research to other scientists across the globe. The research is regularly presented to other members of the scientific community in conference presentations and seminars. Where appropriate, upon publication of the research a press release will be made to inform the general public of the advance. We will also use some of the more recent vehicles for publication which enables the publication of negative data to maximise the dissemination of our research.

Species and numbers of animals expected to be used

- Mice: 3300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All the research outlined in this project will use mice as an animal model. Mice are a suitable model for these studies because they are mammals, and almost always contain a recognisable counterpart to any human proteins that we identify in our in vitro screens. Consistent with this, many pathogens that infect humans also infect mice with similar

pathogenic outcomes (e.g., Schistosoma mansoni, the parasitic worm that causes schistosomiasis in humans). Thus, mice can be used as an appropriate model for preclinical work. Mice have a long history of making important contributions to the understanding of human biology and many valuable resources (such as gene-deficient mice) are available. Therefore, they enable us to make scientific advances with an increased confidence of correctly interpreting the outcomes of experiments designed to discover new treatments and therapeutics to improve human health. We will use adult mice because they have a well-developed immune system.

Typically, what will be done to an animal used in your project?

Objective 1: Animals will receive vaccinations with the aim of inducing an immune response. Typically, individual mice will receive an initial vaccination followed by two booster immunisations. It will usually be necessary to take small amounts of blood to assess the antibody responses. These procedures are very similar to those that are given to babies and children as part of their routine vaccinations.

Objective 2: Animals will be vaccinated as described above and then challenged with a pathogen to determine if the test vaccine candidate works. To quantify how much pathogen is present, we can use an advanced form of imaging where a chemical is given to the infected animals and reacts with a gene in the pathogen to emit light. The administration of the chemical is done by injection and will be repeated several times during the course of the infection.

What are the expected impacts and/or adverse effects for the animals during your project?

For most (>95%) procedures, we expect that the animals will experience no more than mild transient discomfort during the procedures. In some cases (<5%) we may observe complications which could include irritation at the site of injection, and stress symptoms from pathogen infections that unexpectedly exceed established thresholds; in the latter case, this is estimated to last for no longer than a few hours.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

We do not expect that any procedure will exceed the moderate category. The vast majority of procedures performed under this licence (>95%) will cause only mild and transient discomfort to the animal.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Objective 1: We need to use animals to make antibodies where in vitro alternatives have not been found to result in antibodies suitable for our work, or to select mouse monoclonal antibodies for our passive transfer studies where there are no suitable in vitro alternatives.

Objective 2: We need to use animals in our preclinical vaccine screening approaches because there are few or no adequate in vitro infection models available for the pathogens that we wish to study. A vaccine candidate that showed efficacy in an animal model would also lend significant weight to its candidature for progression towards a human vaccine.

Which non-animal alternatives did you consider for use in this project?

For objective 1, we considered alternatives such as phage, yeast and mammalian display. For objective 2, one considered option was to add antibodies to pathogens directly rather than directly infect the mice.

Why were they not suitable?

For objective 1, we have found that antibodies produced using in vitro methods are not suitable for our purposes because they usually have low binding strengths. We must use antibodies that have long binding half-lives (hours) to withstand the stringent wash steps of the staining protocols. A scientific justification is provided in Appendix 1 but is due to the limit on transformation efficiency of E.coli (which limits library sizes to just ~109 clones) and there is no well developed method of affinity maturation which can replace the in vivo process of somatic hypermutation. Where the antibodies are required for passive transfer protection experiments in our mouse infection models to determine the immunological mechanism of protection then we will request dispensation to use mice for monoclonal antibody generation. This is becasue it is essential that we use mouse monoclonal antibodies to avoid any host immune responses to the delivered antibody which would confound our analysis. We are not aware of any available in vitro selection systems that use mouse antibody backbones since almost all are humanised antibodies.

For objective 2, adding antibodies to parasites directly does not avoid the use of animals since they are needed to raise the antisera. Using these models also restricts the vaccine mechanism of action to antibodies and would not appropriately model other aspects of the immune system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For objective 1, we will not generate more than two antibodies per year. Each antibody would usually require immunising around five animals to ensure at least one animal has an appropriate immune response. Allowing for additional attempts, this totals ~50 mice. We will also need to generate polyclonal antisera in mice for use in passive transfer experiments which is estimated at 50 mice.

For objective 2, we envisage that we will be testing up to 20 vaccine candidates per year. We estimate that we will use 2000, 1000, and 200 animals for the Trypanosome, Leishmania and Schistosoma vaccine screens respectively.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For objective 1, to reduce the number of animals that we require to make antibodies, we have designed and developed a method of making more antibodies at one time in fewer animals.

For objective 2, we will use the very latest technologies to accurately quantify the number of parasites in individual animals over time without killing any animals consequently leading to a reduction in the number of animals used. Where a new host-parasite combination is being used, we will use pilot experiments to establish the inter-individual variability of the infection and attempt to reduce this so that smaller group sizes can be used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For objective 1, where we require multiple antibodies at once, we will consider co-immunising mice with protein mixtures to reduce the number of animals that we require.

For objective 2, we will ensure that pilot studies are performed to refine infection protocols to reduce the inter-individual variability between animals within a cohort. This typically can include selecting the most appropriate route of infection, for example using intravenous rather than intraperitoneal delivery, or direct inoculation rather than by insect bite. In some cases, we are asked for pathogen samples from other researchers and we will use tissue samples taken from animals from control groups which is an example of tissue and sample sharing.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have refined the protocols for the percutaneous infection of mice with Schistosoma mansoni by developing an anaesthesia apparatus that has reduced the stress to the animals during these infection protocols. We have also adopted, where possible, the use of light-based imaging to accurately and objectively quantify parasitaemia - this has worked particularly well for Trypanosoma spp. and Leishmania spp. infections. This has the major benefit that the efficacy of a vaccine candidate can be assessed without the infection proceeding to the stage that adverse effects are experienced.

Why can't you use animals that are less sentient?

We require the use of a mammalian species which contains an adaptive immune system that has clear similarities with the immune system used in the target species for our vaccines that include humans and livestock animals. We must use adult animals that have a fully developed and functioning immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will be refined by continual improvement and discussions with the scientists and animal technicians, NACWO and NVS to create a culture where the welfare of the animals is central to experimental design. Regular training and protocol review will ensure that any refinements will be implemented promptly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The National Centres for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) web site provides a resource of up-to-date protocols, publications, guidelines, videos and other information that enables the rapid dissemination of the most up-to-date best practices.

Discussions with other scientists at conferences and within the establishment will ensure that improvements in local practices are quickly implemented. Examples of where procedures have been recently refined are the single use of needles, using lances (thin needles) for blood biopsies rather than tail snipping, providing enrichment in the cages (fun tubes, mirrors, blocks, food as seeds), adopting tube handling, and use of animal body cues such as the grimace scale to observe pain.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly discuss refinements for animal experiments with the NACWO, NVS, and animal technicians. We will keep abreast of developments discussed and implemented by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) through their monthly newsletters and blogs. The animal facility holds regular forums and updates on the current best practice and latest developments.

103. Investigating the mechanisms driving cardiac fibrosis and its effects on cardiac function

Project duration

4 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cardiac fibrosis, heart remodelling, fibroblast growth factor 23, arrhythmia

Animal types	Life stages
Mice	adult, pregnant, neonate, embryo, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to characterise the pathways by which fibrous connective tissue in the heart, termed cardiac fibrosis, leads to cardiac dysfunction and to identify novel therapeutic interventions to prevent or reverse cardiac fibrosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Due to ageing populations and lifestyle changes, the total number of deaths caused by cardiovascular diseases (CVDs) is increasing – by ~21% from 2007-2017. High mortality rates as well as high level of morbidity contribute to the high economic burden of CVDs.

The treatment for CVD is increasing over time, with prescriptions and operations costs around £6.8 billion in England, the majority spent on secondary care. Centre for Disease Control (CDC) data in US show that Americans suffer 1.5 million heart attacks and strokes each year, which contributes more than $320 billion in annual healthcare costs and lost productivity. By 2030, this cost is projected to rise to $818 billion, while lost productivity costs to $275 billion.

Many of these deadly and debilitating CVDs are associated with cardiac fibrosis. Cardiac fibrosis contributes to both electrical and structural remodelling of the heart which ultimately leads to decreased cardiac function, heart failure and arrhythmias. However, with no efficient treatments directly targeting cardiac fibrosis, it presents an ever-growing clinical challenge.

Our work and that of others has identified a protein called fibroblast growth factor 23 (FGF23) to be associated with the development of cardiac dysfunction in patients with CVDs, particularly in patients with heart rhythm dysfunction (atrial fibrillation) and reduced kidney function (chronic kidney disease). Our in vitro data suggest that FGF23 can promote accumulation of fibrous connective tissue in the heart. This is likely to contributes to cardiac electrical dysfunction and lead to development of debilitating and lethal heart disease. We propose that interrogation of this new mediator of cardiac electrical dysfunction will illuminate novel cardiac biology insights and therapies targeting cardiac fibrosis and thereby reduce patient suffering and death.

What outputs do you think you will see at the end of this project?

We will publish the data in relevant academic journals and present at national and international conferences. The studies may demonstrate utility of the therapeutic interventions for treatment of cardiac fibrosis and electrical dysfunction. If they do, we will look to patenting the products.

Who or what will benefit from these outputs, and how?

Short to medium term we expect that the knowledge gained from this project will be shared with the scientific and clinical community and published in peer reviewed journals (output expected during the project). Thus the academic community will be the primary benefactor of this work. Once the mechanisms of cardiac fibrosis development have been studied and been better understood, the results will be used to inform the clinical colleagues of these findings and work with them on determining whether similar mechanisms also drive cardiac fibrosis in patients (output expected after the project).

The long term benefit of the work will be a better understanding of the mechanisms by which cardiac fibrosis develops and whether it can be treated using the therapies targeted against the FGF23. This will open new avenues to reduce cardiovascular disease risk for example in atrial fibrillation or chronic kidney disease (output expected some 1-5 years after the project), with the ultimate aim to prevent or ameliorate high cardiovascular morbidity and mortality.

How will you look to maximise the outputs of this work?

Publication in the relevant scientific literature and presentation of the data at international meetings is likely to be the primary output for this work. Existing collaboration with our clinical colleagues will also be further strengthened. The intention is that this work generates valuable datasets that will inform clinical practice and may provide a novel therapeutic avenue for the treatment of cardiac dysfunction in patients suffering with atrial fibrillation and with chronic kidney disease.

Species and numbers of animals expected to be used

- Mice: 2300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the lowest mammalian species with sufficiently similar cardiovascular physiology to that of humans, allowing transfer of findings to man. We have however introduced a human mutation that allows for improved sensitivity of mice to commonly used therapeutics, mimicking the response seen in humans. Specifically, a human mutation has been introduced in the gene responsible for sodium handling. This mutation will allow us to better translate our findings.

Adult mice of a specific age range (8-20 weeks of age) will be chosen to minimise variability.

Typically, what will be done to an animal used in your project?

Some animals (less than 20%) will undergo minor surgery to implant an osmotic mini pump or MedRod implant under the skin to chronically deliver recombinant FGF23 or vehicle control for up to 6 weeks.

Alternatively, an animal may be given two doses of FGF23 (or vehicle control) daily for seven days via subcutaneous/intraperitoneal injection. These animals will then undergo non-invasive assessment of structural and functional changes to the heart. This will include echocardiographic imaging and ECG monitoring under anaesthesia before recovery. Blood sampling will also be carried out to measure any circulating factors influenced by FGF23. In the majority (if not all of the animals), the heart will be excised under terminal anaesthesia for further Langendorff perfusion or cell isolation for assessment of cardiac and cellular function to maximize the data obtained from each animal.

What are the expected impacts and/or adverse effects for the animals during your project?

We will use CD-1 wild type mice or a genetically modified mouse line. The mouse line we plan to use are usually not expected to experience any adverse effects. However, if any of the mice develop unexpected phenotypic changes, the animals will be humanely killed.

Based on published data, the dose of FGF23 planned under this PPL has been shown to successfully cause activation of downstream signalling pathways, leading cardiac hypertrophy, with no other reported side effects in the mice.

To test the effects of a therapeutic intervention, some mice will be treated with FGF23 alone, a FGF23- targeted therapy, FGF23 and a FGF23-targeted therapy, or vehicle control (phosphate buffered saline). Pharmacological agents may be administered either by mini-pump/MedRodTM implantation or intraperitoneal/subcutaneous injection.

The agents administered will not exceed the recommended maximum volumes for dosing. FGF23 safety profile when injected subcutaneously, intraperitonealy or intravennously in animals is well documented. However, if animals display signs of toxicity such as reduced mobility and grooming or up to 20% weight loss compared to the controls, the terminal experiment will be performed or mice will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals (80%) will undergo a non-recovery procedure, as they will only undergo heart extraction under terminal anaesthesia.

Small number of animals (20%) will experience moderate severity, due to cumulative effects of FGF23 delivery, echocardiography and heart extraction under terminal anaesthesia. However, every effort will be made to minimise any adverse effects.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cardiac electrical function is complex, involving the interaction of multiple factors, including many cell types and physical and neurohormonal local controls, that cannot currently be studied without animal models. Our understanding of the processes involved, and their relative importance, limits our ability to use computer modelling, though this is a goal we are working towards.Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially be adopted in order to replace in vivo animal use.

Which non-animal alternatives did you consider for use in this project?

We have explored the use of stem cell-derived cardiomyocytes. Work on stem cell-derived cardiomyocytes continues in my lab and we are currently replacing animal work where possible. For example we have just successfully differentiated human induced pluripotent stem cells into cardiac fibroblasts and are starting to use these as alternatives to mouse primary adult cardiac fibroblasts.

Why were they not suitable?

Stem cell-derived cardiomyocytes, either in 2D or 3D culture, do not fully recapitulate the complexity of the heart, including many cell types and physical and neurohormonal local controls.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Expected effect size will be determined through consultation of the literature, previous experience of techniques proposed or through small pilot experiments when possible.

We have used statistical methods to calculate how many animals we need to get meaningful data. This was determined based on the number of different FGF23 concentrations we plan to investigate in vitro, on differential effects on atrial and ventricular chamber of the hearts.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing the experiments, we performed statistical analysis to ensure we use the minimum number of mice per group that will be informative. Importantly, we also employ a variety of approaches to reduce animal usage, including:

1. Using littermate pairs to reduce variability of genetic and behavioural background

2. Performing and analysing experiments in a blind fashion to reduce investigator-induced bias

3. Using standardised experimental methods to reduce variability

4. Optimising tissue usage through the use of innovative technology, such as RNAseq, optical mapping, novel cell isolation technique, etc..

5. The NC3Rs EDA tool will be used to design experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To maximise the information gained from a single animal we aim to perform multiple in vivo and in vitro analyses. Where possible, cell line work and in vitro manipulations have been designed to yield the maximum possible information and reduce animal use.

Better reporting of research should result in better science and more effective use of animals in experiments. Therefore, our findings will be reported (using the ARRIVE guidelines) in the scientific literature and at conferences, thereby minimising risk for future unnecessary animal experiments conducted by others.

Furthermore, literature will be continually reviewed to ensure that we are not repeating published work and that our hypotheses are based on the most up to date knowledge.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Majority of animals will be used for non-recovery work. Where this is not the case, our experimental protocols have been developed to limit harm to the animals, being as short as reasonably possible. We will continue to make efforts to refine protocols and further reduce the welfare costs. Current best practices (e.g. needle sizes used will be kept to a minimum, use of minipumps to deliver FGF23) will always be followed.

The use of osmotic mini pumps to deliver the protein of interest over a long period of time (up to 6 weeks) reduces the need for repeated handling and injections and therefore reduces the distress caused to the animal. Analgesics will also be given pre- and post-operatively to ensure the least pain is felt by the animal following surgery. Strict aseptic procedures will be used in order to prevent infections.

Echocardiography will be carried out under general anaesthesia (up to 30 minutes) so as to limit animal distress and equally to produce better quality data . As the animal is likely to only undergo this procedure up to 2 times over the course of the 6 weeks of treatment it is more stressful to the animal to try and acclimatize it to the imaging process without anaesthesia.

The apparatus for ECG/Blood pressure measurements is already refined to ensure the least distress to the animal i.e. tunnel used to secure animal in natural position and kept in dark throughout procedure.

Blood sampling will follow published guidance on suitable volumes which can be taken while minimising harms to animals.

In addition before conducting each experiment, it will be discussed with the NACWO and NVS to ensure animal welfare is maintained throughout the experiment and that minimum suffering is caused to acquire the scientific endpoints. We will also review each experiment on completion to see what lessons can be learned from the study in terms of endpoints (scientific and humane) and any animal welfare issues that may have arisen during the experiment that could then guide the next experiment.

Why can’t you use animals that are less sentient?

The mouse is the least sentient mammal that is most similar to humans in terns the way their heart works.

Majority of our work will use animals that are terminally anaesthetised. However, experiments studying the long terms effects on the heart cannot be done in terminally anaesthetised animals. For some experiments we will also use cellular models of disease however, these cannot completely replace the need for the use of mice as they cannot replicate the complexity of the whole animal physiology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Majority of animals will be used for non-recovery work so will only ever experience minimal suffering. This is possible due to our state-of-the-art optical mapping technologies, allowing for monitoring of heart electrical activity ex vivo.

To minimise the welfare cost to the animals, we will use good animal husbandry, and will provide enriched environment in the cage to keep the animals happier. We will also better handling techniques to reduce the distress that animals experience during handling.

For all procedures, the mice will be carefully monitored and if adverse events are observed, monitoring will increase in frequency and steps, steps will be taken to alleviate them or the affected mice will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the PREPARE guidelines to ensure our experiments are planned and conducted in the most refined way. LASA guidelines will be consulted to ensure correct dose volumes are selected for the specific route of injection/blood sampling. We will also stay up to date with the NC3R website resources and guidance on the best and most refined practices. All the data will be published according to the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regularly monitor the guidance given by the NC3R's website, making use of the online resources to ensure the project is carried out efficiently and using the best methods for animal welfare.

104. Treatment of chronic inflammatory disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

rheumatoid arthritis, therapy, inflammation, immunoregulation, autoimmunity

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new treatments for immune-mediated inflammatory diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is estimated that up to 1% of the population worldwide suffer from rheumatoid arthritis, with around 7% suffering from some sort of autoimmune disease. Furthermore, these figures are rising due to increased longevity and an ageing population. This project seeks to develop new ways to treat these conditions and to improve the quality of life of patients suffering from immune-driven inflammation.

What outputs do you think you will see at the end of this project?

Although there have been considerable improvements in the treatment of chronic inflammatory diseases like rheumatoid arthritis, there remains considerable unmet need. Many patients do not respond adequately to current medications and even in those who do respond, disease usually relapses when treatment is withdrawn therefore there is a need for continuous therapy. The principle objective of this research is to develop new treatments that provide long-term reduction in disease activity without the need for continuous drug administration. During the course of the project we aim to test new therapies which could progress through to human clinical trials. Hence the primary output will be new compounds for subsequent evaluation in man. We predict that new drugs will be identified that are effective in reducing pain and helping patients to lead more active and productive lives. In addition to the development of new therapeutic approaches, this research will provide information about why inflammation fails to resolve in some individuals, leading to chronic disease. This information will add to existing medical knowledge, resulting in scientific publications and presentations at international meetings.

Who or what will benefit from these outputs, and how?

It is envisaged that this research will provide the scientific rationale for carrying out clinical trials of at least three new compounds or forms of therapy for patients with rheumatological diseases within a period of five years. If these trials are successful, the wider patient population should benefit within ten years. This benefit would be in the form of improved treatments, aimed towards disease remission, and improved quality of life. In the shorter term (within five years) the scientific community will benefit through disseminated knowledge, leading to a greater understanding of chronic inflammation.

Companies may also benefit through the identification of therapeutic targets, enabling new drug development opportunities. In the longer term, the scientific knowledge gained from this project will also benefit patients with other autoimmune diseases, including multiple sclerosis and type 1 diabetes, as many pathological processes are shared by multiple inflammatory diseases.

How will you look to maximise the outputs of this work?

We aim to collaborate fully with clinicians to determine priorities and maximise outputs. Collaboration with other research groups is also key to making progress and will form a major part of our work. In addition, we aim to collaborate with the pharmaceutical industry to expedite the translation of basic research findings into new drugs for patients. We will attend national and international meetings and disseminate and discuss our work in an open and honest manner. Peer-reviewed papers remain the major mechanism for disseminating our research findings and we also aim to share our findings with patients via patient participation groups.

Species and numbers of animals expected to be used

- Mice: 13000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Inbred strains of mice will be used in this study. Mice are suitable because they are known to develop autoimmune arthritis in a similar manner to humans. Furthermore, there are a wide range of reagents available for mice which means that disease processes can be studied using conventional laboratory practices. Mice also have a relatively short life-span and it is possible to study factors present during development which could predispose to disease in adulthood.

Typically, what will be done to an animal used in your project?

Mice will be bred and maintained. A proportion of the mice will be immunised with an antigen in order to provoke an autoimmune response. These mice will develop arthritis which will be treated with novel anti-arthritic drugs. Blood samples may be taken and non-invasive imaging may be performed under anaesthesia. The mice will be humanely killed at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Arthritis causes pain and limping but is short-term. Mice with arthritis are normally maintained for 7-10 days and then killed. Analgesics will be administered during the arthritic phase where possible. Some of the drugs may have unexpected adverse effects and these will be monitored carefully.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols we expect the majority to experience subthreshold severity (approximately 85%), and a small number to experience mild severity (approximately 10%) and less than 5% to suffer moderate severity. For the mice on experimental protocols, we expected the majority (approximately 80%) to experience moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are necessary because arthritis is not a static process confined to a single tissue and culture techniques do not offer a realistic alternative. Rather, the inflammatory process is dynamic and highly complex, involving trafficking of cells from distant sites to the joint via the circulation. Hence, modelling the effects of treatment on arthritis must at some stage involve whole animals, rather than isolated tissue extracts.

Which non-animal alternatives did you consider for use in this project?

Where possible we use cells and tissues from patients and we have considered a synovial cell culture systems to study the effects of anti-arthritic therapies.

Why were they not suitable?

Synovial cell cultures do not model the whole body. They are useful for studying the effect of a treatment on a particular cell type but they do not inform us about the effect of the treatment on arthritis.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical methods are used to predict the number of mice per group needed to demonstrate a significant effect.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of animals will be minimised through careful planning of experiments and by the use of cell based culture systems whenever possible. The use of NC3R's Experimental Design Assistant is used to plan experiments and all experimental plans are discussed in

detail before embarking on the work. Mouse colonies will be kept at a minimum to ensure that the minimum number of mice is used throughout the study. Animals will only be bred to meet the experimental requirements and both sexes are likely to be used for experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The maximum amount of data possible is gleaned from each experiment through the use of next generation sequencing and other technological advances. This means that we don't have to repeat experiments to get more information. We also perform pilot studies with very small numbers prior to embarking on big experiments. This ensures that ineffective compounds are weeded-out at an early stage. In addition, our breeding strategy ensures that we breed the minimum number of mice possible to achieve the goals of the study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Human rheumatoid arthritis may last for decades, resulting in years of reduced quality of life. In contrast, we will use mouse models of arthritis that are of short duration (7-10 days) and therefore have limited impact on lifetime suffering. Furthermore, wherever possible we will use the most refined arthritis model, that affects only one joint, and we will administer analgesics to alleviate pain. Where possible, genetically-altered strains will be used with which have no harmful phenotype.

Why can't you use animals that are less sentient?

Mice are the least sentient species for which animal models of arthritis have been developed. Fish are unsuitable as they lack synovial joints.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We aim to improve pain management through increased use of analgesics, provided that they don't influence scientific endpoints. Specifically, a blocked trial design will be devised

to establish whether metamizole and buprenorphine can be used to alleviate pain without affecting arthritis. If both approaches are unsuccessful, we will trial the use of pregabalin, gabapentin and amitryptyline as analgesics. Another important refinement is to minimise the amount of time that animals are maintained with arthritis. Hence acute, rather than chronic, models will be used wherever possible. Mice with arthritis are provided with moist palatable food at cage floor level to ensure that their nutritional requirements are met. Mouse colonies will be kept at a minimum to ensure that the minimum number of mice is used throughout the study. We aim to perform further research into the milder adjuvants than complete Freund's adjuvant, which will be used as little as possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will also consult the NC3Rs website on a frequent and regular basis and will follow the guidance laid out in the following article, of which I am a co-author.

Hawkins P, Armstrong R, Boden T, Garside P, Knight K, Lilley E, Seed M, Wilkinson M, Williams RO. Applying refinement to the use of mice and rats in rheumatoid arthritis research. Inflammopharmacology (2015) 23:131-50.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular meetings are held within the University to keep abreast of developments in the 3Rs. I am a reviewer for the journal: ALTEX: Alternatives to Animal Experimentation, and receive regular notifications of significant articles from them. Regular contact is maintained with the Named Information Officer. Within our research group, we discuss animal experiments on a regular basis to ensure that best practice is maintained.

Home Office

105. Determination of cns efficacy and safety pharmacology

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Central Nervous System, Efficacy, Safety, Pharmacology

Animal types	Life stages
Mice	adult
Rats	adult
Guinea pigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this Project is two-fold. Firstly, the safety evaluation of test substances which may induce adverse side effects on the central nervous system. Test substances may be novel chemical entities (NCE's) as potential new drugs.

Secondly, to determine the efficacy of therapeutic substances interacting with the central nervous system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Disorders of the Central Nervous System (CNS)/Mental illness is a growing problem, with 1 in 4 people experiencing mental health issues each year, with an associated economic and social burden.

● Depression is a leading cause of disability worldwide, often occurring in conjunction with other mental health issues and associated with suicide and heart disease.

● Anxiety affects a significant number of people, and over recent years has been seen to be increasing among young people.

● Psychosis and schizophrenia are also on the increase, with the latter being increasingly connected to cannabis consumption at an early age.

Such conditions can be hugely debilitating for the individuals and challenging for care givers and family. Although a number of treatments are available for such conditions they are often associated with varying degrees of side-effects. For example, anti-psychotics may cause weight gain, suicidal feelings/behaviour, seizures, sedation, neuromuscular effects, emotional effects and heart problems.

As such, new medications are required which have improved or equal efficacy with lower associated side-effects.

For the treatment of Schizophrenia, medications have primarily targeted the positive symptoms (e.g. hallucination, delusions, disorganization speech and behaviour), however, more recently, there has been an increase in drugs being developed to treat the negative symptoms of this condition (e.g. lack of emotion, low energy, low motivation and impairment of social interactions).

Data from this project will be used to improve human health by supporting the development of new medicines for these and other related disorders, and also assessing novel drugs for their potential to produce unwanted behavioural/CNS side-effects and support the requirements of regulatory submissions to ensure drugs are safe for humans to take.

What outputs do you think you will see at the end of this project?

The benefits of this programme will be two fold. Firstly it may contribute to the development of new drugs that help alleviate CNS disorders that are common in society, like anxiety, depression and epilepsy. These new drugs may work better in the clinic, relieve or cure diseases and have better side effect profiles. We may, by our work, also

contribute to better knowledge and understanding of these types of disease, and that knowledge may be used to develop further new drugs.

Secondly, the models on this project may be used to assess the safety of a test material, and find a dose that causes no effect, or identify an unwanted effect. This is important when planning future trials in humans, to make sure any starting dose in a clinical trial is safe for the patients taking it.

Who or what will benefit from these outputs, and how?

In both the medium and long term, patients will benefit by having newer, modern and safe drugs that are more effective than the current options.

How will you look to maximise the outputs of this work?

The work will be shared with customers who will use it to determine their future strategy, or for submission in documents required by regulatory authorities. Whilst we have no direct control over what happens to the data after we have shared it, we trust from information given to us that it is used for regulatory purposes or to support regulatory purposes (e.g. to support drugs progressing to clinical trials). Previously however, we have collaborated with customers and shared data we have produced in the form of Scientific publications that are in the public domain.

Species and numbers of animals expected to be used

- Mice: 4500
- Rats: 7000
- Guinea pigs: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Most of our experiments will be carried out on mice and rats as these are the smallest relevant species that we can use that have an central nervous system (brain and nervous system) that is comparable to humans. In some specialist cases we may use other animals (the guinea pig) because what we are trying to find out is better done in that particular species rather than in the rat or mouse.

The only other time we would use a species other than a mouse or rat is to continue work that has been previously done in that species. For instance if previous work, and results gained, had been carried out in a guinea pig, it would make no scientific sense to start the next stage of a programme of work in a rat or a mouse.

We will be using adult animals in our studies, as we do not expect to be investigating CNS drugs for use in young animals or children.

We very occasionally use guinea pig pups for a specific test to measure anxiety. This is a well characterised model, dependent on the pups being separated from their mothers for short periods, hence we have to use animals of this age (the test won't work with adult animals).

Typically, what will be done to an animal used in your project?

Typically on this project, animals are dosed over a short period of time (sometimes only once, rarely longer than a week) with test materials, and observed and tested for effects on their nervous system before being humanely killed. These observations include measurement of activity and alertness, and a lot of them don't actually require us to even touch the animal as they are observational assessments, or require only minor manipulations. Most studies would last a matter of days (much less than a month) although some, very occasionally may last for longer than that.

Dosing of animals is commonly done orally using a flexible tube, or by injection using a syringe and needle, maybe directly into a vein, or into a muscle into the arm or leg, or just under the skin.

Blood samples are usually taken from easily accessible veins in the neck or the tail of rats or mice. We are limited to how much blood we can take at once or over a month. If we need a large blood sample, we would do this when the animal is anaesthetised and we would not let them recover consciousness.

Where possible, we try and take any of the tissues and samples we need after the animals have been humanely killed.

Sometimes we need to induce a condition in animals to test if a new drug can alleviate the condition. For example if we are looking at a drug to treat people having convulsions, we have to give an animal a drug to make them convulse, after we have given the test drug. We use a drug we have a lot of knowledge and experience of, so we know the right dose to use, and constantly watch an animal when it is being administered it via infusion. As soon as an animal starts to convulse, we stop dosing and kill the animal immediately, to stop any suffering. We sometimes also need to assess whether or not drugs affect the 'sleeping time' of an animal when dosed with a known sleep inducing drug. This is a test to ensure drugs don't depress brain function on their own. When animals are sent into sleep we watch them, and keep them on a warm surface until they have recovered, when they are humanely killed.

In one protocol we also have to surgically prepare animals by cannulating a vein so we can administer test materials directly into the animals bloodstream. These surgeries are usually very rare, and are carried out under the supervision of a vet, by a trained surgeon. We take as much care to avoid any infection in our animals as a surgeon would if

operating on a human. We 'scrub up' and wear mask, gowns and gloves just like they would. We watch our animals when they are recovering from surgery and give them extra heat and bedding and food and water until they have recovered. Animals would also be give supportive medicines like pain relief as needed, on the direction of a vet.

We very occasionally use guinea pig pups for a specific test to measure anxiety. This is a well characterised model, dependent on the pups being separated from their mothers for short periods, hence we have to use animals of this age. No overt distress is caused to the animals.

What are the expected impacts and/or adverse effects for the animals during your project?

When dosing an animal by injection or taking blood, The amount of pain an animal feels is similar to what a patient would feel having an injection done by a doctor. If we have to repeatedly inject animals using a needle and syringe, we would choose different sites to do this where possible. If we can take blood samples when an animal is deeply unconscious then we do. If we need to take repeated blood samples or need to dose repeatedly then we try and use different sites. Of course everyone who performs these procedures are trained to a high standard.

Animals undergoing surgery receive the same sort of care as a patient would in hospital. We discuss their pain relief and use of antibiotics with a vet before we start. We administer drugs as necessary and give them plenty of time to recover from surgery before we use them in experiments.

Sometimes we have to confine animals in tubes for dosing and sampling or special chambers to measure respiration. We can introduce the animals to these situations slowly, and watch to see if they are ok. Usually most animals are absolutely fine in these new surroundings and don't suffer any distress or anxiety.

Any animals who are tested to see if a drug prevents convulsions, are made to convulse with another drug (after we have dosed with the drug with think prevents convulsions). We constantly watch them when giving this drug, and as soon as we see them start to convulse they are killed humanely.

Measuring whether a drug affects 'sleeping time' by administering an agent that causes sleep, can cause animals to get cold because they are not moving around. However we warm all these animals whilst asleep, and as soon as they have met the test we have for them being fully awake, then the experiment is over and they are humanely killed.

Dosing with drugs may cause adverse effects in some studies, although this is rare, as we usually have a good idea as to what doses are safe from other studies. We do observe our animals at least twice a day, and the people who do this know the signs when an animal is ill. If an animal is ill, we would check it more frequently, and get more senior staff involved

in its care for advice, including vets. We also help sick animals out by giving more bedding, more heat and special food to make them more comfortable.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

On the last project, about 95% of animals were classified as having displayed mild severity, due to the procedures they had performed.

It's impossible to predict the proportion of severities expected on a service licence, as this will be dependent on what study types we are asked to perform.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The Central Nervous System is an extremely complex, poorly understood system which controls a wide variety of functions essential to life including breathing and heartbeat. There is no adequate model to replace the whole animal experimental model, as the complex, co-dependent mechanisms under investigation cannot be adequately modelled in vitro.

In many cases the protocols listed in this Project will be used later in the life cycle of a test substance and in many cases, particularly for pharmaceuticals, tests in test tubes will have been conducted previously (often by the Sponsors) to ensure the drugs do what they are meant to, and are safe, before we expose them to testing in animals.

As a service provider we do not own the test materials under evaluation, therefore, using test tube methods for testing drugs is not appropriate. However, available literature is reviewed prior to commencing any animal procedures if required. Prior to conducting animals studies, clients are requested to provide information relating to their test material candidate, together with details of other work performed, relevant regulatory requirements and a justification for conducting in vivo investigations.

For some protocols the licence, the tests are legally required by regulators around the World to make sure new drugs don't have ill effects on the nervous system, otherwise they cannot enter trials in humans.

Which non-animal alternatives did you consider for use in this project?

Although there are presently no non-animal models for behavioural responses, in vitro information e.g receptor binding/functional assays and chemical structural analysis will typically form part of the over profiling of candidate drugs

Why were they not suitable?

Non-animal studies are unable to evaluate behavioural responses to new drugs produced by the nervous system.

To fully assess the pharmacodynamic effects (effects of a drug on the body) of a new drug testing in animals is necessary. Only in a fully operational circulating system can the drug's distribution, metabolism, excretion which may alter or intensify the efficacy or adverse effects of the new medicine be fully understood.

For these reasons animal models remain essential in the development and safety assessment of new medicines.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers we have used are based on figures of previous usage from previous projects, or a projection thereof (based on estimated incidence) based on requests received from customers in the past. It is, however, impossible to accurately predict the number of studies that may be performed, in the circumstances.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments will be designed in order to achieve the scientific objectives using the minimum numbers of animals. For study types that are less well established and for which historical data may not be available, the literature will normally be consulted to help establish the group size. Alternatively, there may be other data to aid this process. The Department of Statistics are often consulted to assist in this process particularly where the study type is not routine.

Whenever possible, common control groups will be used in order to minimise the numbers of groups used.

For less established study types, preliminary pilot studies may be conducted whereby smaller numbers of animals may be used to generate data in order to ensure that the experiment operates to expectations and to generate some data which may be used to optimise the study design.

Experience has shown that occasionally, Sponsors have a preference with regard to their design and numbers of animals to be used. Rationale for the design will be requested from the Sponsor and such designs (particularly where they are at variance with EU requirement or studies usually conducted here) will be discussed internally (and with the Home Office as appropriate) and forwarded to the Department of Statistics for advice. Such advice will be taken into account when determining the design/numbers to be used in the study with the goal of using the least number of animals to achieve the scientific objective.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For studies where a new drug is being tested in animals for the first time, we would often test that in a small group of animals (usually 3-5) to give us confidence that the dose levels we chose are safe, and the drug affects the system its designed to, without making an animal ill. These are called pilot studies.

We will try and get as many outputs as we can from a single animal where possible, without adversely affecting its welfare. So if we need to get a blood sample to confirm the presence of a drug or biomarker, for example, we will often do that in the same animal, rather than use separate ones, when possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Greater than 80% of animals used on a previous project involved a single dose of test material followed by observations which largely involve not actually touching the animal after dosing (a few behavioural tests do involve handling and a mild application of a stimulus). Similarly measuring locomotor activity usually involves placing an animal in a cage using an automated system, or a shorter visual observation and counting of movements by eye.

In some studies we may need to take serial blood samples from animals to find out how the test material is handled in the body. Taking a blood sample from an animal causes about the same amount of pain as having a blood sample taken by a nurse. All of the people who do this work are trained to do this without causing any undue pain or distress.

To test for anticonvulsant activity of a drug, you have to induce a convulsion using a specific drug at a fixed dose. As soon as a convulsion is observed, the animal is humanely killed. During the administration of the drug the animal is watched throughout. Similarly to assess sleeping time (a test to measure if a test material has the ability to stimulate or depress CNS function) then you have to dose the animal with a drug that causes them to fall asleep sleep. We monitor the animals throughout this time, keep them warm, and as soon as the animal wakes up, and we have measured this time, the animals are humanely killed. Again these animals are constantly watched during their sleep and kept on a heated surface to maintain body heat.

In the rare cases we need to surgically prepare animals, we consult a vet prior to surgery to agree doses of pain killing drugs and antibiotics if required. We then perform the surgery using the same principles of sterility and post operative care as if it was a patient undergoing surgery in a hospital.

We very occasionally use guinea pig pups for a specific test to measure anxiety. This is a well characterised model, dependent on the pups being separated from their mothers for short periods, hence we have to use animals of this age. Separating the pups from their mother makes them anxious and allows us to test potential drugs for anxiety, to see if their behaviour changes with or without the drug.

Why can’t you use animals that are less sentient?

Rodents (rats, mice and guinea-pigs) will be used in all of the studies conducted under this licence. Rodents are considered to be of the lowest neurophysiological sensitivity that will allow us to achieve the study aims and are considered suitable for the predicting what's likely to happen in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is of utmost importance and Good Surgical Practice will be observed for any animal undergoing surgical procedures. Surgery will be conducted using aseptic techniques (to prevent infection) which meet at least the standards set out in the Home Office Minimum Standards for Aseptic Surgery. Before we start surgery, we agree with a Vet what pain killers or antibiotics the animals need both before and after the surgery. When recovering from surgery, we give the animals extra heat and monitor them closely until they start behaving normally again. We then check them at least twice daily before they go on study.

In addition, care is taken to provide as much environmental enrichment as possible . This is things like plastic shelters in their cages, blocks to gnaw on, extra bedding for warmth and if they need it, food supplements after surgery.

Dosing and sampling procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm and will be the minimum consistent with the scientific objectives of each study. In addition, suffering will be further minimised by implementing clearly defined humane endpoints to prevent excess suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For any surgical interventions, then the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) will be followed.

For blood sampling and dosing then the following guidelines/literature will be followed:

First report of the BVA/FRAME/RSPCA/UFAW joint working group on refinement, Laboratory Animals, 27, 1-22 (1993).

A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Journal of Applied Toxicology, 21, 15-23 (2001).

Regulatory guidelines

ICH 7A SAFETY PHARMACOLOGY STUDIES FOR HUMAN PHARMACEUTICALS.

ICH Topic M 3 (R2) . Non-Clinical Safety Studies for the Conduct of Human Clinical Trials and Marketing Authorization for Pharmaceuticals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This will be achieved by regular discussions with our Named Information Officer, colleagues in Animals Technology, and by attending appropriate training courses and conferences, or getting feedback from such events.

106. Therapeutic potential of tregs

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

T regulatory cells, Therapy, Transplantation, Autoimmunity

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to explore novel strategies for increasing T regulatory cell numbers. T regulatory cells (or "Tregs" for short) are immune cells that play a key role in keeping the immune system under control.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work as there are many instances where increasing Treg numbers would be beneficial for patients.

For example, increasing Tregs may help prevent the rejection of transplanted organs. Organ rejection occurs when the recipient's immune system "sees" the donor organ as

foreign, triggering a response that ultimately destroys the transplant. Currently patients receiving organ transplants are treated with immunosuppressive drugs which reduce the risk of rejection by dampening down their overall immune response. However these drugs are not fully effective (despite these drugs a significant proportion of patients still reject their transplant), and they have side-effects, including leaving patients more susceptible to infections. Increasing Treg numbers may: (i) reduce the risk of rejection further and/or (ii) allow the dose/duration of immunosuppressant treatment to be reduced, so reducing side effects.

Increasing Treg numbers may also be helpful in treating patients with autoimmune diseases - such as multiple sclerosis. Autoimmune diseases occur when a patient's own immune system mistakenly "sees" their own tissues as foreign, damaging them. In multiple sclerosis it is the coating of the nerves in the brain and spinal cord that is attacked and damaged leading to disability; this coating is called myelin.
Dampening down an over-reactive immune system by boosting the number of Tregs may be a safe therapy to try.

What outputs do you think you will see at the end of this project?

We expect to see several outputs at the end of this project. Including:

1. Generating new information. In particular we will determine if we can increase Treg numbers within our animals using two strategies (a) by transplanting laboratory expanded (outside the body) Tregs into our animals; (b) by giving a drug called IL-2.

2. Publications and presentations. We expect to publish the results of these studies in peer-reviewed scientific journals. We also expect to present the findings of our work at local, national and international scientific meetings.

3. Intellectual property that may support a planned patent application. We have recently identified a novel type of Treg, present in the blood and tissues of humans. In addition to testing "standard" Tregs in our animal models, we will also test these "new Tregs" in this project. We hope this will generate additional data to support our planned patent application.

4. Data to support future funding applications/clinical trials. We are very excited about the potential therapeutic applications of our work. And we hope that data generated in this project will help us apply for additional funding to take this work forward and "nearer to the clinic".

Who or what will benefit from these outputs, and how?

Beneficiaries of this work will include:

1. In the short-term - our work will benefit the clinical and scientific community working on Tregs, including individuals working on strategies to increase Tregs within the body.

2. In the medium to longer-term - if we demonstrate that IL-2 increases Treg numbers in one of our animal models (which will mimic what happens to the immune system of patients with multiple sclerosis (MS) receiving treatment with an immune-depleting drug called alemtuzumab) we will carry out a clinical trial of IL-2 in MS patients treated with alemtuzumab. Alemtuzumab is a highly effective treatment of MS, but it has side-effects.

In particular, 50% of patients treated with alemtuzumab develop thyroid autoimmunity - that is, after treatment, their immune system starts to attack and damage their thyroid gland (instead of damaging the protective coating of the nerves). We believe we can reduce the risk of this happening by boosting Treg numbers with IL-2. If we are correct our work will significantly benefit individuals with MS, allowing them to receive treatment with a highly effective drug, without the risk of complications.

3. In the long-term our work on laboratory-expanded Tregs and our "new type of Treg" has the potential to help patients undergoing organ transplantation, and also patients who suffer from autoimmune conditions such as MS.

How will you look to maximise the outputs of this work?

We will maximise the outputs of our work by:

1. Collaborating with other groups - including groups working on therapies for MS, and groups working on understanding Tregs. We have a strong collaboration record.

2. Disseminating new knowledge - through presenting our work at local, national and international meetings and by publishing our work in peer reviewed journals. We will also aim to publish any novel protocols we develop, and negative data/unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 2,250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

1) We will use adult mice that lack an immune system of their own (such as NOD-scid IL2Rgammanull - also known as NSGs) to answer objective 1 "Are expanded human CD8 Tregs suppressive in vivo?" Because these mice lack an immune system, they can be "humanised". That is - when human immune cells are transplanted into the mice (by injection), they can survive and form a working immune system. This process is called engraftment. We have extensive experience of working with NSGs and know that they are the best type of mice to use for these sorts of experiments.

2) To answer objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?" we will use adult human CD52 "transgenic" mice (hCD52tg) or wild type mice. hCD52tgs have been genetically engineered to express a human version of a molecule called CD52 on their immune cells. This allows us to mimic what happens to the immune system when patients with multiple sclerosis are treated with a drug called alemtuzumab. Alemtuzumab binds to, and depletes, cells expressing CD52 (immune depletion). After treating the mice with alemtuzumab we will see if we can increase Treg numbers by giving the mice IL-2. hCD52tg mice have previously been shown to closely mirror immune depletion and immune recovery seen in humans following treatment with alemtuzumab, so are the appropriate animals to use to address this question. In this project we will also

study the effect of low- dose IL-2 in promoting Tregs following other immune-depleting drugs, including cladribine another treatment licensed for multiple sclerosis. Wild-type animals or hCD52tgs can be used in these experiments.

Typically, what will be done to an animal used in your project?

To answer objective 1 "Are expanded human CD8 Tregs suppressive in vivo?" adult NSGs will receive a human skin graft. During this procedure a small piece of human skin (obtained with appropriate consent, typically from deceased organ donors or from patients undergoing cosmetic surgery) will be stitched onto the mouse's back after removing a very small piece of mouse skin. This will be done under a general anaesthetic and the mice will be given painkillers afterwards if needed. Once the skin graft has healed, the mice will be "humanised" by transferring human immune cells plus or minus Tregs intravenously (i.e into a vein) or intraperitoneally (i.e. into the body cavity). Prior to immune transfer the mice may be exposed to low dose irradiation, that makes 'space' for the incoming human immune cells to grow. Read out from this type of experiment is rejection of the skin graft (from time of humanisation). Transferring Tregs into the mice should delay or prevent graft rejection. Mice may be imaged to see where the Tregs have redistributed within the mice, if done this will be performed under a general anaesthetic.

For objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?" adult hCD52tg mice (and non transgenic litter mate/ wild-type controls) will be treated with alemtuzumab (or other immune-depleting drugs such as cladribine). Following immune depletion, the animals will be treated with low dose IL-2 or placebo (i.e. an inactive sterile liquid) given subcutaneously (i.e under the skin). The ability of low dose IL-2 to increase Treg numbers will be assessed by serial blood tests.

What are the expected impacts and/or adverse effects for the animals during your project?

1) For objective 1 "Are expanded human CD8 Tregs suppressive in vivo?"

All mice will undergo a brief surgical procedure under a general anaesthetic to receive a skin graft. Similar to humans, it is common for mice to be a little "groggy" for a short while post- anaesthesia, and for a day or so they may go off their food slightly. The mice are expected to recover well from the skin-grafting, and no adverse effects or only mild soreness at the graft site is anticipated.

No or minimal adverse effects are expected from transferring a human immune system (humanisation) of these animals other than the transient discomfort from the injection.

2) For objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?"

Treatment with alemtuzumab has been shown to cause either no or very mild effects when given to hCD52Tg mice.

From the literature, we expect no or only very mild effects from from treatment with cladribine.

IL-2 is a naturally occurring chemical messenger (or "cytokine") and is not known to cause any adverse effects in treated mice when given at low doses.

Administering alemtuzumab (and other immune-depleting drugs such as cladribine) and IL-2 will require the mice to have an injection which may cause transient discomfort at the injection site.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For objective 1 "Are expanded human CD8 Tregs suppressive in vivo?"

- Mild - 25%
- Moderate - 75%
- For objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?"
- Mild - 90%
- Moderate - 10%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals to address objective 1 "Are expanded human CD8 Tregs suppressive in vivo?" because this is the only way to assess the full suppressive capability of these cells, including how they migrate into different tissues. Whilst experiments done in the laboratory in test tubes and petri dishes (in vitro) are useful, and will be used as much as possible throughout the project, they can not mimic cell to cell interactions that take place in a tissue/organ environment over time. For this, experiments in living animals (in vivo) are needed.

We need animals to address objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?" because it is not possible to mimic immune depletion and recovery over time in the laboratory. Furthermore, it is not possible to assess the behaviour of IL-2 within the body in a "petri dish".

Which non-animal alternatives did you consider for use in this project?

There is no non-animal alternative to address objective 1 "Are expanded human CD8 Tregs suppressive in vivo?"

To address objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?" we did consider going straight to a small clinical trial in humans. We considered this because low dose IL-2 is being given to human patients in other clinical

settings and is well tolerated. However, as described below, we concluded that this is not appropriate.

Why were they not suitable?

We did not think it was appropriate to go straight to a human study to address objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?", because, despite low dose IL-2 being safe in humans in other clinical settings, from our extensive in vitro work, we have concerns that it may cause problems after alemtuzumab or other such immune-depleting drugs.

Low dose IL-2 normally only expands Tregs. Other immune cells (called T-cells) also express the receptor for IL-2, so can respond to it. But their level of receptor expression is much lower than that of Tregs, so they are unable to respond to low doses. However, we have shown (through extensive in vitro studies) that expression increases after alemtuzumab (and the same may apply following treatment with other immune-depleting drugs). It is possible therefore, that low dose IL-2 might expand up unwanted aggressive T-cells (as well as Tregs) post-treatment. In patients this might lead to a worsening of their disease. It is therefore essential that we test this novel treatment strategy in mice first.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number has been estimated from our extensive experience of doing this kind of work. We have estimated that 250 mice will be required for "rederiving" (i.e. establishing a new colony of mice from frozen eggs and/or sperm) any further strains of mice we need for this project. Up to 2000 mice will then be used to answer the experimental questions.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase we (i) sought guidance from the NC3R's experimental design assistant on-line tool and (ii) reached out to collaborators who have extensive experience of the specific animal models we are using. In addition, we have in house experience of use of low dose IL-2 to expand Tregs in vivo, and our number estimates are based, in part, on these data. Our experimental design has also been informed by effect sizes seen in vitro (particularly for our work on response to IL-2 post-alemtuzumab).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise animal usage we will:

Breed animals as efficiently as possible - attempting throughout the protocol to match breeding with experimental need as closely as possible. This will require careful experimental planning.

Throughout the project we will perform our experiments on small groups of mice (3-5 animals at a time), in pilot studies, and will review the results prior to extending our work to larger numbers/ we will adapt our work accordingly.

Share animals with local collaborators - this is particularly relevant for NSGs where there are a number of groups locally using this animal model. This is something we routinely do on our current licence.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The two mouse strains that will be used during this project (i.e. NSGs and hCD52tg) are normal in appearance. The NSGs are more susceptible to developing infections and the hCD52tg will become more susceptible once treated with alemtzumab - but this will be mitigated by keeping these animals in a near-sterile environment.

Animals used to answer objective 1 "Are expanded human CD8 Tregs suppressive in vivo?" are not expected to suffer any distress other than that caused at the time of the skin graft surgery. A transplant model is required to address objective 1, and skin grafting is the least invasive transplant model and the transplant model with least expected complications. The surgery is done under general anaesthesia and pain relief is administered. The mice are closely monitored for the few hours following surgery and until they fully regain consciousness, this normally occurs over the first 2-3 hours by which time they are usually behaving normally. Mice will then be followed closely over the next few days and weighed daily. We expect the mice to recover well from the surgery but will be watching for weight loss and any signs of over-grooming at the site of the skin graft. Mice will remain whenever possible in their social groups.

Animals used to answer objective 2 "Does low dose IL-2 increase Tregs following lymphocyte depletion?" are not expected to experience any harm, aside from the transient discomfort from the injection(s). We expect little in the way of any adverse effects from these experiments but will monitor the mice daily and keep constant weight measurements for each mouse.

Why can’t you use animals that are less sentient?

We cannot use a “lower species” for our work, that is less sentient - because we need to study an animal with a similar immune system to that of humans, and therefore we need to study a mammal.

Furthermore, the two models we are planning to use in this project - engrafting of a human immune system, and transgenic expression of the human protein CD52 - have only been established in mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals used on this project will be monitored daily for any signs of ill health or distress. Particular care will be taken after skin-grafting, with increased frequency of observation over the first few hours post-operatively, and through the use of pain medication which if need be could be provided in the way of flavoured jelly (or such-like) that can be self-administered by the mouse. Immediately post- operatively mice will be kept warm and then will be housed in cages with additional soft bedding.

Throughout our project, we will aim to improve the quality of life for our animals – for example by providing enrichment, housing mice in social groups whenever possible and by avoiding single housing (apart from in exceptional circumstances, which will be time limited).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are aware of, and will always aim to adhere to, good practice guidelines (as given by the Laboratory Animal Science Association; LASA). For example for objective 1 "Are expanded human CD8 Tregs suppressive in vivo?" we will ensure that we follow the LASA guidelines for performing aseptic surgery (as given in the updated 2017 document) – such as writing a pre-operative plan, administering pain medication and fluids as required and most importantly ensuring that the procedure is performed by a researcher who is fully trained.

We are also aware of the ARRIVE Guidelines (version 2.0), including their reporting guidelines around the importance of including information on experimental design and statistical analyses and strategies to minimise bias and how to report in publications.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will remain informed about advances in the 3Rs by speaking to colleagues locally (including veterinary surgeons, senior animal house technicians etc) and by reading information sent to us by the local licencing department. We will also ensure that we stay up to date by visiting relevant websites (including that of the NC3Rs and Norecopa) and by attending relevant conferences and training events.

As a project team we will meet regularly to ensure that we are adhering to the 3R guidelines, and implementing any changes, effectively.

107. The ecophysiology of fish

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

energy, metabolism, mitochondria, behaviour, growth

Animal types	Life stages
Atlantic salmon	embryo, neonate, juvenile, adult, pregnant, aged
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The efficiency with which animal cells produce energy seems to vary widely among animals. We aim to understand why this variation persists; one reason why it might is that animals that are inefficient in their use of energy might gain a benefit of ageing more slowly.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to understand why the efficiency of energy use varies among individual animals (and how it might vary over time in the same animal) because this will greatly

influence their capacity to cope with changing environments. Animals that are more energetically efficient need to consume less food per day, so can cope in situations where food availability is low. They may also be able to compete more effectively for that food, or for other resources such as shelter or mates. However, if this greater efficiency comes at a cost of greater damage to their tissues, they may age faster (or have to invest more in repairing tissue damage). This could have consequences for their lifespan, and hence for the optimal age at which they should start to reproduce. Therefore not all environments are likely to select for the same outcome to this dilemma, so producing animals with different levels of energetic efficiency. This is of fundamental biological interest but also is of applied significance, since it should influence our approach to selecting animals for captive breeding and reintroduction programmes as well as any agricultural or fish farming breeding programme.

What outputs do you think you will see at the end of this project?

This project should generate many new findings related to the links between metabolic rate, energy efficiency and performance in animals. The results are also likely to show how the optimal energetic efficiency in animals depends on the environment in which it is living. The results will be presented in the form of scientific publications and seminars, together with articles and talks aimed at a more general lay audience.

Who or what will benefit from these outputs, and how?

This is a fundamental science project that aims to provide knowledge on how animal cells optimise the supply of energy for the body. It does not have a directly applied aim, but the information generated will be relevant to those involved in selective breeding programmes, whether for food production or for conservation, since it will highlight whether the importance of maximising energy efficiency depends on the environmental conditions.

How will you look to maximise the outputs of this work?

The aim will be to publish all valid experimental results, regardless of the size of the observed effects or whether these supported the original hypotheses. We will aim to promote successful new approaches, both directly by using these approaches in collaborations with other research groups and indirectly by describing these approaches in our scientific publications. Our research group has a high profile and our previous research has been highly cited, so we would expect that we would not have difficulty in disseminating our new research to the scientific community.

Species and numbers of animals expected to be used

- Other fish: No answer provided
- Zebra fish (Danio rerio): 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

There is pronounced variation among individual freshwater fish in both their behaviour and their physiology, thus making them ideal for this kind of study. Moreover they live in simple environments, the essential features of which can be replicated in the laboratory; this has the combined benefit of reducing stress on the fish while generating results that are applicable to the real world. All life stages will be used since the study involves examining the impact of the environment experienced in early life on the performance of the animal in adulthood.

Typically, what will be done to an animal used in your project?

Experiments will typically involve anaesthetising the animal up to a maximum of 20 times, but more usually 2-3 times, in order to measure/photograph it. In laboratory experiments, fish will generally be randomly assigned to treatment groups that differ in an environmental variable such as the temperature or water flow in which they are living, or the composition of their diet. After a period of time of 2-4 weeks (rarely 2-3 months) their metabolic rate or swimming performance may be measured, and the fish humanely killed in order to collect a tissue sample for measurement of cellular function. In a small number of experiments fish may receive an injection of a substance designed to allow measurement of the rate of protein synthesis or rate of ageing; each fish will typically only receive one injection. In field experiments, wild fish will be captured, anaesthetised and measured and then returned to the site where they were caught. None of the procedures will involve surgery.

What are the expected impacts and/or adverse effects for the animals during your project?

The fish used in this project will only be subjected to benign procedures such as brief anaesthesia (typically lasting less than 3 minutes, for purposes including measuring and/or photographing), manipulation of environmental conditions (e.g. diet, temperature) or measurement of metabolic rate or swimming performance. At most they are expected to experience transitory mild pain when being given an injection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the severity to be Mild for all animals.

What will happen to animals at the end of this project?

- Killed

- Kept alive
- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research programme described here addresses questions about the behaviour and physiology of whole animals in response to their environment and so the objectives cannot be met without conducting field and controlled laboratory experiments using animals.

Which non-animal alternatives did you consider for use in this project?

It is not possible to conduct studies in this area using non-animal alternatives.

Why were they not suitable?

There are no means to study the behaviour and physiology of animals in response to their environment using non-animal alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Both field and laboratory experiments will be designed to minimise the number of fish used, based on previous experience and previous published research that has used similar approaches. The numbers appear large because in some cases large numbers of fish will be anaesthetised in order to measure population differences in the growth rates of fish living in different environments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Both field and laboratory experiments will be designed to minimise the number of fish used. These experiments will combine measurements across a broad range of traits to reduce the total number of fish used while maintaining high statistical power.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

These experiments will combine a broad range of measurements to obtain the maximum information from each fish and so reduce the total number of animals used while maintaining high statistical power.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Freshwater fish exhibit pronounced variation among individuals in their behaviour and physiology, thus making them ideal for this kind of study. Moreover they live in simple environments, the essential features of which can be replicated in the laboratory; this has the combined benefit of reducing stress on the fish while generating results that are applicable to the real world. None of the protocols that will be used in this project should cause more than very transient pain.

Why can't you use animals that are less sentient?

The aim of the project is to examine the relationships between the behaviour and physiology of the animal and its performance in contrasting environments, and so fully functioning juvenile or adult animals must be used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are continuously refining our husbandry regimes and scientific procedures to minimise any welfare costs of the experiments (an example being that we now sometimes avoid the need to anaesthetise a fish by weighing it in a container of water).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The relevant Home Office ASRU Advice Notes (e.g. 03/2015 Re-homing and setting free of animals; 02/2016 Working with animals taken from the wild), the ARRIVE guidelines, and Buchanan, K.L. et al. (2012) Guidelines for the treatment of animals in behavioural research and teaching. Anim. Behav. 83: 301-309).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive regular updates on advances in the 3Rs from my establishment's AWERB, NVS and NTCO, who point me in the direction of training events (e.g. regular experimental design courses), workshops (e.g. the RSPCA fish welfare meeting) and new scientific papers describing methodological or husbandry advances.

108. Immune mechanistic models of autoimmune disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Autoimmune Disease, Adoptive Transfer, Immune Cells, Therapy, Inflammation

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project’s aims and objectives are to evaluate therapeutic entities in in vivo mechanistic models, which are based around key aspects of immune mechanisms involved in human autoimmune diseases, including graft-versus-host disease and transplantation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Although many advances have been made in recent years in our knowledge and understanding of human autoimmune disease in identifying cell types and mediators

involved in the mechanisms driving the disease process, a great unmet need for novel therapeutics that treat and cure autoimmune diseases still persists. This project will address some important immune mechanisms involved in human disease and the mode of action of novel therapeutics in modifying these mechanisms.

What outputs do you think you will see at the end of this project?

This project will address some important immune mechanisms involved in human disease and the mode of action of novel therapeutics in modifying these mechanisms with the aim to develop new therapies for patients with severe autoimmune disease.

This project will also aim to publish and share novel findings with the immunology community.

Who or what will benefit from these outputs, and how?

This project will address some important immune mechanisms involved in human disease and the mode of action of novel therapeutics in modifying these mechanisms.

Short term outputs of this project include a broader scientific understanding of immune pathways involved in autoimmune disease and the mechanims of action of certain novel targets and therapeutics.

However, of note is that novel therapeutics will in average require 10 years from an idea all the way through clinical development and onto the market to benefit patients with severe autoimmune diseases.

How will you look to maximise the outputs of this work?

We will have regular collaborations with scientific key opinion leaders in academia and industry with the aim to further advance our common understanding and accelerate the development of our therapeutics. We will also endeavor to publish key learnings in peer reviewed paper and scientific conferences.

Species and numbers of animals expected to be used

- Mice: 9000
- Rats: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The immune system of rodents (mice and rats) shares many similarities to the human one. Mechanistic models in rodents can be used to research novel pathways and the mode of

action of novel therapies in models that translate into clinically relevant mechanistic models.

Typically, what will be done to an animal used in your project?

Animals may undergo procedures involving injections. The animals may experience short term discomfort caused by the injection. For all procedures anaesthesia will be used where appropriate and animals will be carefully monitored to ensure that discomfort to the animal is limited. All procedures have been ethically reviewed and all animals undergoing procedures will be well looked after by trained staff that work closely with a veterinary surgeon. At the end of each experiment all animals will be humanely killed, by a Schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

All short-term mechanistic models in this project are generally not expected to cause any signs of disease. Animals will be closely monitored and any animals displaying prolonged signs of pain and discomfort will be humanely killed, by a Schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity is between mild to moderate with most animals in the mild category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

At present, there are no alternatives, as in in vitro technology or computer modelling and simulations that can replace the requirement of the use of animals. Autoimmune and inflammatory processes are complex and involve many different cell types in the context of a microenvironment which cannot be reproduced in in vitro models. A better understanding of all of the components involved in these processes will help in establishing viable alternatives in the future.

Furthermore, the regulatory authorities for the development of drugs state it as a requirement that novel drugs are tested in vivo for their pharmacological activity, efficacy and safety.

Which non-animal alternatives did you consider for use in this project?

Wherever possible, in vitro cell based assays will be used to study functional responses of immune cells in isolation or combination. And an up-to-date knowledge of the literature and latest technology will help replace in vivo experimentation wherever possible.

This includes the following databases for alternative methods:

- The John Hopkins Centre for Alternatives to Animal Testing (http://altweb.jhsph.edu)
- Animal Welfare Information Centre (http://awic.nal.usda.gov/)
- European Centre for the Validation of Alternative Methods (http://ecvam.jrc.it/index.htm)
- Fund for the Replacement of Animals in Medical Experiments, FRAME (http://www.frame.org.uk/)

Why were they not suitable?

Autoimmune and inflammatory processes are complex and involve many different cell types in the context of a microenvironment which cannot be reproduced in in vitro models. A better understanding of all of the components involved in these processes will help in establishing viable alternatives in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based upon the typical n numbers required in an individual experiment and the number of experiments likely to be performed over a 5 year period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Optimum group sizes have been established for all protocols and are generally between 8-10 animals per group. These numbers are under continuous review, which take into

account the experimental variability and disease incidence to ensure statistical empowerment and meaningful and interpretable results.

A close collaboration with our Statisticians has led to a reduction in numbers of animals used for protocols which are used for projects on a routine basis.

Experimental data will be analysed using appropriate statistical tests. Experience with the experimental protocols will be applied, to ensure the appropriate group sizes are used to identify any statistically significant differences between the groups whilst minimising the numbers of animals undergoing the protocol.

Wherever possible, multiple readouts will be carried out and combined into one experiment to maximise the results obtained and reduce the number of animals used overall.

Bioimaging and multi-coloured flow cytometry, including the use of the CYTOF, will enable longitudinal studies in one animal over time and more complex readouts being combined.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A significant proportion of our drug discovery process involves in vitro assessment of compounds using cells and cell lines, with many thousands of potential drugs being screened to identify the most promising compounds/antibodies. However, in order to study complex inflammatory responses, further testing is required in animals in which disease symptoms have been induced.

To ensure the fewest number of animals are used, only the most effective compounds/antibodies that have been pre-screened for activity in vitro will be examined in animals. Only a limited number of these compounds/antibodies will be evaluated in this project. and those molecules will have been previously evaluated in simpler in vivo mechanistic models.

An initial pilot study consisting of a single high dose group plus control may be conducted initially to determine efficacy prior to larger multi dose group studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All new molecules will have undergone in vitro profiling prior to testing them in vivo. Pharmacokinetic studies will have been carried out to ensure that suitable dosing regimens are applied to produce the required exposure to show in vivo efficacy.

In our experience, adverse drug reactions have generally been found to be rare (<1%) with in vitro screening assisting in the identification of entities that are likely to be toxic. All protocols are under constant review, so that any new data from the scientific and clinical literature can be considered in the development and optimisation of the animal models.

Within each protocol, we aim to limit animal suffering through a careful choice of stimuli and adjuvants used. Distress scoring sheets are in place for some protocols and employed to help monitoring of the animals.

Why can’t you use animals that are less sentient?

Rodents (mice and rats) are the most appropriate species to use to study immune mechanistic responses and immune inflammatory responses. The use of transgenic mice leads to more robust readouts especially when following particular cell populations.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

A greater knowledge of our established models allows us to select the most appropriate model to use to study a particular mechanism implicated in disease. Distress scoring sheets are used to monitor the severity of adverse events and experimental data are under constant review to determine that the correct level of in vivo immune activation is achieved with minimum stress to the animal. Humane endpoints are employed to limit animal suffering.

As we learn more about the models in terms of response rates and clinical signs, we continue to refine protocols with updated animal welfare sheets, adjusted protocols and endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance will be taken from organisations such as the nc3Rs and LASA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continuously review and learn from the literature and wherever possible incorporate any new advances in our 3R strategy.

The nc3rs.org website is a useful source of information regarding advances in the 3Rs which can be consulted for updated advice. Additionally advice will be sought from the NVS.

109. Mechanisms of cardiometabolic disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Obesity, Diabetes, Lipids, Lipotoxicity, Cardiometabolic

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine how obesity causes metabolic complications.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Obesity is one of, if not the leading cause of multiple major diseases. These include diseases traditionally classed as "metabolic" such as diabetes, and cardiovascular diseases such as heart attacks, stroke, and heart failure. Increasingly, however, obesity is also recognised to be a significant risk factor for diseases such as cancer, asthma, kidney

failure and arthritis. Obesity can also increase the risk of severe complications and death from infectious diseases such as Covid 19.

However, we know that what links obesity to diseases is not the weight itself. If you walk around carrying an 80 kg backpack all day, you do not get diabetes - you become physically fit. We believe that what connects obesity to metabolic diseases is primarily a failure in fat tissue itself. Each individual has a genetically and environmentally determined limit on their ability to store fat safely. When that limit is reached, fat begins to accumulate in other organs and cell types. Scientists have now found that this accumulation happens in almost every organ and cell in the body they have studied, from the liver and muscle where it causes insulin resistance which leads to diabetes, to the immune system, where it can increase our risk of asthma and arthritis. We aim to study how fat tissue stops working and when it does, how to either prevent lipid accumulation in other organs, or make that lipid accumulation less damaging.

In an ideal world we would combat the diseases caused by obesity by treating obesity itself. However, despite decades of work by academics and the pharmaceutical industry, it has turned out to be nearly impossible to design drugs to reduce food intake and body weight. Given that we can't make people lose weight, trying to reduce the damage obesity does to our bodies is an essential approach to reducing the disease burden (as of 2016 the WHO estimated that 1.9 billion adults are overweight worldwide). It is estimated that obesity and its associated cardiometabolic diseases will cost the UK economy 50 billion GBP per year by 2050 (www.gov.uk). Furthermore, obesity has a tremendous quality of life cost, increasing the likelihood of developing diabetes 5 fold, some cancers by 3 fold, and high blood pressure, a major risk factor for heart disease by 2.5 fold. Overall, obesity was estimated to account for 23.1% of all deaths in the UK as of 2017.

What outputs do you think you will see at the end of this project?

We have **six objectives.** Our first three focus on how fat tissue (also known as adipose tissue) stops working. Healthy fat tissue **a)** buffers the amount of fat (known as lipid) in our blood to allow us to safely cope with eating different types of food; **b)** stores nutrients for the long term; **c)** secretes a mixture of proteins that regulate all aspects of our body's function. When fat tissue stops working correctly, these functions break down and the lipid that should go to fat tissue ends up in other organs like the liver and muscle where it stops insulin working, leading to diabetes. It can also cause heart failure by poisoning the heart, and it can also cause inflammatory diseases like arthritis by poisoning the immune cells.

In our first three objectives, we will determine **a)** the mechanisms and genes responsible for causing a breakdown in lipid buffering; **b)** determine how our bodies wound healing systems, which lead to scarring, get inappropriately activated in fat (and other tissues) and stop it working; **c)** validate how three genes that have been identified as possibly limiting adipose tissue function in humans actually stop fat tissue working.

These three objectives are essential as all three represent understudied or new processes/genes that may link obesity to metabolic complications and thus provide new drug targets.

Objective 4 focuses on how to combat the metabolic defects of failed fat tissue. As mentioned above, when fat fails, lipid goes to other organs. If we can reroute this fat to organs which can burn it (muscle and a specialised thermogenic organ called brown fat), we can stop it from accumulating in other tissues that cannot burn it. However, if we are to send fat to organs that can burn it, it is essential to make sure we can also actually activate their fat burning systems, otherwise they will simply fill with fat and stop working themselves.

Turning on fat burning systems is an attractive approach, as it potentially allows treatment for a collection of "cardiometabolic diseases" including diabetes and heart failure. In addition to treating these diseases, it may also cause weight loss through increasing energy expenditure.

Objective 5 focuses on how lipid accumulation in other organs causes toxicity. Under this license we will look at how the toxic accumulation of lipids in organs and cell types, including liver, heart, muscle, pancreas, and the immune system, leads to a wide range of obesity-associated metabolic diseases.

Objective 6 is a more specific objective to validate a better model of human liver disease progression. Liver disease (known as NAFLD) goes through several stages. The mildest is called "non-alcoholic fatty liver" (NAFL). The next stage is called "nonalcoholic steatohepatitis" (NASH). NAFL is characterised by inappropriate fat accumulation, whereas NASH has fat accumulation, inflammation and liver scarring. We currently have no good models to study how NAFL turns into NASH. Three dietary models of fatty liver disease have been selected to best mimic human NAFLD, and in particular to look at how NAFL turns into NASH. These models have been selected based on historical human and animal data from thousands of experiments. However, the data has been collected over the years and is patchy and non-standardised. We will test the three best candidate models to determine which is the best.

Objectives 1-5 will primarily produce scientific papers as their main output. In addition, we have links with industry and will look to move the results from these objectives into early-stage clinical trials and biomarker discovery. Biomarkers and things we can measure in the blood that tell us about the stage of disease help decide when and how to treat people, and provide information on whether drugs work. We disseminate our data at conferences and via web based media outlets predominantly targeted at the scientific community. In addition to scientific outputs, we also engage with the public and produce lay science pieces.

Who or what will benefit from these outputs, and how?

In the short term, the primary beneficiaries will be the scientific community. The immediate beneficiaries will be those working in the field of metabolism. However, given the range of diseases obesity is a risk factor for, we expect our research to be of benefit to the fields of immunology, cardiovascular disease, hepatology (the study of the liver) and cancer.

Our work will help to inform human clinical trials in both academia and industry. In the longer term, we expect our research to benefit the pharmaceutical industry, where the genes and processes we identify will provide new targets for creating drugs to combat obesity-associated diseases. We have links with the university technology transfer office to maximise the value of our work by patenting it where appropriate.

In particular, **objective 1** may also benefit nutritionists and dieticians. This objective strongly focuses on the impact of the timing of nutrient usage and how it can worsen or improve metabolic disease. As such, it may lead to personalised diets for people with different macronutrients at different times of day (e.g. fat in the morning for some people, carbs for others and vice versa).

Finally, if our work leads to new treatments for the metabolic complications of obesity it will benefit the general public.

For objective 6, the overall benefits will be the same. However, the benefit to the pharmaceutical industry will be short-term rather than longer term as we expect an immediate adoption of the chosen optimised model of fatty liver diseases for the development of new drugs.

How will you look to maximise the outputs of this work?

We have many national and international collaborators with whom we share our data and ideas.

We will publish our work in open-access publications. In addition to traditional dissemination routes, we have a website where we post videos regarding our work, in particular technical approaches we have developed for studying metabolism.

Furthermore, we actively engage with the public via lay science pieces and specific web-based media and podcasts.

Concerning the publication of unsuccessful approaches, this perhaps misses the point of science. One of our most successful publications in terms of citations, describes a paradoxical lack of phenotype in a mouse - sometimes the absence of "success," i.e. finding negative results - can be more important than finding many significant changes. Indeed we are currently preparing a manuscript comprised of exclusively non-significant (“unsuccessful”) results which we think will be of great importance to the field.

Species and numbers of animals expected to be used

Mice: 22500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using weanling and sexually-mature adult mice up to 15 months of age. This allows us to study cardiometabolic diseases, which are now recognised to impact all ages but become particularly prevalent in middle age. These are the least sentient species suitable for studying metabolism, which involves the complex interplay between many organs. Moreover, there is a large amount of data regarding specific strains of mice and how they develop metabolic diseases, making them suitable to study the function of genes that affect specific aspects of human cardiometabolic diseases.

Typically, what will be done to an animal used in your project?

We will be studying mice that develop metabolic disease. These will typically be induced by feeding a modified diet (e.g. high-fat or high-fat/high-sugar diets). Animals may remain on these diets for up to 14 months (from weaning at 3-4 weeks) but typically for a much shorter duration, and this would be expected to lead to obesity, insulin resistance and other obesity-associated metabolic complications, including liver disease, reduced heart function, and inflammation.

We will use genetically modified animals to work out the mechanisms that connect obesity to metabolic diseases. This will enable us to tell which genes/processes predispose us to develop metabolic disease or alternatively protect us against it. We know that temperature is a critical variable for controlling mouse metabolism and we may house mice at different environmental temperatures to control for this. Equally, we will use altered temperatures to investigate how mice make heat.

In a small number of animals under this license (less than 5 percent), we will perform a bone marrow transplant to study how the immune system affects metabolic disease. We will need to irradiate mice and give them bone marrow from another mouse.

In addition, an animal may undergo one or more of the following procedures, but a typical animal will experience no more than five of these:

Mice may receive drugs to alter their metabolism or to delete genes selectively at specific times or in particular organs, either through injections (these can be into a vein, into the body cavity, under the skin or directly into an organ), or orally (by mouth via a tube inserted into the stomach or in drinking water). Not all animals will receive such drugs and the volume and number of injections used to administer drugs will be the minimum needed.

Mice may be given substances known as tracers which allow us to understand more about their metabolism. Tracers are substances that allow us to study a metabolic process but do not affect it. For example, we can give a mouse a glucose tracer to determine if it has insulin resistance in its liver, muscle, or both. Not all animals will receive such substances. We give tracers by injection into their body cavity, into their veins or under their skin, and/or orally (in their food, drinking water, or via a tube into their stomach). Typically a single tracer injection is sufficient with/without administration of the tracer in drinking water, but some mice may receive up to 4 injections.

We may house mice alone for periods of time (typically no more than 3-4 days, but on occasion up to 4 weeks). This is necessary to measure the amount of energy they are expending, their activity and food and water intake, and to determine what nutrients they are burning and when. We will also singly house mice for food intake assessment. This can take as much as 2-3 weeks to get a reliable measure of food intake as mice can fluctuate their body weight by +/- 5% in 24 hours under free living conditions (equivalent to 4 kg in an average human!). As such their food intake is very variable over the short term but becomes more stable in the longer term.

Mice may be scanned using a non-invasive imaging method (e.g. TD-NMR) to examine their body fat percentage. Animals are briefly restrained (usually less than 3 minutes) in a plastic tube. This is both painless and harmless.

Some animals will be anaesthetised for less than 1 hour so that we can image their organs (usually heart or liver) using either ultrasound or MRI. We need to anaesthetise the mice in order to obtain clear images without the animal moving around. No animal would be expected to undergo this more than 6 times in their lifetime with at least 1 week between each imaging procedure.

At the end of the experiment, each animal will be killed using the most humane method that is possible, that does not prevent us from obtaining good scientific data.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals developing features of metabolic disease will show a range of adverse effects, including: obesity and insulin resistance, inflammation, tissue fibrosis and reduced heart function. They may experience some general discomfort associated with their increased body weight and become lethargic. Conversely, some specific diets (particularly to cause fibrosis in the liver) can cause mice to lose a large amount of weight. This weight loss happens in all mice and is not in itself a sign of illness. As weight loss is not a good sign of ill health when mice are on these diets we have to carefully monitor animals in other ways to ensure that they are not unwell. None of our interventions are expected to cause pain. Some genetically-modified animals might be expected to show similar adverse effects, whilst others would be protected from the impact of metabolic disease.

Animals undergoing bone marrow transplants may be unwell for several days after the irradiation, eat less, and thus lose weight. They are expected to start to recover body weight after 14 days and fully recover by 4 weeks.

Mice are not expected to experience any lasting harm from injections per se. Tracers would not be expected to cause any adverse effects. Drugs which alter metabolism may lessen or worsen the adverse effects associated with metabolic disease, but we will test them to make sure they do not cause unwanted side effects that are harmful to the mice.

Single-housing can be stressful for mice, but we will minimise the time each animal is housed alone. Where possible, animals will be re-housed in groups with their original cage-mates following a period of single-housing.

Animals anaesthetised for imaging/implantation of microchips (e.g. for sending body temperature to a receiver) will feel groggy as the anaesthetic wears off but will experience no pain or lasting harm. The imaging processes themselves are painless and harmless.

Non-invasive imaging (e.g. TD-NMR) for body composition analysis requires restraint, which can be stressful to mice, but causes no other pain or harm to mice.

Expected severity categories and the proportion of animals in each category per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

97% mild

3% moderate

What will happen to animals at the end of this project?

Killed

Kept alive

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cardiometabolic diseases involve the interplay between many different organs. For example, the development of diabetes as a result of obesity mostly involves dysregulation of food intake control by the brain, a loss of fat storage by the fat tissue, the accumulation

of toxic fat (known as lipid) species in the liver, muscle and the immune system that prevent insulin working. In turn, the beta cells, the cells in our pancreas that produce insulin, over-secrete insulin to counteract this "insulin resistance". The beta cells can only produce so much insulin and as insulin resistance progresses they ultimately fail. Such a system cannot be modelled in a dish in the lab (in vitro). Instead, it has to be studied in a mammalian system such as the mouse.

Which non-animal alternatives did you consider for use in this project?

We look to use animal alternatives where possible. We use cell culture models (cells in a dish in the lab that allow us to study aspects of how specific organs work) to look at specific mechanisms that occur in isolated cell populations. Results from these experiments can both be informed by our animal work and help us to design better animal experiments.

In addition, we have developed two sophisticated culture systems to help us to study fat and liver.

Firstly, over the past 5 years, our laboratory has been developing a human stem-cell based adipocyte culture system. This protocol takes us in a stepwise manner from stem cells through to fat precursors,

and then ultimately mature fat cells. Importantly it captures all the known developmental stages that the stem cells go through before ultimately becoming fat cells. The stepwise manner of our protocol makes it a powerful tool to probe genes regulating fat cell formation.

In addition to the work on stem cells, we have also developed an improved in vitro (in petri dishes) model of human hepatocytes (the primary cell found in the liver that performs its metabolic functions like controlling blood glucose levels) culture. A long standing issue in the field of liver disease has been the lack of good in vitro models, with even primary isolated hepatocytes losing many of the features they show when still in the mouse. In culture, hepatocytes rapidly regress from being mature hepatocytes and instead come to resemble fetal-like (similar to the immature hepatocytes found in developing babies while still in utero) cells within hours.

We have collaborated with a company that uses special liquid handling systems and complex three- dimensional biological “scaffolds” to produce synthetic organs. We have worked with them to create a model of human liver that includes both the hepatocytes and the other liver cells (Kupffer cells, the primary immune cell of the liver and another liver support cell, called the stellate cell). The results from this system were remarkable – producing a set of conditions which kept hepatocytes in almost the same state as we see in vivo.

Why were they not suitable?

While cellular models, even sophisticated ones such as the "organ on a chip" liver model (a tool that aims to reproduce the biology of an organ in silico), can address specific questions, they cannot allow the study of the complex interplay between multiple organs that leads to metabolic disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include, e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are primarily based on the level of work over the previous two licenses and the amount of funding we have in place and expect to use to fulfil our aims and objectives.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Metabolic disease has a complicated and lengthy disease progression. When we try to study it using diet-induced obesity, early stage events will occur in days, if not hours, of diets being changed, later stage events manifesting over weeks, and long term events that take months to appear. Given that many events happen at many times, perhaps the most critical question for reducing animal usage is to determine the correct length of time a mouse should be fed a high-fat diet for before we begin studying it.

For example, one specific lipid in the liver of mice called arachidonic acid will reset its levels within 24 hours of a change in diet and then remain constant for 3 months. This lipid is a key regulator of inflammation. As such many genes use it to make signalling molecules and there is a sophisticated system is in place to defend its levels. If we work on genes that regulate arachidonic acid levels, then the most suitable length of time to feed a diet to a mouse may be as little as 24 hours. Conversely, fibrosis is the cumulative build-up of scar tissue due to inappropriate activation of wound healing processes. It may take a period of as much as 9 months of high-fat feeding to develop measurable fibrosis in some organs.

To address these questions we have set about modelling the development of obesity associated metabolic complications to allow us to select the optimum length of interventions for studying specific disease processes. We have built several time courses of responses to different diets, which gives us much better information for selecting the length of our intervention.

In addition to optimising the conditions, we carefully consider which control groups are necessary in order to address the scientific question as we design individual experiments, and we use power calculations to ensure that we are using an appropriate number of animals.

We consider carefully how to get the most out of each animal we use. For instance, many of our animal studies involve the generation of models of metabolic disease (often reflecting a human condition such as diabetes, obesity or fatty liver disease). The nature of these diseases is such that they affect many organs of the body. As such, if we plan an animal study designed to probe the effects of diabetes on the liver, for instance, we think carefully about which other organs researchers in the laboratory can work on, such as heart and adipose tissue, and harvest these from the same animals. This reduces the number of animals used overall, increases the amount of data obtained from a single animal, and allows us to examine links between different tissues/organs by combining data from the same animals, thereby enhancing the quality of the information produced.

For several specific techniques we have made changes that enable us to reduce the number of animals we need in experiments.

For body composition we have performed a series of extensive trials to optimise the conditions under which body composition is performed. These allow a low variance in data to be obtained. Variance is how much the data is spread. To be confident a result is accurate, we need either data with low variability or to use lots of mice. By reducing variance we improve data quality, decrease the need for repeat measurements, and reduce the number of animals needed per group. Additionally for euglycaemic-hyperinsulinaemic clamping (the best method for measuring insulin sensitivity), we have comprehensively reworked our protocol to use smaller infusion volumes by using smaller tubing and better mixing taps. This has reduced the time the procedure takes, improved data quality, and reduced animal usage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have increasingly begun to use pilot studies. These were initially used under our previous license to check the safety of drugs in a small number of animals before using them in a larger cohort. However, researchers rapidly realised the benefit in terms of being able to assess the efficacy of these drugs from the pilot animals.

We employ a designated member of staff who oversees our animal program to ensure the breeding of colonies and experimental design is optimal, and animal wastage is minimised. We routinely cryopreserve all our lines to avoid "tick over colonies" wasting mice and also prevent the phenotype of the mice from changing due to being bred for many generations.

We collaborate widely with other groups across the UK, Europe and the rest of the world and regularly ship samples we have banked to these collaborators for their own purposes, maximising the benefit from previously conducted studies.

We are actively engaged in pursuing data science and artificial intelligence based approaches to the study of metabolism. We regularly reanalyse our old data sets with new collaborators who are experts in the field of data science. As approaches move on, more sophisticated or new ways of interpreting gene expression, lipid and protein data are developed. As such, our existing data may lead to exciting new discoveries and new publications with no need for extra mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice.

We will typically use a mixture of genetically altered (we have deliberately introduced some DNA into them), spontaneous genetic mutant animals (e.g. the ob/ob mouse was found in laboratory colonies as a mouse that was enormously fat - it has a single DNA base pair that has gone wrong) and "wild-type" animals (we have not genetically altered them, nor do they have any known mutations). The majority of our genetically modified animals are congenic, possessing the DNA we have introduced into them in all cells from conception. We also work with a number of mice with pieces of DNA called “loxP sites”. These loxP sites allow deletion of the gene in one or more organs by expressing a gene called a recombinase (known as Cre) that deletes anything between the loxP sites. The deletion of the gene is usually caused by making the Cre have the same expression as a gene found in a specific tissue (e.g. albumin, the most common protein in the blood, is produced only in the liver). We can make the Cre inducible. This means it is normally not active, but if we give the mouse a drug, it turns on the production of the Cre recombinase and deletes our gene of interest. In some cases we will use viruses to express the Cre. The genes that will be altered will be chosen to address our objectives. They will largely fall into four categories: Those affecting adipose tissue function, those affecting energy expenditure (thermogenesis), those affecting lipid quality or quantity in organs, and finally those are leading to alterations in fibrosis. Importantly, all of the major areas we are researching are involved in human diseases which cause minimal pain. Even end-stage liver and heart failure are characterised by signs such as weight loss (liver failure) or shortness of breath (heart failure). Therefore, we do not expect our genetic mutations in and of themselves to cause any pain, suffering or distress. The development of metabolic disease is slow, so we will be able to monitor for and kill mice before more serious harms manifest.

We will use two primary routes to induce obesity and study its complications. The first is the use of modified diets that make mice obese and insulin resistant, as well as causing diseases such as liver and heart disease. These are usually high in fat, contain refined carbohydrates, and we may also add sugar to the drinking water. It is notable that human fast food tends to be high in fat and refined carbohydrates, and is often accompanied by sugary drinks, making this a depressingly accurate model of the "western" food intake patterns driving the global obesity epidemic. High-fat diets are preferred by mice when given a choice between them and chow. They can lead to a greasy coat but generally cause no pain, suffering or distress.

In addition to obesity we may use diets to study specific aspects of lipid metabolism, where they contain different types and/or quantities of fat. Equally we may use diets to induce fibrosis that lack specific micronutrients (such as amino acids or vitamins). These may cause weight loss, but the weight loss is not caused by the fibrosis, but due to the fact the diet is not as tasty to the mice (the opposite of the high-fat diets).

The second approach for causing obesity will be to use genetically altered animals that model specific aspects of cardiometabolic disease. The most commonly used animals in our laboratory are the spontaneous mutant ob/ob and db/db animals that lack leptin hormone or its receptor respectively. Leptin tells our bodies we have enough fat. When mice lack leptin, they will keep eating as they think they need to store fat, even though they have large amounts already. A loss of leptin causes massive obesity due to a high food intake. The ob/ob model is useful as it causes obesity without the need for the feeding of altered diets. This can make the ob/ob particularly suited for studies where manipulating dietary lipid composition and content would confuse the interpretation of our results. The ob/ob mice are extremely obese and need some special care. They need to have larger mouse houses. Furthermore, they may develop diabetes and drink and urinate more, requiring more frequent cage changes to stop them from developing sores on their body.

In terms of phenotyping, we use several major types of analyses. Firstly, we use "tolerance tests" to determine the response of mice to different nutrients and/or hormones. This involves an injection or use of a tube that goes into the mouse’s stomach to deliver a fixed amount (known as a bolus) of fat, carbohydrate, protein or insulin, followed by the collection of serial blood samples, usually from the tail vein of the mouse. We take serial samples to see how different metabolites in the blood of the mouse change in response to the bolus. We have a dedicated team of trained technicians who conduct these tests routinely and are able to take the minimal blood volumes that are scientifically necessary. As they perform these tests for multiple groups they are highly experienced and are able to conduct these bleeds without restraining the mouse.

We also assess energy expenditure using a device called an indirect calorimeter. Calorimeters measure heat - which is proportional to how much energy the mouse is expending. We conduct calorimetry in home cages and it has a minimal welfare burden.

We house animals at altered environmental temperatures. Mice are normally housed between 20 and 24oC. We have specialised cabinets to control the temperature we house mice at. Almost all mice can tolerate temperatures as low as 4 degrees and as high as 30 degrees well. Considerable evidence suggests higher environmental temperatures make the metabolism of mice for many parameters we are interested in (development of fatty liver, cardiac function, energy expenditure) more comparable to humans. Equally, lower temperatures can allow us to study processes such as heat production in more detail. The cabinets we have are able to keep the temperature within 1oC of the target temperature preventing dangerously high or low temperatures from occurring. Rarely some genetically altered mice will not be able to survive in the cold. We carefully monitor animals from strains we have not studied before when we place them in cold cabinets for the first week to make sure they are able to tolerate low temperatures.

Finally, we have a number of specialised techniques including clamping (a sophisticated technique for assessing insulin sensitivity that provides better and more detailed information than tolerance tests) and thermogenic capacity (a technique for measuring the most energy a mouse can expend) measurements. In the literature these are both routinely conducted on conscious or unconscious mice. We perform them at the end of the experiment on unconscious mice that have been given anaesthetic. The mice are killed before they wake up meaning they suffer as little pain and distress as possible.

Why can’t you use animals that are less sentient?

We use less sentient animals where possible and have published using flies to study specific research questions. However, two of our major focusses in this license are on adipose tissue function and thermogenesis (the process of heat production). Flies do not possess adipose tissue. Furthermore only mammals and birds possess the major thermogenic organ brown fat. As humans are mammals, then a mammalian system is more suitable for translation to humans than an avian system.

We do use terminally anaesthetised mice for some procedures, however metabolic disease takes years to develop in humans and months in mice. As such we need to conduct tests in either conscious mice, or using recovery anaesthesia, to track the development of metabolic diseases over time.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have made multiple refinements to our techniques over the past few years. We undergo a continual practice of reviewing our procedures in order to improve them from both welfare and scientific perspectives. Indeed, these are not separate endeavours. The researchers under the license are all aware that the higher the standard of welfare, the better the quality of the data, making them committed to all aspects of refinement.

With respect to glucose tolerance tests (a test where we administer a single large dose of glucose and then see how well the animal can return its blood glucose to normal) we have

implemented various stable isotopic forms of glucose. Stable isotopic forms of glucose are types of glucose that are biologically identical to normal glucose, but have atomic "labels" which we can detect using a device called a mass spectrometer. We can use stable isotopic glucose to determine changes in the mouse's own glucose production (from the liver) during a GTT and separate that from the glucose we have given the mouse. As such we can see if our mouse has changes in liver function, which can occur in insulin resistance, as well as more general problems dealing with a large amount of glucose. Stable isotopes are biologically identical to normal glucose and therefore provide more data from the same experiment for no more pain suffering or distress.

For clamping we have added stable isotopes allowing the harvesting of tissue (as the samples are non- radioactive). This allows molecular analyses and histology to be connected to gold-standard measures of insulin resistance (for example we can see if mice with bigger adipocytes, or more inflammatory molecules in their blood are more insulin resistant).

For calorimetry we have improved our data analysis by regressing the variable RER against change in body-weight, reducing the variance ("variance" is how noisy the data is – the noisier the data the more mice you need to be confident an effect is real) and improving the biological meaning obtainable from the data. We also singly house mice ahead of calorimetry experiments to acclimate them to the new environment before conducting the tests. Furthermore our new calorimeter is an open circuit system, with smaller sensors for things such as movement. This means we can house mice that were formally group housed close to their cage mates, with better vision of them and, because it is not a fully sealed chamber, they can also hear each other.

For altered temperature housing we use temperature chips which allow us to monitor the mice for drops in body temperature without using more invasive approaches like rectal thermometers.

For feeding of modified diets we have reduced the amount of diet added to the cage and increased diet changes to improve palatability of the food for the mice and as a by-product data consistency. High fat diets go "off" more quickly than chow ones as the fats in them can become rancid and have an unpleasant odour and taste. Furthermore, through highly precise food intake measurements we have been able to identify the importance of consistency of when animals are culled after a diet change. The replacement of old high-fat diets with new leads to a spike in food intake. This is important as spikes in food intake may change the expression of genes or cause increases in hormones like insulin in blood. By controlling when mice are culled after a diet change we reduce unnecessary noise, (and decrease variance) and reduce the number of mice we need to be sure a result is real.

Feeding of modified diets. Certain modified diets (particularly those that cause fibrosis in liver) can cause mice to lose weight. This weight loss is not a sign the mice are sick - all the mice lose similar amounts of weight and end up lean. However, this means we cannot

use weight loss as a sign mice are not well. To improve our ability to assess mice we have now included body condition scoring. We use a chart that includes pictures for reference as well as clinical signs to make sure our mice are healthy. We conduct such scoring weekly, unless mice are showing lower body condition scoring in which case we may do it more frequently.

We have now included deuterated water (D20) tracing. D20 is water which heavy hydrogen (deuterium) has replaced the normal hydrogen. When our bodies make fat from sugars they incorporate hydrogen or deuterium from water. If we give mice D20 we can detect the new fat and distinguish it from the old fat using a mass spectrometer. Alterations in how much fat our body makes occur in diseases like diabetes and NAFLD. This provides additional important scientific information with no additional welfare burden to the mice.

For administration of agents we implemented an agent safety protocol. This follows a classic 3+3 design used in phase 1 human clinical trials and involves dosing 3 animals with the drug for one week to determine the agent is safe. We are also able to collect serum and tissues from these samples to provide pilot information for subsequent larger studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Laboratory Animal Science Association (LASA) guiding principles documents of aseptic technique(https://www.lasa.co.uk/current_publications/)

ARRIVE (Animal Research: Reporting of In Vivo Experiment) guidelines for preparing papers for publication (https://www.nc3rs.org.uk/arrive-guidelines)

PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for planning our experiments (15 topics including formulation of the study, dialogue between scientists and the animal facility, and methods) (https://www.ncbi.nlm.nih.gov/pubmed/28771074).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project license (PPL) holder is subscribed to the National Centre for the Replacement and Reduction of Animals in Research (NC3R) monthly e-mail newsletter and uses the NC3R website (https://www.nc3rs.org.uk) as a resource for guidelines, practical information, links to publications and video and training materials. The PPL holder has attended the international Federation of European Laboratory Animal Science Associations (FELASA) conference. In addition the animal technicians who work for the PPL holder's institute regularly attend both Laboratory Animal Science Association (LASA) and FELASA conferences and disseminate information regarding 3Rs approaches to the institute. The PPL holder is an editorial board member of Laboratory Animals, the official

journal of both LASA and FELASA, which published advances in animal welfare and husbandry matters.

Advances in the 3Rs will be disseminated to the laboratory through the weekly laboratory meetings and through meetings with our technician core in order to have a holistic approach incorporating the license holder, researchers and technicians.

110. Developing and studying novel mouse models of glioma development and progression

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, brain, IDH, gliomas, hydroxyglutarate

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To investigate the role of specific genes, identified in human patients and in vitro models, in glioma development and progression, in order to understand the disease process and thus improve prevention, early diagnosis and treatment options.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Gliomas represent 75% of all primary malignant brain tumours in adults. They can be divided into less aggressive (oligodendroglioma and astrocytoma grade 1 and 2) and more aggressive (oligodendroglioma, astrocytoma grade 3 and glioblastoma grade 4) tumours. Because of their malignant behaviour and the fact that they cannot be cured by current therapies, they represent some of the most devastating cancers. The aim of current treatments is simply to delay tumour progression and modestly extend survival. Despite decades of refinement, this approach results in a median survival time of just 12-14 months for glioblastoma, a survival trend that has remained mainly static in comparison to other cancers. A better understanding of the underlying mechanisms is urgently needed in order to design new and successful therapeutic strategies.

Advances in cancer treatment and patient survival often follow a greater understanding of the molecular basis of the disease. Through combined genetic, biochemical and metabolic studies, researchers have begun to uncover some of the early events in the development of brain cancer. It is now understood that glioma is caused by metabolic disturbances due to alterations in a specific gene called 'IDH1' (and less frequently, IDH2). However, very little is understood about how these changes actually drive malignancy, or in which specific brain cells these alterations arise.

Our work aims to develop accurate mouse models of glioma by targeting IDH1 alterations to specific brain cells, and to use these models to look at genetic and metabolic interactions with other common changes identified in patients. Here in this proposal we aim to identify an optimal glioma model, before applying this model to study the role of two important genes, D2HGDH and CIC, in glioma development.

Overall, the work is important because it not only has the potential to significantly improve the ability of researchers to accurately study glioma in vivo, but also to identify therapeutic targets and potential new treatments.

What outputs do you think you will see at the end of this project?

Our principal output at the end of the project will be important new information on glioma development, including advances in mouse models of glioma that more faithfully recapitulate the human disease, and improved understanding of the molecular and genetic interactions between IDH1 and other common glioma alterations. The work will generate high profile publications in scientific journals and inform on new therapeutic targets and treatment options to fight these tumours in humans.

Who or what will benefit from these outputs, and how?

In the short term our findings will contribute to an improved understanding of how gliomas develop and progress, which will be disseminated to members of the scientific community through scientific publications in high impact journals and presentations at scientific meetings. Identification of a more accurate mouse model of glioma will also represent a major advance that will be of direct benefit to the whole brain cancer research community.

In the medium term, our work may suggest specific molecular targets to be used in designing new therapeutic strategies. Thus pharmaceutical companies committed in designing new treatment options for brain cancer will benefit from our work. In the longer term, we hope that the work, and subsequent clinical application of our findings by pharmaceutical companies, will improve treatments and outcomes for patients affected by glioma and related cancers.

How will you look to maximise the outputs of this work?

All the new mouse models generated by our group will initially be made available to collaborators and then to all other researchers following publication.

We aim to continue collaborating with various research groups with different and complementary knowledge and expertise, which will help to maximise the transfer of knowledge arising from the work. The findings will be communicated in open access scientific journals and at international conferences to make them broadly available prior to publication.

We do not underestimate the value of a negative result, therefore whenever possible we shall publish these in scientific journals or make them available for example though an open access platform like BioRxiv.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We propose to use mice because they represent the least sentient animal model that most closely recapitulates human tumour development and because their genome is relatively easy to manipulate. Our laboratory also previously developed a preliminary model demonstrating that mice are suitable for modelling glioma development. This prior work has established protocols and endpoints that can be applied in the mouse models described here. The genetic variants to be studied here are available as established mouse strains, thus avoiding the genetic manipulation and breeding required to generate these models in a different animal type.

Where possible we will use all strains on a C57BL6 pure background to avoid experimental variation and the necessity for increased numbers. Conditional genetic alterations will be induced in young adult mice (generally around 6 weeks of age). Adult mice are relevant because glioma is a disease of human adults, and because some of the genes are lethal when deleted earlier in life.

Typically, what will be done to an animal used in your project?

In a typical experiment, animals will be bred with other mutant strains to obtain the required combination of genetic alterations to allow the role of genes in specific cell types to be studied. When necessary, young adult mice will be injected with the inducing agent (tamoxifen), and then aged to specific time-points (e.g. 4, 8 months), when they will be humanely killed and samples collected and analysed. In those cases where the timeline of disease progression is unknown, mice may be aged for up to 15 months until they develop symptoms of tumour formation.

What are the expected impacts and/or adverse effects for the animals during your project?

Since animals used in the proposed project represent models of human brain tumours, some of them will develop symptoms similar to those of human patients affected by a similar disease. These symptoms can be related to the tumour being in the brain (e.g. change in behaviour, hydrocephalus) or general symptoms of sickness (hunching, loss of weight, lethargy). Based on our previous studies some mice may develop the described symptoms from 4-6 weeks after tamoxifen administration. The duration of these adverse effects may be variable, but when an animal develops symptoms such as weight loss (up to 20%), lethargy, hydrocephalus or visible tumour mass, they are humanely killed and samples collected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity (65%)

Moderate severity (35%)

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In the proposed project I am planning to investigate the functional mechanisms of brain tumour onset and progression in order to improve early diagnosis and treatment. To

achieve the aim of the project I need to use animal models as they are more informative and provide major advantages over in vitro, ex vivo or in silico models:

1) Cancer is a disease arising from specific cell types within a complex multi-cellular environment, which cannot be faithfully recapitulated by homogenous in vitro cell models.

2) The genetic alteration is targeted to a specific cell population which provides the opportunity to investigate the physiological function of a gene and its pathogenic role when mutated, in the correct cell type and context.

3) Animal models allow us to explore the mechanisms of cancer development and progression from early stages and to understand the influence of different combinations of genes (which is limited by using in vitro and ex-vivo models).

4) Animal models also allow us to study the biological properties of a developing tumour in a more physiological system, including a vasculature, immune cell infiltrate, tumour microenvironment, and an intact blood-brain barrier (which are not possible non-animal models).

Which non-animal alternatives did you consider for use in this project?

For the reasons outlined above, non-animal models are not suitable for studying early glioma development. That being said, whenever possible my group conducts experiments before and in parallel to in vivo work using in vitro models, in order to provide supporting data and to test hypotheses that may not at first require an in vivo model. These approaches include pathology analyses of human brain tumour samples, and analyses of cerebral brain organoids, glioma tumourspheres and glioma cells.

Why were they not suitable?

Non-animal models can be useful in answering some questions, but are not suitable for studying tumour development in the context of a tissue. This is because cancer onset and progression is a complex and dynamic phenomenon, which is not cell-autonomous, relying on the interactions and communication of the cancer cells with other cell types. Emerging data have highlighted the role of the tumour microenvironment, which interacts constantly with the tumour influencing its development: non- malignant cells of the tumour microenvironment (immune cells, fibroblasts, blood vessels) have a dynamic and often tumour-promoting function at all stages of carcinogenesis. Such factors, including hypoxia and metabolic disturbance, are known to be important determinants of brain cancer tumourigenesis. Hence, animal models represent the only viable model in which to undertake the glioma studies described here.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been estimated by taking into account:

1) The experimental plans, including the number and size of treatment and control groups required to generate meaningful results.

2) Our previous data performed in similar experiments over the last 10 years.

3) Data from published literature using animals in similar experiments.

4) Published data used to undertake calculations that inform animal number.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We designed our experiments to address a limited number of specific scientific questions that are based on a strong rationale and need, thereby reducing the number of required strains and breeding. We carried out calculations to make sure that the minimum number of animals is used to get a statistically relevant answer. To plan our experiments we also used guidelines such as PREPARE and on-line tools such as the NC3R Experimental Design Assistant.

An important step in designing our experiment is to control for or reduce any sources of unwanted variation, such as the ones deriving from age or sex of animals. We aim to use animals of both sexes in our experiments, and to balance the number of females and males in each experimental group. We also aim to use age matched mice in each group. All our experiments will be done by using mice on the same genetic background to avoid the influence of any possible genetic variation along the study. We also use randomisation and blinding to minimise experimental variability.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible littermates will be used as controls to minimise variability, maximise the use of the available animals, and reduce unnecessary additional breeding.

We will use established mouse strains which will avoid the breeding required for generating new transgenic lines.

We have applied our experience of previous mouse studies on IDH1 glioma models to inform the experimental design, thereby helping to reduce animal numbers.

At the end point of each experiment we will appropriately and accurately store all samples in order that they can made available for collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically engineered mice carrying inducible (conditional) genetic variants that predispose to brain cancer. The conditional nature of the intervention limits the potential suffering to only the period following treatment with the inducing agent. Some of the models will then develop gliomagenesis (or possibly gliomas) over time, depending on their genotype. All the models used in the project require induction of genetic changes in adults, to allow for normal development. Induced mice will be compared with their control littermates, Any animals develop signs of potential glio such as weight loss, change in BCS or hyper act will be humanely killed To preserve and study brain tissue architecture some animals will be terminally anesthetised, perfused and fixed before applying a Schedule 1 method. To collect large non-haemolysed amounts of blood some animals will be terminally anesthetised and a large blood sample collected before applying a Schedule 1 method.

Why can’t you use animals that are less sentient?

Species that are less sentient than mice do not have the physiological similarity with humans or functional tumour microenvironment necessary to undertake the research proposed in this project. Furthermore, the longer life span of mice compared to less sentient species allows the time required for the multistep process of tumourigenesis. Since cancer onset and progression is dynamic, the use of animals that have been terminally anaesthetised is not possible. It is also not possible to use less sentient more immature mice for this study because faithfully modelling adult brain cancers requires the use of adult mice. Furthermore, the majority of the genes studied in the project are required for normal development precluding earlier interventions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Since we propose to induce new mutants/new mutant combinations, we will perform pilot experiments in which animals will be monitored closely by the PIL holders and animal facility staff, to check the development of any adverse effect. Any information collected from these pilot experiments will be used for refinements that will be applied in the

following experiments. Whenever possible, the use of the most refined whilst scientifically justified routes of administration of recombinant agents and refined handling will be used. As animals age monitoring increases and recorded using bespoke scoring sheets.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will publish in accordance with the ARRIVE 2.0 guidelines to ensure data can be reproduced in other establishments. We will share date obtained at conferences and meetings.

All dosing according to LASA guidelines and we will make use of PRPEARE in advance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will check the 3Rs website (https://www.nc3rs.org.uk.), sign up for the NC3Rs newsletter follow seminars on the responsible research in practice website (https://www.responsibleresearchinpractice.co.uk/), and regularly discuss with colleagues. Finally we will also follow any advices regarding ways to implement the 3Rs given by NACWOs/NVS at our licenced establishment.

111. Creation and repair of ano-rectal fistulae in a porcine model

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Fistula, ano-rectum, therapy, stem cells, scaffold

Animal types	Life stages
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine what combination of stem cells and biomaterials has the greatest impact on promoting new tissue growth in an ano-rectal fistula track.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Currently there is no gold standard treatment for treating ano-rectal fistulae and achieving long term healing. Patients with active fistulae experience considerable pain and reduced quality of life.

The expected benefits for patients with ano-rectal fistulae include:

The potential for different therapies to be applied as less invasive surgical procedures. This approach would preserve the anatomy of the surrounding tissue and thereby prevent incontinence (inability to control bowel movement).

If successful, it may also be used for fistulae in other parts of the body (e.g. head and neck; this area is currently not under investigation).

What outputs do you think you will see at the end of this project?

One output from this study will be publishable data which will be disseminated through peer reviewed journals and national/ international scientific conferences/meetings.

An Additional output may be patentable product(s) (identified once detailed analysis of the competing market has been undertaken) which can be commercialised and offered clinically to patients (once regulated studies have been completed). If a successful product is identified, it is likely to take longer than 5 years (outside the duration of this licence) before being offered clinically.

Who or what will benefit from these outputs, and how?

Long term the additional benefits will be to the patients, approx. 2 per 10,000 of the population in the UK experience chronic and recurrent fistulae, a successful treatment outcome would significantly improve patient's quality of life, reduce hospital visits and in-patient time thus reducing NHS cost.

How will you look to maximise the outputs of this work?

Output will be maximised by presenting at clinical meetings to obtain relevant feedback in order to ensure the final approach can be clinically adopted explore collaborative opportunities both with regards to cell type and source, biomaterials and mode of application/delivery Present at relevant focused meetings/conferences

Species and numbers of animals expected to be used

- Pigs: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The pig is an established model for ano-rectal fistulae. The model was developed and published by our group. The pigs anatomy, size, diet and physiology is similar to humans for this model and is the most appropriate translational model available. The model allows

fistulae to be created in pigs which mimic human ano-rectal fistulae and have similar pathophysiology. Smaller animals do not provide appropriate clinically translatable data.

Female pigs are used in preference to males as their pattern of glandular distribution (groups of specialised cells that produce secretion to aid lubrication) within the internal anal sphincter (muscles that help the anus to open and close) is similar to humans.

Typically, what will be done to an animal used in your project?

For each animal under the first general anaesthesia (GA), 3 ano rectal fistulae will be created using an indwelling seton (a surgical thread), a blood sample and any tissue biopsies may also be taken at this stage, (these will be used to harvest cells and used as part of the therapy). The animal will be allowed to recover.

Approx. 30 days later, under a second GA the fistula will be treated. The seton within the fistula track will be removed, the fistula curetted (i.e. cleaned out) to remove granulation tissue (old scar tissue). A different treatment will be applied to each fistula (based around a combination of different biomaterial and cells). An MRI/CT image may be taken and the animals allowed to recover. Additional MRI/CT images (under GA) may be taken at monthly intervals to assess the healing of the fistula track.

The duration of the treatment stage may vary between 2 -6 months depending upon the healing outcome under investigation. All Animals will be killed at the end of the treatment stage and tissue removed for histological and molecular analysis (i.e. the tissue will be analysed under the microscope and using different laboratory techniques)

What are the expected impacts and/or adverse effects for the animals during your project?

In our experience of this model, all animals tolerated the procedure well showing little discomfort over the duration of the study. Any pain was transient and was alleviated by pain relief following each surgical procedure. They did not experience any weight loss or abnormal tissue growth.

Animal suffering will be kept to a minimum by regular monitoring by experienced husbandry staff. Prior to, and following the creation of the fistula and treatment application, animals will placed on a softer mash diet for a approx. 3 days to ensure the production of soft stool and prevent straining. Pigs are normally fed a pelleted diet which is harder.

The use of immuno-suppressive drugs (helps to prevent rejection when cells from one individual are placed into a different individual) may be considered when it is not possible to obtain sufficient number of autologous cells (i.e. cells from the same animal) without impacting on the animal's physiological function.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of this model is 100% moderate.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project will address a clinical question i.e. is it possible to heal an ano-rectal fistula similar to that seen in humans using the different therapies proposed. As such, a clinically translatable (a treatment plan which is transferable to humans), relevant large animal model is needed. All work leading up to this stage that could be done either in vitro (in a petri dish or in the lab, specifically is the material cell friendly ie cytotxicity) or in smaller animals (potential material degradation and immune response) has been completed.

The next phase is to assess the combinational therapy (combined cells and biologically derived materials) for its intended clinical application and for this a large animal model is required.

Which non-animal alternatives did you consider for use in this project?

A non- animal alternative animal was not considered as we require a large animal model for direct clinical translation.

Why were they not suitable?

We require a large animal model for direct clinical translation and all necessary biocompatibility studies (i.e any toxicity relating to the materials, specifically immune response and material degradation) have already been conducted in rodents.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experimental design is based on our previous studies (resulting in published data) using this model to assess a commercial collagen paste together with fibroblasts (special cells involved in healing). The previous data will also help to determine the group size, cell dosage, and the amount of biomaterial for each experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to minimise the number of animals, up to 3 fistulae will be created in each animal with no additional cumulative adverse effect thereby reducing the overall number of animals required. Control fistulae created will receive no treatment, however, based on previous experience/data, controls may be created per study and not per animal (i.e. it is not necessary for there to be a control in every animal).

Biological variability within the animal model will be controlled by using the same sex and similar weight animals and is based on our previously published study and experience.

The use of non-invasive assessment (e.g. MRI imaging), whilst potentially increasing the number of anaesthetics an individual animal has over the course of a study, can significantly increase the amount of information gained per animal and therefore reduce the overall number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Post-mortem tissue sharing between different projects and collaborators will also ensure maximum usage of each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The pig is the most appropriate animal model with regards to anatomy and physiology when compared to humans for the creation of fistulae of relevant size. In our experience of this experimental design, all animals tolerated the procedure well showing little discomfort over the duration of the study.

Ano-rectal fistulae created in pigs are unlikely to be as debilitating because unlike humans who sit on their “bottom” thereby placing pressure on the ano rectal fistula, pigs predominantly lie on their belly or on their side resulting in less pressure and soreness on the outer surface of the ano-rectal fistula

Additionally, this model allows for the creation of fistulas of comparable size and potentially similar complexity. Whilst this is the best model, we have been able to develop it is recognised that the pig is quadrupedal (stands on 4 legs) while man is bipedal (stands on 2 legs) resulting in different pressure distribution on the fistulae.

Animal suffering will be kept to a minimum by regular monitoring by the Named Animal Care and Welfare Officer (NACWO) and the Named Veterinary Surgeon (NVS) throughout the study. Prior to, and following the creation of the fistula and subsequent treatment, animals will be placed on a mash diet for a minimum of 3 days to ensure the production of soft stool and prevent straining.

All surgical procedures will be performed in line with human clinical practice, whilst the animal is under general anaesthesia (GA), (for animal welfare and practical purposes a GA is necessary). Pain relief will also be given where appropriate to ensure overall animal wellbeing.

Why can’t you use animals that are less sentient?

Less sentient species are not appropriate because the data generated cannot be clinically translated (i.e. studies of fistulae in rabbits or rats would need to be repeated as their physiology is very different).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

By acclimatising the animals to single housing prior to the initial surgery, any adverse effects or injury to the fistula site from pen mates can be minimised. Animals will be monitored regularly, pain relief administered (if appropriate) and given a mash diet for a minimum of 3 days to ensure the production of soft stool to prevent straining.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The use of best surgical practice adherence to the principles set out in the LASA (Laboratory Animal Science Association) guiding principles document combined with good pre- and intra- operative care and monitoring will minimise unnecessary suffering.

The Norecopa, NC3Rs and LASA (and similar animal research and welfare) websites

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will review the current literature (encompassing changes in veterinary research and human surgery) and any revisions to the regulatory guidelines along with input from the

local Named Information Officer (NIO),

Named Animal Care Welfare Officer (NACWO),

Named Veterinary Surgeon (NVS) and other local animal care staff.

As well as checking the Norecopa, NC3Rs and LASA (and similar animal research and welfare) websites and implement any changes where appropriate.

112. Tissue function and metabolism in heart disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cardiac function, heart failure, metabolism, diabetes

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult, juvenile, neonate, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To increase our understanding of the biochemical reactions leading to impaired energy supply in the failing heart, to limit worsening of heart function and to identify as well as test new drugs targeting metabolism.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heart failure remains a major cause of death worldwide, despite great advances in medicine and therapy over the past few decades. Nevertheless, little is known about what makes hearts fail at the heart cell level. Thus, the key aim of the projects outlined here will be to advance our knowledge and understanding of the changes that occur in heart cells that cause hearts to fail. In turn, this information may help with early diagnosis and successful therapy for failing hearts aimed at improving energy supply in the heart cells by organelles called mitochondria (powerhouse of the cell). Where possible, information from animal studies (including diabetic heart disease) will be translated into studies undertaken by our collaborators who are clinicians involved in our studies. All the findings of the studies will be presented at conferences and published in academic journals (open access).

What outputs do you think you will see at the end of this project?

Experiments performed on this licence will help us understand how changes in cardiac metabolism lead to poor cardiac function and heart failure in order to develop new therapies and new ways to diagnose. All the findings will be presented at conferences, deposited in curated, public data repositories and published in academic journals. All project data will also be made available via research data management at our university.

Who or what will benefit from these outputs, and how?

Changes in the way heart produces energy by mitochondria (powerhouse of the cell) to power its work lead to series of changes to its structure and work causing it to fail. Our research aims to improve our understanding of the changes at the heart and mitochondrial level which underpin poor cardiac energy production by heart metabolism which triggers heart to fail.

Successful results of our studies, specifically identification of changes at the cell level and changes to energy producing pathways in diseased heart would also pave the way for new approach to treat failing hearts (including in type 2 diabetes) - something scientific research largely failed to achieve to date. They would be also be preventive as they would help us understand what leads to faulty mitochondrial causing energy starvation in failing heart as well as identify new and direct drugable target to treat heart disease (ie mitochondrial metabolic intermediates, metabolic transporters, immune system components).

Successful outcomes of our studies would also enable early diagnosis in clinics (blood sample analysis for metabolite and biochemical profiling).

Work generated using this licence would also identify novel concept with extensive and immediate translational potential for patients: for example re-purposing failed drugs for type 2 diabetes to treat faulty mitochondria and energy supply to stop and reverse heart failure in type 2 diabetes. Given that this drug has been fully approved for human use, any beneficial effect would be immediately translatable to clinical trials.

How will you look to maximise the outputs of this work?

Published (anonymised if applicable) data will be made available within 24 hours of the manuscript publication. Following consultation with the innovation office at our establishment, regarding any patentable IP position throughout the duration of the project, all data will be passed to the public domain in the form of open access publications and presentations at international conferences, once this is appropriate. All project data will also be made available via research data management group at our establishment. Published outputs will be assigned a DOI used to reference the data in publications and will be published under creative commons licence (CC-BY) allowing other to use, follow or continue the work. Appropriate metadata (Dublin core standard used; excel speadsheets with raw data, author names, study abstract) will be published with the research data to enable other researchers to identify whether the data could be suitable for their own research .Data will be managed, stored and curated by an open-access institutional repository of research outputs.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice and rats will be used for the studies as these are extensively validated animal models for study of cardiovascular disease including diseases of metabolism such as type 2 diabetes.To obtain relevant measurements of cardiac function it is necessary to use an animal model with a four chambered heart like the human heart. In addition, as metabolism and contraction of the heart are inextricably linked, it is essential to study metabolism in the intact beating heart.

Typically, what will be done to an animal used in your project?

We use both commercially available and bred genetic murinae models to investigate the role of specific gene changes in heart disease, obesity and diabetes. In most cases the animals do not show any overt adverse effects, however if any more severe phenotype may occur (such as hyperlgycaemia in diabetics) these animals will be monitored closely (tail blood sampling for glucose, insulin or markers of inflammation). In terms of dietary modification this may involve increased calories (western diet), introduction of metabolic modifiers to a diet such as glucose lowering agents, lipid metabolism inhibitors, vitamin supplements or metabolic sensitizers. On occasion, labile compounds such as vitamin B supplements or metabolic inhibitors may be given via oral gavage or injections. Non-

invasive imaging (echocardiography) will be used to non-invasively monitor heart function and reduce a number of animals required for the studies.

What are the expected impacts and/or adverse effects for the animals during your project?

In most cases the animals do not show any overt adverse effects, however if any more severe phenotype may occur (such as hyperglycaemia in diabetics) these animals will be monitored closely. Possible expected impacts may include weight gain, increased blood glucose, increased appetite and increased urination.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Total number of animals in the project: 5300

Number of mice:3900 (73.5%) moderate

Number of mice:1000 (18.9%) mild

Number of rats:400 (7.5%) moderate

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is commonly accepted by biomedical experts that animal models are required to fully understand the pathogenesis of complex human disease, as well as to test novel potential therapeutic strategies that research such as ours may unveil. The mouse models we plan to use are directly relevant to the human heart failure condition, a syndrome that accounts for a high level of deaths and for which there is currently significant unmet clinical need in terms of effective, life-saving therapies. To obtain clinically relevant measurements of heart function it is necessary to use an animal model with a four chambered human like heart. Furthermore, as metabolism and contraction of the heart are inextricably linked, it is essential to study metabolism in the intact contracting organ. Therefore, this study requires an integrated approach monitoring cardiac metabolism simultaneously with heart function and as such there is no appropriate alternative to using animals and isolated animal hearts

as the experimental model. Small animals, specifically mice, are widely used in the study of hypertrophy, diabetes, metabolic derangement and heart failure. We aim to use these validated approaches which provide hugely valuable information relevant to humans- which we have a lot of experience of using over the years.

Which non-animal alternatives did you consider for use in this project?

The HL1 cell line, a mouse atrial tumour cell line which represent many of the metabolic properties of the cardiomyocyte will be used where possible, for example to investigate the effect of changes in energy supply on function of mitochondria. Isolation of cells for primary cell culture offer potential for many studies including fluorescent studies but must still be collected from individual experimental animals models. The use of isolated perfused heart preparations has proved appropriate in our previous studies for investigating biochemical adaptations in parallel with analysing heart function.

Opportunities for studies on human heart tissue are limited owing to availability, sample size, and limitation in sensitivity of some of the methods used. We also employ computer-based prediction tools in addition to cell experiments to study targets. It is not currently possible to use solely computer models for these studies, although our findings may help guide future computer programs to help understanding of energy metabolism involved in heart failure.

Why were they not suitable?

Unfortunately, cell models of heart disease, heart failure and type 2 diabetes are limited in their ability to provide information that is useful in terms of translating experimental findings into therapy. Cell culture systems have complications of losing morphology, poor viability and are often derived from neonatal hearts rather than mature hearts. In addition, these do not provide an adequate measure of integrated heart function.

Human atrial samples are more likely to be available than ventricular tissue however they are less likely to be representative of heart failure. Specialised techniques for analysing changes at the cell or molecular level in disease require use of tissue samples as well as appropriate control samples - something that is not always feasible when using samples of human origin.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The minimum number of animals for statistical significance will be used, calculated using power calculations with information based on past experience and on consultation with biomedical statisticians.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Redundancy of studies will be avoided through good systemic reviews done prior to any study and the use of tools such as The Experimental Design Assistant (EDA) from the NC3Rs will help to ensure that the minimum number of animals will be used consistent with scientific objectives, methods to reduce subjective bias, and appropriate statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The minimum number of animals for statistical significance will be used, calculated using power calculations with information based on past experience and on consultation with biomedical statisticians. In the measurement of cardiac metabolism using energy substrates labeled with carbon 13 isotope in the isolated heart, we have designed experiments which determine use of two different substrates simultaneously, thus reducing the overall numbers of animals needed. Through regular exchange of information with other research groups in the University we ensure that, where possible, students requiring tissue other than heart coordinate their studies with those doing heart perfusion, thereby using one animal for two experiments

Longitudinal imaging (echocardiography) will impact on animal number; maximising experimental data obtained per animal through the acquisition of a large number of experimental outcomes (functional parameters).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Ultimately the critical issue involved in heart failure, is whether treatments lead to improved or deteriorating pump function. Thus, it is essential that integrated studies are carried out in which cardiac function is assessed in parallel or simultaneous with cellular or metabolic

manipulations. Creating experimental models of hypertrophy and administration of beneficial or deleterious compounds provides an in vivo model, which can then be studied in vivo, or at the organ, cell and molecular level by in vitro experimentation (as described above).

We measure cardiac function and metabolism in transgenic mouse models bearing a genetic modification identified in a clinically observed cardiac disorder or relevant signalling pathway. In some cases, we use a range of techniques to induce closely related disease phenotypes. These can give precise information about aspects of a disease or differences between stages of disease progression. The latter can also be modelled by allowing animals to age following induction of the phenotype, which may impose a greater stress on each animal than short term induction of a more severe phenotype but is more physiological and provides information on long-term changes resulting from the disease. In each case we select the most refined model to answer our questions Genetic models of diabetes will be used to explore specific changes to metabolic signalling. (ie type2 diabetic mice, obese mice, Zucker diabetic rats to study type 2 diabetes). When instituting a protocol that is new to our lab we perform a pilot study, after consultation of the literature and with collaborators, to confirm the appropriate protocol for the species and strain we are studying. There is the possibility of mortality in pilot studies, but we limit this as much as possible by careful monitoring of the animals for clinical signs of distress. We use these studies to define protocols and humane end-points to minimise mortality in larger studies.

We use non-invasive techniques wherever possible, eg dietary modification to elevate plasma fatty acids and giving therapeutic compounds in drinking water if applicable. For substances that need to be administered over a number of days, and cannot be introduced via the diet, we will use slow-release devices such as osmotic minipumps where possible.

Regular advice and updates on techniques, such as anaesthesia and surgery are sought from the NVS and NACWO, to ensure best practice. When implementing new procedures, where possible, arrangements to visit other departments where these techniques are already in place would be made. The animals are provided with environmental enrichment where possible, at the recommendation of the NACWO, including a variety of housing, tunnels and nesting materials.

Murinae (rats and mice) have been widely used for studies on the heart allowing functional measurements to be made relatively straight-forwardly and reproducibly and for providing sufficient tissue for further analyses. There is a large database of information about the rat and mouse hearts that ensures experimentation on models of disease can provide clear and definite outcomes.

Why can’t you use animals that are less sentient?

Alternative strategies to the use of animal models have been carefully considered but there are no non- sentient alternatives to answer many of the important medical, biochemical and physiological questions in the field of heart failure. A mouse atrial tumour

cell line, HL-1 cell line, does exist which has been shown to mimic many of the metabolic properties of the cardiomyocyte and this cell line will be used in place of animal tissue where possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The aim of this project is to use non-invasive techniques wherever possible and seek regular advice and updates on techniques, such as anaesthesia and surgery, to ensure best practice.

Discomfort and injury to animals will be limited to that which is unavoidable in the conduct of scientifically valuable research and analgesic, anaesthetic, and/or tranquillising drugs will continue to be used where appropriate to minimize pain and/or distress to animals

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Peer-reviewed, published literature will be a primary method for following best practice guidance as well as 3Rs advice from NC3Rs (including institutional 3Rs symposia, NCR3s page, NC3R events and workshops).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Peer-reviewed, published literature is a primary method for staying informed about advances in 3R. Redundancy of studies will be avoided through good systemic reviews done prior to any study and the use of tools such as The Experimental Design Assistant (EDA) from the NC3Rs will help to ensure that the minimum number of animals will be used consistent with scientific objectives, methods to reduce subjective bias, and appropriate statistical analysis.

113. Preclinical evaluation of cancer therapeutics

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Therapy, Immunotherapy, Pharmacodynamics, Efficacy

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project licence is to provide a high quality demand led service, testing the efficacy and tolerability of novel anti-cancer therapies in validated rodent models of cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This will provide data to support IND (Investigational New Drug) submissions for Sponsors, and assist earlier drug development strategies (go/ no-go decisions based upon pre-clinical efficacy).

What outputs do you think you will see at the end of this project?

There is an unmet need for new cancer therapies given relapse rates, the fact that the disease may become resistant to treatment and the percentage of patients that experiencing long-term treatment side effects. The aim of this project is to provide data from preclinical models of cancer to biotech and pharma in order to identify those compounds most likely to have the greatest clinical potential and highlight those with limited efficacy or serious side effects for rejection or reformulation as early in the development stage as possible.

In early stage drug discovery, therapeutic candidates are generally subjected to a series of in vitro screens to identify activity on a cellular level, without the need to use animal subjects. Testing the toxic potential of a drug on cells in vitro (screening against cell lines and primary cells from various tissues) provides some indication of potency and specificity compared to current therapies, but ultimately the most promising drugs need to be tested in an animal model that is as predictive as possible of the human condition. Animal models allow us to establish how a potential drug may be absorbed by the body and/or tumour, observe any beneficial effects and if/when they cease becoming beneficial and what interventions are needed. This means we can determine appropriate dosing routes and optimise the schedules with which treatment is given. We can then analyse the success of the intended drug- related effects on the disease. The most frequent and well characterised models are those in rodents, where one can demonstrate a degree of efficacy relative to a current standard of care drug. They also highlight those drugs that are either ineffective or have serious side effects (filtering out those potential drugs with little benefit or limiting side effects as early and as accurately as possible).

Who or what will benefit from these outputs, and how?

The initial benefits will be to the pharmaceutical industry. The predictive models we have developed and continue to refine provide efficacy and mechanism of action data that will enable informed decision making on both drug development selection/prioritisation and on optimal dose routes/scheduling in the clinic. By reducing the risk of later stage failures, there is cost/speed benefits for clinical trials. The benefit for them is therefore a reduced number of unproductive human volunteer studies (and a reduced risk of adverse effects due to dose scheduling errors) and most importantly the development of improved – more effective – cancer therapeutics.

How will you look to maximise the outputs of this work?

The information we provide to the industry is as extensive as we can provide, from in-life parameters showing efficacy of the drug, to analyses of tissues post-mortem that will help confirm the mechanism of action of the drug and perhaps identify biological molecules that may represent a response to therapy. With this data, we aim to support our clients to progress their drug into clinical trials and, in the longer term, be of benefit to patients as a standard of care. Because of the in-house experience and expertise we have with efficacy testing, it is conceivable that this will help minimise the number of animals that would have been needed, reduce time points and drug concentration variation but also acquire the most information out of an experiment without the need for repeats. Thus, our work certainly helps implement the 3Rs in practice.

Species and numbers of animals expected to be used

- Mice: 5650
- Rats: 1250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The programme requires that models are used which closely mirror the human disease situation. Adult rodents (rats and predominantly mice) are suitable for these studies as the work cannot be conducted in lower vertebrates, invertebrates or cell lines due to the poor resemblance of these options to the clinical setting.

Typically, what will be done to an animal used in your project?

Animals that have been obtained from a supplier will be acclimated to their new housing for at least 1 week. After this period, for tolerability studies, 1-2 animals will be dosed once or multiple times, using the same or increasing concentrations of test item. Careful monitoring of the animals will take place immediately after dosing to assess any dosing/drug-related effects, and periodically thereafter (typically twice a day).

Pharmacokinetic/pharmacodynamic (PK/PD) studies are used to determine how a drug is absorbed by the body, where it goes to and how long it stays there, and what effects it might have on the body. For PK/PD studies in non-tumour bearing and tumour bearing animals, small groups of mice or rats will be dosed with a drug (or the same solvent without any drug, if using controls) via a known route, and at a volume, concentration and schedule that is known to be well tolerated.

In cancer studies, animal models have been developed that show the disease at the relevant site, e.g., lung cancer models that develop cancer in the lung, as opposed to

subcutaneous models where the cancer cells are engrafted subcutaneously even if this is not where they would normally grow. These are described as orthotopic models.

For efficacy or PK/PD studies in animals with locally growing cancer, tumours will be established by subcutaneous injection of tumour cells. Careful monitoring of the animals and the implantation site will be performed, as well as normal health and well-being observations. Efficacy will be determined by achieving a desired effect on the disease with little to no unintended affects to health or well-being. This may include calliper measurements that can be performed on conscious animals with minimal distress. Test Item (or the same solvent without any drug, if using controls) will be administered via a known route, and at a volume, concentration and schedule that is known to be well tolerated.

For efficacy or PK/PD studies in orthotopic models, or animals with cancers that affect the entire body, tumours will be established by intravenous, intrafemoral, intraperitoneal (through the abdominal wall), intracranial, or intrathoracic injection of tumour cells. If the implantation technique requires aseptic surgical intervention, animals will be anaesthetised, and analgesia may be given during and after surgery. Careful monitoring of the animals and the implantation site will be performed, as well as normal health and well-being observations. This may include calliper measurements that can be performed on conscious animals and/or in vivo imaging of anaesthetised animals. Test Item (or the same solvent without any drug, if using controls) will be administered via a known route, and at a volume, concentration and schedule that is known to be well tolerated.

Blood samples may be collected periodically via a tail vein bleed in conscious animals. We will always follow the NC3Rs guidelines/limits for peripheral blood sampling.

Animals may be subject to in vivo imaging. This most often involves an intraperitoneal injection shortly before anaesthetising the animal for the imaging procedure. Animals will always be allowed to sufficiently recovery from anaesthesia (return to normal eating and drinking and peer interaction) before the next imaging session. Imaging is generally performed 1-2 times per week. For studies where we are trying to determine which organs/tissues are affected by the disease, which only a small proportion of animals will experience, optical imaging may need to be more frequent. The imaging sessions are about 5 minutes and as animals are anaesthetised with inhalable anaesthesia they recover quickly.

Recovery may be aided by keeping the animals warm and giving them mashed food.

Animals may receive radiotherapy, either locally or whole-body irradiation on one or several occasions, under anaesthesia. Animals will always be allowed to sufficiently recovery from anaesthesia (return to normal eating and drinking and peer interaction) before the next imaging session.

The endpoint for a study will usually be a specified timepoint, tumour size/burden (based on previous data and standard of care for the cell line) or if a humane endpoint has been

reached. At this time a final terminal bleed may be performed under terminal anaesthesia and tissues harvested after euthanasia for analysis. The length of the studies will vary, but generally falls between 1 and 3 months.

What are the expected impacts and/or adverse effects for the animals during your project?

Frequent adverse effects after test item administration may be weight loss and diarrhoea. Less frequent adverse effects may be bruising, anaemia, loss of appetite, reduced movement, grooming and postural changes. Infrequent adverse effects may be abnormal breathing, tremors, convulsions and reduced peer interaction.

Animals will experience stress due to restraint and transient discomfort from needle insertion and/or anaesthetic injection or inhalation of gaseous anaesthetics (100% incidence).

Repeated intravenous injection can result in irreversible damage to the vein and very occasionally, a haematoma/bruising may develop.

Intraperitoneal injection (through the abdominal wall) is likely to be painful if the needle injures an abdominal organ or if the substance being injected is an irritant.

Oral administration (gavage) is associated with minor discomfort. Very occasionally damage to the oesophagus may occur or substances may enter the lungs resulting in dyspnoea.

Slow-release pellets and osmotic minipumps are small and cause no appreciable effects. Animals may experience a lowered body temperature during anaesthesia. Animals may experience pain on recovery from anaesthesia.

Animals will experience stress due to restraint and a transient discomfort from blood collection (100% incidence). Animals may become overheated or dehydrated from spending too long in the hotbox.

Subcutaneous injections of tumour cells are associated with a momentary discomfort. Very occasionally, a haematoma or bruising may develop. Very rarely, tumours may grow to a size that could cause discomfort or interfere with animals ability to satisfy thirst or hunger. Rapidly growing tumours may ulcerate.

With all surgical procedures there is some risk of development of infections or wound complications (<1%). Use of genetically altered or immunocompromised animals may exacerbate the frequency of infections.

In cancer studies, animal models have been developed that show the disease at the relevant site, e.g., lung cancer models that develop cancer in the lung, as opposed to subcutaneous models where the cancer cells are engrafted subcutaneously even if this is not where they would normally grow. These are described as orthotopic models.

Orthotopic or metastatic tumour models may have various adverse effects, dependent on the site of implantation. Metastasis is clinically relevant, and there are a number of cancers that will initially grow at a primary site, but cells will break away, travel around the body and then develop as secondary (or metastatic) tumours elsewhere in the body. Common sites of metastatic disease after intravenous implantation include the lungs, liver, ovaries, kidneys and spleen.

For orthotopic models, such as leukaemia, animals may gradually become anaemic, weak, lethargic and lose body weight. Infiltration of the spleen or liver of disease can lead to enlargement of these organs which may be palpable.

For orthotopic/metastatic models implanted intraperitoneally, tumour formation may occur in one or several organs in the intestinal cavity. This may also lead to the formation of ascites (collection of fluid in the abdomen) which could cause discomfort, affect behaviour, and mask weight changes.

For orthotopic models in bone, animals may experience pain on recovery from anaesthesia and tumour formation may affect integrity of bone, invade surrounding muscle tissue, or hinder movement.

For orthotopic models in specific regions of the brain, animals may experience pain. Tumour formation may affect the physical condition and general behaviour, including displays of repetitive or uncontrolled movement, fitting, head tilting or abnormal responses to stimuli.

For orthotopic models of the thorax, tumour formation may cause discomfort and laboured breathing.

Animals receiving whole body irradiation, may experience a reduced appetite and hence weight loss and possible loss of condition. Radiation sickness evidence by diarrhoea could develop (less than 5%).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for mice and rats under all protocols under this licence is moderate. Based on the previous 5-year licence period, 85% of mice and 55% of rats are expected to experience the moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project requires that the models used are ones which closely mirror human disease. Animal models address issues which current in vitro tests cannot accurately determine such as the therapeutic index of a new agent, whole body pharmacokinetics (PK) and pharmacodynamics (PD). PK/PD studies are used to determine how a drug is absorbed by the body, where it goes to and how long it stays there, and what effects it might have on the body. Use of animals is needed to address the development and treatment of disease in an environment which is the closest to the microenvironment found clinically.

There is not currently an alternate representative of these systems that can be accurately studied that does not involve the use of an animal model.

Which non-animal alternatives did you consider for use in this project?

We have, and continue to, develop complex in vitro predictive models. We have validated 2D and 3D tumour culture models, including those that mimic the response of cancer stem cells vs a more hierarchical tumour tissue. However, to-date none are sufficient to replace the animal models themselves.

Why were they not suitable?

All compounds tested will previously have been screened using in vitro models to determine those candidates suitable for in vivo testing. These include studies that demonstrate the mechanism of action (eg. regulation of proliferation, induction of cell death, target cell specificity). Their limitation is, that although they allow assessment of test items on specific aspects of the disease process, they are insufficient in modelling the complex interaction of the different cellular systems present within an in vivo tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on the number of animals used during the previous 5-year licence period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The most important aspect of the proposed programme of work, which will reduce the overall number of animals used, will be a careful selection of only those targets that offer a realistic prospect of therapeutic exploitation. This will be done on the basis of in vitro target validation studies and any available in vivo data, and work may be turned down if there are insufficient in vitro data available. In vivo models will not be used for random compound screening and all experiments will be hypothesis led. All experiments will be conducted following standard operating procedures and include appropriate controls, so that the efficacy of test items can be accurately assessed. The number of animals used will be the minimum number required to test the experimental hypothesis at the required level of statistical power and significance. We regularly consult academic and commercial statisticians. For example, data produced under the previous licence have been reviewed and the suggestions for improved analysis have been included in this licence application.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Several of our tumour models utilise imaging, which helps reduce animal numbers as the progression of disease can be followed in the same animal over time. We regularly seek statistical consultancy, sometimes providing historical data, to ensure that our power analyses are correct for each model we offer. Internal expertise in tissue analyses, allows us to fully characterise the cellular changes associated with disease as well as the expression of key factors on the surface of tumour cells and surrounding cells. This information is utilised to refine existing/validated models so that the most appropriate model is chosen for clients' compound's mechanism of action.

Outsourcing work using these models to CROs such as ourselves, results in a greater level of assay standardisation, reducing the number of studies performed. We are exploring the possibility of sharing control data between studies to further reduce animal use, where Sponsors will allow.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To test the efficacy of novel anti-cancer drugs it will be necessary to induce sufficient levels of disease. Some studies will be performed in immunocompromised mice, rats will only be used where suitable.

More severely immunocompromised mouse strains may be required for some tumour models, and when they allow for the testing of human based immunotherapies (in this case mice may be carrying a humanised immune system).

We will predominantly use subcutaneous cancer models in mice. Animals will receive treatment delivered by an appropriate route of administration. Treatment response is determined by 3x weekly calliper measurements of the tumour. These types of models are a good way to determine if a drug has anti-cancer activity, however they do not allow for all types of disease. For this purpose, we have established and validated imaging models of cancer using labelled tumour cells implanted into the normal anatomical position. Since the cells are labelled, tumour burden can be monitored in the same animal over time using imaging methods. The endpoint for several of these models is now based on imaging signal rather than humane endpoints, reducing suffering.

On occasion, syngeneic tumour models in mice may be used. These models are developed by administering tumour cells derived from the equivalent strain of animal, i.e., a mouse receiving cells derived from the same strain of mouse. They are most useful for sponsor's who wish to test therapeutics in a fully functional immune system. For subcutaneous tumours, some treatments may cause transient inflammation/ulceration, which has been shown to resolve, and the mice then produce useful data with minimal residual distress from the skin. Hence, a transient window is needed to prevent premature termination due to a short-term effects. Ulceration is a clinical sign of a well-functioning immune response. However, tumours will be monitored and scored 3x weekly, and animals with increasingly significant damage, (tumour score = ulcerated), will be humanely euthanised by a schedule 1 method.

The frequency will depend upon the cell type and the kinetics of tumour growth. Where possible, cell lines that induce ulceration will be avoided. This is particularly relevant in therapies targeting the immune response to the tumour which may necessitate the allowance for ulceration.

Why can't you use animals that are less sentient?

Rodent models are the best characterised of all experimental oncology models, with mice being much more heavily investigated than rats. Furthermore, work cannot be conducted in lower vertebrates, invertebrates or cell lines due to the poor resemblance of these options to the clinical setting. Rodents provide a cost and time effective platform in general for most pre-clinical testing. For the purposes of oncology testing, the use of higher species is not required because there is a wealth of knowledge on different types of cancer in rodents, as well as decades of in-house expertise with such models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Over the lifetime of our previous licence, we have established and validated several imaging models, where the disease burden can be monitored in the same animal over

time, which means that less animals are used. The endpoint for several of these models is now based on imaging signal rather than humane endpoints, which means less suffering. Furthermore, we have refined the tolerability protocol and lowered the severity from severe to moderate for this protocol in this licence application. We have increased the number of different data read-outs that can be obtained from a single study.

We have introduced an ulceration score sheet to refine our tumour observation methods. This will help to ensure all staff are aware of what constitutes an 'ulcerated' tumour, and the endpoints are consistent. It will include descriptions of the appearance of the tumour; timelines based on historical data, i.e. time taken from implantation of cells to ulceration of tumour; and visual aids that can be updated for different cell lines and mouse strains. The frequency of monitoring will alter as the appearance of the tumour site changes, i.e. the frequency will increase with the severity of the observation.

We will continue to refine our models and anaesthesia and analgesia will be employed for any surgical procedures. Blood sample volumes and number of samples will be kept to a minimum.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Workman P et al. (2010). Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102(11):1555-1577.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are regularly getting informative emails from the NC3Rs and we make sure to attend seminars and workshops about the subject. We are keeping up to date with the literature within the field of pre-clinical cancer research and are actively looking to implement refinements of our models. Our standard operating procedures are reviewed on a regular basis to accommodate refinements.

114. New therapeutic strategies to treat chronic pain

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Chronic pain, Therapy, Sensory Nervous System, Neurophysiology, Analgesia

Animal types	Life stages
Mice	adult
Rats	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to expand knowledge and understanding of the mechanisms underlying the development and manifestation of chronic pain states and to use this knowledge to develop new therapeutics and novel strategies to treat these conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic pain has been described as "The Silent Epidemic". It is estimated to affect more than 40% of the UK population reporting pain that persists 3 months or longer. Incidence increases with age; prevalence among over 75's may be as high as 62%. Chronic pain is associated with high incidences of anxiety, depression, sleep disturbance, insomnia and decreased physical activity. There are also broader implications, with chronic pain sufferers less likely to be in full-time employment. A range of pharmaceutical strategies have been used to treat patients but these are frequently ineffective, especially in severe forms of pain. A consequence of this is the ever increasing use of opioid-based drugs, the chronic use of which is associated with severe side effects including, respiratory depression, sedation, tolerance and dependence. The social consequences have been devastating with an increasing rate of prescription opioid overdose deaths occurring across developed societies, "The Opioid Epidemic", with an estimated 90,000 casualties estimated in the US alone in 2020. The socio-economic burden is similarly highly significant, the annual cost of chronic pain in USA estimated around $600 billion (i.e., expenses, lost income, lost productivity). The cost of medication to treat adult patients with chronic pain in the US is estimated >$17 billion annually and forecast to increase. The numbers are staggering, the treatment of pain represents a significant current and future medical challenge owing to the shortcomings of current analgesics together with the largely unmet clinical need is beyond question.

The work outlined in this project will directly contribute new knowledge of the fundamental mechanisms contributing to the development and manifestation of chronic pain states and provide intelligence to drive new therapeutic strategies without the adverse side-effects associated with current treatments.

What outputs do you think you will see at the end of this project?

We will produce data that significantly advances our understanding of the mechanisms underlying chronic pain, in particular pain associated with nerve damage.

We will produce peer reviewed publications and present data at scientific conferences.

We will produce data sets to be shared with academics and the biotechnology/pharmaceutical industry.

We plan to produce data and intellectual property that can be patented.

We plan to produce data that informs clinical development of new treatments for pain and new therapeutic approaches to treat pain.

Who or what will benefit from these outputs, and how?

In the short-term, research papers and presentations at national and international conferences will be of benefit to both research scientists in academia and clinicians. This work will also be of interest to industry including pharmaceutical, biotechnology and medical device sectors. The new information will enhance our understanding of mechanisms contributing to chronic pain at the single cell, tissue and whole organism level.

In the short to medium term, the biotechnology and pharmaceutical industries will be interested in new therapeutic targets to treat chronic pain states, and in new therapeutic strategies to treat these conditions through alternative approaches such as medical devices.

In the medium term, the development of intellectual property, patents, investment and new companies will facilitate creation of new jobs and economic benefits. With our significant assets already in the pipeline, not yet patented, we are ready to move forward to early stage clinical development over the course of this license.

In the longer term, 5 years and beyond the term of this license proposal, the beneficiaries will be patients suffering chronic pain. Delivering successful pain relief without the adverse side-effects associated with current medications will deliver significant health and socio-economic benefits.

Other beneficiaries will be pain clinicians, all of whom complain and highlight their current "lack of tools" to treat chronic pain.

Finally, animals are likely to benefit as treatments developed for conditions such as pain and epilepsy are frequently used to treat domestic animals.

How will you look to maximise the outputs of this work?

We maximise outputs from this work by disseminating new knowledge through research publications and presentations at conferences.

We also actively engage with a network of industry partner collaborators globally where key data on "gold-standard", or positive control compounds are made freely available and shared, improving data quality, reliability and reducing the need for animal use to repeat experiments unnecessarily.

Scientific reports are shared with permission of collaborators with other industry collaborators providing key intelligence on pain targets whilst not disclosing compound details.

Our extensive experience over the past 20 years or more and going forward puts us ideally placed to advise on the highest quality, efficient preclinical development strategies for industry collaborators and partners, ensuring minimal requirement for animal use and suffering.

Historical data from our lab will always be used to advise industry collaborators on the validity of their therapeutic targets and likelihood of success or failure of their approach.

Species and numbers of animals expected to be used

- Mice: 4000
- Rats: 7500

- Guinea pigs: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will principally use mature (6 weeks and older), male rats and mice to investigate mechanisms underlying changes in nervous system function in chronic pain. Adult rodents are required as they have a mature fully-developed nervous system, unlike neonatal animals that are still growing and undergoing development, rendering it impossible to separate changes in nervous system function, resulting from chronic pain from those associated with development. Although we will primarily use males, as females have different pain responses, and differ in pain development during different stages of their oestrus cycle, we will also use female rats and mice in these studies. As guinea pigs have certain attributes more comparable to man, we may on the rare occasion that this is the case, use these animals.

Typically, what will be done to an animal used in your project?

Our aim is to generate model animals that mimic human pain/hypersensitivity scenarios and to achieve this we use procedures, outlined below, that cause nerve injury or inflammation and sensitization. The vast majority of models developed are associated with minimal discomfort but show hypersensitivity to an external stimulus such as touch or heat which is carefully monitored for all models. A range of techniques are used to investigate behavioural responses and electrical activity in the nervous system, and at the conclusion of the experiment, tissue may be harvested for further analysis.

Prior to performing any procedures, we test each animal for abnormal hypersensitivity to touch or heat. This is done by applying a light touch test stimulus (von Frey filaments), or a focused heat stimulus, applied directly to the paw. Those that do not have a normal sensitivity to sensory stimuli are excluded from further studies (approximately 2-5%).

Surgical procedures to generate animal models: For nerve or tissue injury models, animals are anaesthetised and either a nerve, muscle, tendon or bone is manipulated. Following complete recovery of consciousness and freedom of movement, animals are returned to their home cages. These procedures take approximately 10 minutes to perform per animal.

Procedures involving injection of substances to generate animal models: These include models of cancer chemotherapy, where animals undergo tail vein injections twice a week (maximum of 5 injections) with chemotherapeutic drugs. A fibromyalgia model where reserpine is injected daily for 3 days (under the skin or in the muscle). Inflammatory pain models where the agent is injected into the foot (once only) or knee-joint (two injections over two days). A Parkinson’s disease (PD) model where the chemical is injected daily for

4 days, or under anaesthesia, two small holes are drilled in the skull and a chemical injected into precise areas of the brain at a single dose'. In this case, the holes are secured with dental glue, and the animal allowed to recover in a temperature-controlled chamber before returning to the home-cage and their cage mates.

Administration of drugs in animal models: Potential new medicines will be administered during studies of animal behaviour, and during experiments to monitor changes in electrical activity of nerves. Drugs may be administered orally in food or water, or via a flexible tube inserted into the stomach. Chemicals may also be administered by injection delivered into the fluid surrounding the spinal cord or directly into the brain via thin tubes that have been implanted under anaesthesia prior to experiments with test chemicals being undertaken. In some instances, injections may be involve directly puncturing the skin with a needle and guiding the needle to the target without the need for surgery.

Behavioural tests: Animals that have undergone procedures described above will be assessed using behavioural techniques. Animals are placed in specialized chambers and allowed to acclimatise to this environment. Sensitivity to heat is tested using infra-red illumination and sensitivity to touch is tested using a brush or fine plastic fibres of different sizes, (force; von Frey hairs) applied to the hind-paw or cheek until they slightly bend, very much like the way these hairs are used in the clinic. The intensity of stimulus is gradually increased until a withdrawal response is observed indicating discomfort. Weight bearing tests will determine whether one hind leg is favoured indicating discomfort in a limb; grip force test will be used to measure changes in paw strength; movement and coordination will be tested using an accelerating rotarod and narrow beam walking tests. All behavioural tests are repeated to ensure data accuracy and animals are rested between repeated tests. Each test session takes less than 5 minutes. The maximum number of sensory stimuli any animal will be subjected to is 42 in any one session, with a maximum of 4 sessions in a day spaced at least 1 hour apart with animals returned to their home cages to rest between sessions. In long-term studies, these behavioural tests may be repeated once a week for between 2 and 24 weeks. For movement and coordination tests, animals are trained on the devices prior to testing.

Labelling of nerves for recordings: In some animals, we will record electrical activity from specific nerves to investigate hypersensitivity signaling. Nerves will be identified by labelling with a dye/tracer or virus expressing fluorescent proteins, injected into the nervous system (brain or spinal cord) under anaesthesia. This recovery surgery takes no longer than 30 minutes. Following recovery from surgery, animals are returned to their home cage for 2 to 5 days for dye injections, or housed for between 2 weeks and 8 months for virus injections. Animals are then humanely killed or placed under terminal, non-recovery anaesthesia and tissue is used for nerve-recordings of electrical activity.

Monitoring blood pressure, heart rate and electrical activity in nerves: Recordings of electrical activity in the nervous system, blood pressure and body temperature will be undertaken in freely moving animals using either wire-free or wired-connected devices. Animals will be placed under general anaesthesia and sterile devices implanted into blood

vessels, on the surface of the brain or attached to fine needles positioned in discrete regions of the brain. Following recovery from surgery, these devices allow blood pressure and brain activity to be monitored in the awake moving animal. For devices connected by wires, sterile, head mounts will be implanted under the skin and secured with dental cement to the skull. Following this procedure, animals are housed individually for at least 7 days before being returned to their home cages and cage mates. On the day of the experiment, animals are transferred to soundproof recording chambers where continuous monitoring of brain activity, blood pressure and core body temperature is undertaken over a 3-hour period.

Monitoring electrical activity in nerves under terminal anaesthesia: Recordings of electrical activity in the nervous system will also be undertaken in animals under anaesthesia. In these experiments, animals will be put on a ventilator and anaesthetic or test compounds will be administered intravenously through implanted tubing. Body temperature is monitored and maintained with a temperature-controlled blanket. Samples of blood (no more than 4 samples over 2 hours) and brain fluid (no more than 6 samples taken over 2 hours) may be taken to monitor the animal throughout the experiment. Nerve recordings are conducted through implanted electrodes placed in discrete regions of the brain or spinal cord. Recording will be performed over a period of between 1 and 6 hours. At the end of the experiment, animals will be humanely killed using an overdose of anaesthetic.

Number of procedures: Throughout these studies, no animal will be exposed to more than 4 procedures including a maximum of 2 surgical procedures. Animals typically experience one surgical/chemical procedure, or virus/tracer injection. Animals are closely monitored in the hours and days following surgery. Animals typically undergo one type of behavioural test, in some cases with repeat trials.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of animals in these studies will not show any indication of ill health or significant loss of quality of life. Animals in all studies continue to interact socially and are not expected to lose weight. All animals will be monitored and any animal that is likely to exceed the severity limit will be humanely killed.

Animals that undergo recovery anaesthesia with minor surgery to generate models of pain are expected to recover completely within 24 hours and behave normally. These animals and those in which chemical injections are used to generate models of pain, will be more sensitive to heat and/or touch in one limb or area for the duration of experiments, ranging between 3 to 5 days, to 2 to 4 weeks in the majority of cases. They often show a change in gait and may have spontaneous foot lifts of the affected paw or may protect the affected area. Most experiments will be complete within 4 weeks, but on rare occasions these studies will run up to 6 months, these latter studies only undertaken in a small proportion of animals when the effects of repeat dosing with a potential new medicine or treatment are tested. The condition and welfare of all models is carefully monitored throughout and

on the rare occasion that an animal is identified likely to exceed the severity limit, it will be killed by anaesthetic overdose.

Parkinson’s disease animal models may show abnormal behaviour, specifically they have difficulty maintaining balance and co-ordination when moving. This behaviour may last for several weeks.

Some animals will have minor surgery or an injection into the body or a limb to induce a short-lasting state of hypersensitivity but will recover rapidly from these interventions. The discomfort is typically

transient in nature with only a minority showing any sign of discomfort, for example a slight limp or lack of use of the affected limb. These features are usually lost after 6 to 48 hours and animals behave normally, interacting socially, being mobile and easily able to self-care. In the case of a facial nerve, increased facial grooming for the first 2 to 5 days following surgery can be seen but this again diminishes after 5 days and the animals behave normally. As with all models, these welfare and condition of the animals are closely observed and monitored. Animals that have devices or catheters implanted are expected to recover rapidly within 1 day post-surgery and will be given pain killers and post-operative care whenever necessary.

Some animals will be used under terminal anaesthesia for nerve recordings. However no adverse effects are anticipated and animals are humanely killed using an overdose of anaesthetic on completion of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats and mice with surgically induced chronic pain: Mild (10%) to moderate (90%)

Rats and mice with chemically induced chronic pain: Moderate (90%) with a minority classified as severe (10%). Those classified as severe will recover well within 1 to 2 days.

Rats and mice with symptoms of chronic pain induced by a physical intervention, for example models with UV light-induced blisters, will have a severity rating of moderate (75%) or mild (25%).

Freely moving rats or mice with implanted devices or tubes will have a moderate (100%) severity rating.

Rats or mice injected with dyes or viruses: Mild (50%) to moderate (50%) severity rating.

What will happen to animals at the end of this project?

Humanely killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research questions we seek to address requires the use of animal models. Pain is complex, arising from integration of activity within a fully functioning nervous system that can only be investigated in models with intact neural circuitry comparable to that involved in human pain perception. Thus, no suitable alternatives exist to address underlying mechanisms contributing to pathophysiology associated with chronic pain.

Experiments carried out on in vivo animal models will be limited to those questions that be answered using other, alternative methods. cannot

Which non-animal alternatives did you consider for use in this project?

Over the course of our previous work, we have introduced multiple in vitro assays into our research wherever possible. These include human cell lines, cultured neurones, dissociated neurones, ex vivo isolated nerve preparations and ex vivo brain and spinal cord slice preparations. Once molecular targets/pathways are identified, detailed mechanistic studies will use in vitro systems. By concentrating efforts on the isolated tissue/cell systems for detailed studies on mechanism of action of new therapeutics, we anticipate being able to reduce the number of animals used over the course of the studies.

Data generated over the course of this project is subject to mathematical/systems biology approaches, seeking to develop predictive, computer-based models of neural networks in chronic pain states. Two models are under development: one defines abnormal electrical activity in peripheral nerves associated with chronic pain. The second model details the functional operation of neural circuits in the spinal cord in chronic neuropathic pain. Details of the data underpinning the models and the models themselves will be made freely available for use in future experimental design and to reduce the number of animals needed in research.

Recording abnormal electrical activity in animal models of chronic pain is technically challenging and takes years to train and develop the knowledge to maximise the potential of experiments. Currently the only way to develop these skills is by gaining “hands-on” experience with live samples. We have engaged a company to design virtual reality training programs. By creating a virtual reality lab environment the aim is to train students and staff in both the practical and theoretical aspects of recording electrical activity in nerves and through running simulations of how to maximise the quality and potential of

experiments. We anticipate having this training aid available over the course of this new project and will be made widely available as a training tool. We believe these tools will significantly reduce the need for animal models and tissue samples.

Why were they not suitable?

Ultimately chronic pain syndromes manifest via interactions of multiple interconnected neural circuits spanning the periphery, spinal cord and brain and cells and tissues of the body. This level of complexity cannot be fully replicated in in vitro systems. Computer models are in their infancy and seek to replicate aspects of these systems and considerably more data is required to provide the intelligence needed to inform the models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates outlined here are based upon studies undertaken during our previous projects. We have over 20 years of extensive experience using these models and are therefore ideally placed to accurately gauge the group sizes required to deliver statistically meaningful data. Group size is continually assessed in a data-driven manner to identify every opportunity to reduce group sizes wherever possible. The most up-to-date statistical methods will be used to inform data analysis and experimental design, again to ensure sample size is driven to a minimum.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We make use of all support and resources available to us. We engage our NACWO regularly and our consultant statistician at all stages of data analysis and experiment design. Other resources that we use are the NC3R's Experimental Design Assistant, the ARRIVE guidelines and the Norecopa PREPARE guidelines. We also use FELASA guidelines for a number of reasons but also to inform our experimental design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have made and continue to make considerable advances in our use of isolated cell culture and tissue systems in the experimental design. Our computer models of neural circuits are sufficiently advanced to guide experimental design in some instances and will lead to reduced animal numbers over the course of these studies. By implementing these approaches in the early stages of the experimental design, to provide key intelligence to inform experiments in live organisms, we anticipate significant reductions in the numbers of animals required for live animal studies as these projects progress. Based upon our extensive experience and significant databases we have joined an initiative with industry colleagues to share data generated with "gold- standard" compounds i.e., compounds used in the clinic that act as a positive control in studies. This initiative is designed to reduce the numbers of animals used in research by reducing the need for some control groups.

We will also ensure animal numbers are minimized by analysing tissues in multiple ways and wherever possible we will supply tissues to other researchers and vice-versa. Wherever necessary, pilot studies will be undertaken to optimise experiments and their design before committing to a full study. In most models we are able to use the side opposite to the site of injury, reducing the need for separate control models, thus reducing animal numbers. For studies with genetically modified organisms, we will acquire the models from external suppliers to avoid duplicating breeding programs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a range of models that mimic clinical symptoms with each model representing a chronic pain condition with different underlying aetiology and pathophysiology. Since no model encompasses all symptoms and elements of chronic pain, we use multiple models in order to capture scenarios as close to clinical reality as possible. The rat and mouse models outlined here are used as they are the lowest vertebrate group where well characterised, minimal severity hypersensitivity models of pain have been developed and characterized. All of the models outlined either target a specific part of the nervous system or a limb thereby restricting symptoms to localised areas whilst reducing suffering, distress or lasting harm to the animals. Other models directly mimic a human condition and are controlled to minimise animal suffering. Furthermore, the preclinical models outlined here

are extensively studied, documented and exhibit the classic behaviours associated with acute and chronic pain, including elevated sensitivity to mechanical and thermal stimuli.

Nerve damage models of pain are used where the nerve of a back leg of an animal is ligated (tied up) with the exception of a model of trigeminal neuralgia where a facial nerve is ligated. These models are prepared surgically under anaesthesia to minimise suffering and animals recover quickly. The pain in these models is localised, again minimising the harm and discomfort to the animal as a whole. Other models are used that directly mimic human conditions in which we control the treatment to mimic the condition but cause the least pain, distress, suffering or lasting harm to the animal. Chemotherapy- induced neuropathic pain is also modelled in-line with the clinical scenario where animals are treated with chemotherapeutic agents such as paclitaxel, resulting in peripheral neuropathic pain, just as occurs in the clinic. There is no alternative to this approach that would mimic the clinical scenario.

Similarly, myalgia (muscle pain) is modelled by injection of the chemical reserpine into muscle or subcutaneously. Parkinson’s disease (PD) and PD-related pain is also modelled chemically, inducing selective loss of dopamine-producing cells in the brain to mimic the same loss in patients. Surgical or post-operative pain is induced by making a surgical incision on the surface of a hind limb under anaesthesia, mimicking the human condition, and sensitivity to touch or heat stimuli can be tested as early as 3 hours and up to 3-4 days post-induction. Thereafter the animals recover rapidly thus minimising the distress and suffering to the animal. Bone fracture pain is modelled by gentle fracturing of the tibia in a rear limb, under anaesthesia, the affected leg bone being secured using a steel pin (all as part of the same procedure), again to minimise the discomfort and suffering of the animal.

Inflammation is induced by injection of chemical irritants into a hind paw or knee joint capsule with the exception of the blister model in which a concentrated UVB light source is used to create a blister on a rear paw. The models are all minimal hypersensitivity models designed to cause minimal distress and suffering to the animal whilst featuring hypersensitivity to external stimuli, hypersensitivity to touch and temperature being principle outputs that we monitor. In all of these models the chemical irritant is administered to a highly localised, restricted area and the animals rapidly recover within a few days, thus minimising animal suffering and harm. Hypersensitivity to touch is tested with fine fibres of increasing force, von Frey hairs, the force of fibres needed for the model animal to withdraw the limb being recorded, similar to the clinical scenario. Similarly, for hypersensitivity to heat, a paw is subject to increasing temperature and withdrawal of the limb from the heat source monitored. Animals are only exposed to the minimum mechanical or thermal stimulation level that they find uncomfortable and freely withdraw from, thus minimising any suffering, distress or lasting harm. Studies of abnormal electrical activity and the effects of new medicines are for the main part undertaken under terminal anaesthesia, eliminating any pain or distress to the animal. A series of studies recording electrical activity in freely moving animals is achieved by surgically implanting wires and

probes under anaesthesia to limit harm and discomfort to the animal prior to testing the effects of new medicines on brain activity, blood pressure and body temperature.

All of the animal models and scientific techniques outlined here were designed to mimic and record clinical conditions and do so with the minimal, harm, distress or suffering to the animals. They are the most scientifically extensively studied, validated and reported models and are sensitive to known “gold- standard” analgesics used clinically. We will only use those models which are most scientifically relevant to the questions posed and will use the minimal number of procedures to address each question to ensure animals are exposed to the least discomfort, distress, suffering or persistent harm.

Why can’t you use animals that are less sentient?

Our aim is to understand and recognise mechanisms underlying chronic pain and to identify new therapeutic approaches and treatments. Chronic pain syndromes are complex phenomena with multiple causes associated with extensive changes in peripheral nerves, in the spinal cord and brain leading to alterations in behaviour. They can therefore only be investigated in mammalian models with the lowest sensitivity and yet an intact, readily identifiable neural circuitry that is comparable to that involved in human pain perception. The rodent brain is by far the best characterised model for this purpose.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all animal models, animal health and welfare is carefully monitored and documented using established criteria (appended with license), based on adverse effects (exceeding moderate levels on the FELASA working group recommendations, 1994). Biomedical Services Unit staff and our own staff carefully monitor and report any signs of abnormal behaviour or animal health and welfare issues. For any experiments that require behavioural tests, animals are first trained and acclimatized to the environment for testing and all animals are housed in accordance with the home office guidance to maximize their environmental welfare through enrichment. All surgeries and whole organism nerve recordings are carried out under anaesthesia by highly trained staff. Experiments that require implantation of drug delivery devices or recording devices are also performed under anaesthesia with post-operative pain relief to maximize animal welfare and minimize harm. Analgesia is administered wherever possible following surgical procedures. We will continually interact with our academic collaborators, pharmaceutical/biotechnology partners, modelers, statisticians, veterinary surgeon and biomedical services staff will ensure refinement of existing and novel approaches.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Resources that we use are the NC3R’s Experimental Design Assistant and the Norecopa PREPARE guidelines. We also use FELASA guidelines for a number of reasons but also to inform our experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will meet frequently and communicate efficiently with the NACWO, Named Veterinary Surgeon (NVS) and staff at our BSU. Our NACWO keeps us informed of developments with the NC3Rs, relevant scientific papers and organises seminars specifically on the NC3Rs. We will attend NC3Rs webinars and conferences wherever possible.

115. Pathways of filopodial formation

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cell motility, filopodia, cell biology, actin cytoskeleton

Animal types	Life stages
Xenopus laevis	adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to understand how the cells make finger-like projections, called filopodia.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Filopodia are produced when cells move, and they are thought to be sensory, in helping cells find the directions they need to go or how to make contacts with other cells. As a fundamental structure of cells they are widely important for health and disease, in the brain, in cancer and infection as three examples. In the brain, filopodia are produced when nerve cells make connections with each other, which is important for learning, behaviour and mental health. 3-4% of children in the UK are affected by neurodevelopmental disorders, and more than half of those referred to child and adolescent mental health services are found to have a neurodevelopmental disorder (such as autism). A second

example is the spread of cancer cells outside the original organ that they came from, called metastasis. Cancer causes 28% of UK deaths and metastasis is estimated to be the cause of 90% of them. Metastatic cancer cells have many filopodia and we do not understand what these filopodia are doing or how to change them. Filopodia are also formed when viruses infect cells, e.g. human immunodeficiency virus and the COVID virus where they are assumed to spread viral infection around the body. If we can understand and control how cells make or turn off filopodia we might be able to come up with new therapies in the future in any of these areas or others.

What outputs do you think you will see at the end of this project?

We will discover new information about filopodia. We will understand more about where filopodia form, how they reach certain lengths, how long they last for, and how they are suppressed.

The main output of the information will be publications reporting our findings. We will also present our findings at local, national and international scientific meetings. We will generate data that supports future funding applications. There may be new intellectual property that supports a patent application and we may generate data that supports clinical trials in the future.

Who or what will benefit from these outputs, and how?

In the short to medium term, other researchers studying filopodia and related aspects of cell biology will benefit from the outputs by being able to make new discoveries in their own work using the information we found out. In the long term the information we obtain may be useful information for people working on disease and in the very long term may benefit patients. Our data may lead to new ideas for therapies and the scientific tools that we create may be the foundation for new approaches to control filopodia (such as antiviral medicines or anti-cancer drugs).

How will you look to maximise the outputs of this work?

We will disseminate our work in conferences and collaborate with other researchers. We will also disseminate our work by making short videos for a lay audience and present our work at events such as festivals for the general public. We will make the computer code that we use publicly available and upload our manuscripts to a preprint server. Our work will be published open access so anyone can read it for free. Where our work is directly applicable to disease we will engage with patient charities. We will consider publishing unsuccessful approaches too, for example in supplementary information of other papers or as preprints.

Species and numbers of animals expected to be used

- Xenopus laevis: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using adult female African Clawed Frogs and their tadpole stages before they are independently feeding. We are using adult females to obtain their eggs. We use the tadpole stages where nerve cells are moving from the eyes to the brain of the tadpole as this is a well-understood system where filopodia are important and is a native biological system with immature animals.

Typically, what will be done to an animal used in your project?

The female adult frogs are injected with a hormone produced by horses during pregnancy. The frogs are injected under the skin at the bottom of their backs, just above their legs, into a place that contains a sac of fluid, which helps the hormone spread through the body. The hormone causes the egg cells to mature into eggs, mimicking what would happen to the frogs when they produce their eggs normally (e.g. in the spring). The immature egg cells finish their growing process, become eggs and are then able to be fertilized by sperm. A second injection 3-10 days later, of a hormone produced during human pregnancy and purified from urine (the hormone which is detected by pregnancy tests), makes the frogs lay the eggs. The differences between the horse and human hormones have the different effects in maturing the eggs or inducing laying.

After they are injected the frogs are put back into tanks of fresh water. After 5-15 hours the frogs are placed in a specific salt water solution for no more than 20 hours that keeps the eggs fresh once they are laid so that we can use them for several hours after laying. The salt water solution keeps the conditions outside similar to inside the frog's body. When the frogs have finished laying they are put back into fresh water. The frogs undergo the procedure more that 3 months apart. Some frogs lay better eggs than others, if a frog lays bad eggs on more than one occasion and needs to be killed, we will do so humanely.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected beyond transient discomfort of injection. Very rarely, in 0.1% of superovulation procedures, the frogs do not properly lay their eggs and develop a hard, bloated abdomen and become lethargic (become egg bound). This can be a delayed response up to a week after the procedure. Rarely there are mild stress responses that may be related to vibrations or the salt water such as sloughing of their skin in larger patches.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Xenopus Mild 100%

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use animals to make extracts from the frog eggs and to understand filopodia during tadpole development.

Filopodia are small cellular projections which come and go very fast and use similar building blocks as other processes going on inside cells. This makes filopodia hard to study as we cannot see them for long enough and it is difficult distinguish which effect comes from which process in the cell. Extracts from frog eggs can be used to make structures similar to filopodia outside cells which are more stable and not confused by other processes. We use frog egg extracts because they allow us to attain very high levels of sophisticated molecular information, like which types of the building blocks are needed and which ones are used together.

To convert our insights using extracts back to real filopodia we need to use cells. We use cell lines for some of our work however the filopodia produced by cell lines are not fulfilling a proper biological function so we don't know if what we are seeing is meaningful. The nerve cells in frog tadpoles are a well-understood model that use filopodia for finding their way and connecting to other cells. We use tadpole development to provide a biological context where filopodia are important.

Which non-animal alternatives did you consider for use in this project?

Tissue culture cells and fruit flies.

Why were they not suitable?

Cells grown in dishes do not recapitulate the normal filopodia growth and movements, so do not directly replace the tadpole experiments, which themselves replace experiments with mammals. Our experiments with extracts cannot yet be done with tissue culture cells as the extracts that can be made are too dilute. Mammalian brain extracts have been used but these are not as effective as frog egg extracts. The microscopy of the filopodia in fruit flies is not as fast or clear to see as the frog nerve cell filopodia so we would be unable to answer the objectives for this particular project using flies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated based on our previous use and design of anticipated experiments over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Other licence holders have been able to superovulate frogs that lay good eggs 40 times, so we will do this to reduce the numbers of animals used. Bad layers are specifically identified by monitoring quality, rather than after an arbitrary number of superovulations. If bad laying frogs are identified we will kill them humanely.

We will keep frogs in salt solution for a day (if they suffer no visible harms from doing so) as they continue to lay and we can continue to use the eggs thus reducing numbers of animals used.

We use a low amount of extracts for our work by optimising dilution, using a small volume and carefully calculating the levels of reagents we need to use which reduces numbers of animals needed. We also perform pilot experiments to check we are using the correct conditions.

To obtain tadpoles, we fertilize eggs from 1 or 2 frogs at a time and use numbers of embryos that we are confident we will have time to process.

We use control experiments to ensure each experiment is meaningful, collect multiple datasets from each experiment and carefully perform steps to minimise variability.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We share the eggs and sometimes the fertilized eggs with other groups so less frogs are used. We track the quality of the eggs and kill frogs that do not lay good eggs rather than inject them again.

We will trial a double ovulation procedure, where each frog lays twice, which would reduce the number of animals by up to half if successful. We will only use this procedure if it does not increase the harms for each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project uses Xenopus laevis, an amphibian model. We will induce the frogs to lay eggs and do this on repeated occasions as this is similar to what occurs in the wild.

The eggs will be used in two ways. One way is fertilizing them to make tadpoles that are used in immature larval forms before they are protected. The cells of the tadpole that will later become eyes are removed and cultured to obtain nerve cells. As a final approach we may image filopodia from cells directly within unconscious anaethetized larvae (before they are protected).

The second way is crushing the eggs in a test tube to make extracts.

Why can't you use animals that are less sentient?

The use of frog egg extracts is specialised and optimised for the field of study. Because frog eggs are so large they can be easily broken open without too much damage, leading to experiments that cannot be performed with other cell extracts. The filopodia produced by the larval nerve cells we work with have a known function in connecting the eye to the brain and so give us a meaningful setting for working on filopodia. The cells give very high quality microscopy and a biologically relevant setting which are not possible to achieve in any other system. The nerve cell experiments share important reagents with the experiments with extracts and the two sets of work are used in combination to gain the most information with least animal harm.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are transitioning to home-bred males and female animals to reduce the stress induced during traveling and adjusting to different environmental conditions. We keep handling to a minimum. All Xenopus are kept on dark backgrounds in environmentally enriched tanks. Using dark shelving and refuge tubes helps the animals to feel safe.

Frogs are monitored throughout the day while the technicians are in the room. If frogs appear stressed (excess skin shedding, overly jumpy, not eating) the NVS is engaged, and decisions are made as to whether or not it is best to humanely kill the frog. In the unlikely event a frog is in pain (a small number may develop a secondary bacterial infection colloquially called Red-Leg) the frog is closely monitored and if no improvement is seen within 48 hours the frog is humanely killed. Any frogs that have more that 20% body sores from diseases such as Red-Leg are euthanised immediately.

We work with a specialised Xenopus NACWO. All frogs are photographed for ID and health monitoring which is non- invasive and requires minimal handling, improving the clinical signs of the colony. We also monitor egg quality and keep the consistent good layers which reduces the overall number of animals held.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I am following PREPARE guidelines for planning experiments (https://norecopa.no/prepare) and ARRIVE guidelines to report my research (www.arriveguidelines.org). We will use published guidance on use of controls for using reagents that inhibit protein production (morpholino oligonucleotides) to ensure the best control experiments are used.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will discuss with my colleagues in the Xenopus field and consider practical guidance from the Named Veterinary Surgeon and Named Animal Care and Welfare Officer at my institution. I will refer to material from the NC3Rs website https://nc3rs.org.uk/resource-hubs, 3Rs tools in house and external resources such as Norecopa https://norecopa.no/databases-guidelines.

116. Standards in virology

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Vaccine, Influenza, Virus, Disease

Animal types	Life stages
Egg (fowl)	embryo, adult
Ferrets	Adult
Sheep	Adult
Rabbits	Adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

OBJECTIVES AND BENEFITS

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To generate biological materials that support global vaccine production and evaluation (quality control).

To provide biological reagents critical to (a) the World Health Organization (WHO)-led decision process for influenza vaccine composition; (b) global influenza vaccine production; (c) quality control testing of influenza vaccines for the global public

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Influenza vaccines are produced twice a year to meet the needs of the Northern and Southern Hemisphere flu seasons. To ensure the vaccines that are produced contain the types of vaccine virus most likely to give protection to vaccinated people, accurate characterisation of viruses is needed. This involves growing the viruses and making antibodies against them so that the vaccines can undergo quality control before being made available to the public.

Many vaccines need similar biological materials for an assessment of their biological quality - we will replenish expiring stocks with new for these vaccines and for new vaccines that become available.

This work is assuring the biological quality of human viral vaccines that are used globally.

What outputs do you think you will see at the end of this project?

The most immediate benefit is the continued availability of appropriately selected, manufactured and quality-controlled influenza vaccines for the world. Vaccines are produced twice a year to ensure availability for both the Northern and Southern Hemisphere influenza seasons.

The systems and assays used to control vaccines develop gradually over time but are well established and of demonstrated effectiveness. Currently reference materials and working reagents, which include candidate vaccine viruses and serum (containing antibodies against influenza virus proteins), are essential to the continued provision of potent vaccines worldwide including influenza vaccines. Such materials, which ensure the uniformity and quality of the vaccines concerned, must be available for both the Northern and Southern Hemisphere influenza seasons.

We expect to publish scientific papers in open access journals (i.e. available without the reader needing to pay) describing some of the studies that have been undertaken and the ensuing results including novel methodologies to best characterise the reagents, as well as any that in the future could reduce the reliance on the use of animals.

Who or what will benefit from these outputs, and how?

Ultimately, the benefits of the work in this licence is any individual in the world who receives an influenza vaccine or a vaccine for which the establishment provides reagents to measure its biological quality.

The provision of the reagents made under this licence contributes to the control of the potency and appropriateness of the vaccines produced by manufacturers and regulatory authorities and forms a central part of the process by which satisfactory and protective products are marketed globally. The consequences of using a vaccine of low potency or inappropriate strain(s) are that it will fail to protect the recipient.

The products that will be produced under this licence are a critical part of the standardisation and batch release of vaccines for a number of viruses.

For influenza virus, specifically, without the work covered in this licence, there would be a number of short term and immediate consequences:

- A lack of information to feed into the WHO-led influenza strain selection process, potentially leading to a poor vaccine match with currently circulating strains and therefore vaccine failure.

- A lack of new high growth reassortants could lead to a delay in the required number of doses being manufactured in the time available. These 'candidate vaccine viruses' may be used as the starting point for vaccine development.

- The licence supports work required for provision of the antibodies and antigen standards required to batch release (quality control) vaccines: without these reagents there would be an immediate effect on global vaccine supply. The antibodies are specific to different influenza types, or 'strains' and can therefore be used to confirm that the correct vaccine viruses are in the vaccine.

For other viruses there is a longer timeframe before replacement reagents are usually required, but a lack of reagents would also lead to potential vaccine shortage if batch release activities could not be undertaken due to these reagents not being available from the establishment.

How will you look to maximise the outputs of this work?

Staff contribute to WHO written technical monographs that support the process of influenza vaccine strain selection and vaccine quality control. Outcomes of the strain selection process are published on the

WHO website twice yearly. Reagents are made available to global stakeholders.

Whenever possible, scientists publish data in scientific journals - these are 'Open Access' so that anyone can access them free of charge online.

Species and numbers of animals expected to be used

- Sheep: 150
- Other birds: No answer provided
- Rabbits: 20

- Ferrets: 100
- : 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Embryonated eggs are the least sentient animal available. Most influenza viruses are grown in eggs - typically these will be less than 2/3 gestation and only on rare occasions would there be a need to grow a virus beyond this point when there are barriers to virus replication at the earlier stage of egg development.

Animals in which immune responses are required are selected as adults since very young animals may have an immature, and therefore incomplete immune response to the virus or other immunogen - this would possibly lead to a sub-optimal product.

Ferrets are among the few animals other than primates whose response to infection with influenza reflects that of humans; both the immune response and the clinical signs closely resemble that seen in humans.

Sheep are required to generate the large amount of serum required for a reagent for global use. Mice are too small and the response too variable to make them a practical alternative. Rabbits are used when only small-scale antibody production is required.

Fresh avian (here, turkey) blood has been identified as the most suitable for the haemagglutination (and inhibition) assays - to use alternatives would result in less reliable data and potentially greater volumes of blood from other species.

Typically, what will be done to an animal used in your project?

The studies require inoculations and boosters of antigenic material (including virus, virus components for example) with or without adjuvant into animals typically intramuscularly or subcutaneously, though

intranasal can be used for ferrets (may require up to 2 boosters for ferrets no less than weekly intervals; maximum of 6 boosters for rabbits typically weekly intervals; typically 3-6 boosters in sheep and on very rare occasions, up to 12 typically over the same number of weeks);

Subcutaneous implantation of a microchip into ferrets is optional to measure body temperature - it may be necessary to replace this once on the rare occasion that the chip is lost or fails.

Administration of antivirals orally to ferrets to ameliorate infection and symptoms due to infection by virulent influenza, and to reduce the likelihood of disease progression to the severity limit. Delivery will be twice daily for 7 days. The experiment will not typically exceed 3 weeks.

Blood collection from re-used animals. Blood collection from birds allows for re-use only after full recovery is demonstrated and with a minimum interval between collections: a maximum of 6 collections is permitted.

There is a possibility that viruses will need to be propagated in embryonated eggs at or beyond two- thirds gestation if the viruses cannot be grown to usable titres in eggs of less than this gestation time.

What are the expected impacts and/or adverse effects for the animals during your project?

General:

Typically the majority of animals used are not expected to experience significant ill-effects.

For any animal being immunised there may be some local irritation at the site of inoculations particularly where adjuvants are used (adjuvants are chemical compounds that increase the immune response to an inoculation). This will be monitored and advice from a Named Veterinary Surgeon will be sought if any adverse effect is seen. Exudative skin lesions at the site of inoculation are very rare, are expected to respond to local treatments and will not be allowed to persist for more than 24 hours.

Blood sampling procedures are expected to cause no more than minor transient discomfort. Very rarely haemorrhage, bruising, or haematomas may occur – the incidence of these will be minimised through good technique, use of needles of appropriate size and by applying continuous gentle pressure to the site after sampling. Single-use needles are employed. Maximum blood draw volumes will be adhered to and are based on Laboratory Animal Science Association (LASA) guidelines with expert input from NVS and Named Animal Care and Welfare Officers (NACWOs).

Any animals that are unable to readily feed or drink as a result of their condition will be humanely culled immediately. Any animal with deviation from normal health or behaviour which can't be alleviated with minor interventions such as those advised by the NACWO/ NVS within 24 hours will be humanely culled.

Eggs:

Where at, or greater-than-two-thirds gestation embryonated eggs are required, embryos that are adversely affected by the propagating virus may be terminated without delay. Embryo studies are completed prior to hatching thus adverse effects not be expected beyond 2-days.

Ferrets:

The adverse effects of influenza include rhinitis, fever and lethargy. Animals infected with virulent influenza viruses such as potential pandemic avian strains will usually develop fever, loss of appetite and reduced activity levels. Sneezing, nasal discharge, partially obstructed breathing due to mucous production and diarrhoea may also occur, as can be observed during human illness. Anti-viral drugs will be administered to ameliorate infection and symptoms. The virulence for ferrets of these viruses is variable and unpredictable, but if any symptomatic state persists for more than 24 hours, or an animal develops further signs of ill-health, action will be taken to minimise the adverse effects and suffering of the animal. There may be weight loss: a loss of >15% which does not appear to be resolving will result in the animal being terminated. Analgesic and anti-virals may be used but should it appear that humane end points are reached, the animal will be terminated to ensure no further suffering.

Turkeys:

The animals used in this protocol are not expected to experience significant ill-effects. Minor transient discomfort from the sampling may occur. Occasionally haematoma may occur at the sampling site but proficient technique and the application of local pressure after sampling will minimise the incidence. The wing veins of turkeys are very superficial and the blood vessel under the skin can be visualised quite clearly. Any haematoma or damage to the vessel is clearly visible. Past experience of blood sampling poultry has shown that any haematomas tends to resolve very quickly in a couple of days. An inspection of the vessels under the wing would clearly show any evidence of haematoma. In the unlikely event that a sampling site abnormality fails to recover; if it looked like there was no improvement between 48 to 72 hours; or the bird develops other signs of ill health the matter will be referred to the Named Veterinary Surgeon, whose clinical judgement and advice will be followed.

Sheep:

Irritation or muscular stiffness could occur at the inoculation site and this may result in lameness. If so this will be referred to the Named Veterinary Surgeon (NVS), whose clinical judgement and advice will be followed. In our substantial experience these occurrences are very unusual. Viral antigens administered by the intramuscular route are not expected to induce adverse systemic effects and in our experience these have never been observed or reported.

Rabbits:

The use of a specific adjuvant in rabbits has been reported to be associated with the risk of developing granulomas approximately 1 week post inoculation. To minimise this risk, the inoculum will be spread over 4 inoculation sites to to minimise the inoculum volume at any one site. The areas of inoculation are depilated by clipping to improve accuracy of

inoculation. Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The overall severity under this licence ranges from Mild to Moderate depending on the Protocol.

Ferrets approx. less than 50% of ferrets will experience moderate severity levels; typically no more than 30 animals over the lifetime of the PPL.

For the ferrets that will be infected with virulent influenza, the severity may be moderate. Since the outcome of these infections can be unpredictable the animals will be monitored very closely for signs of, reduced food intake, reduced water intake, lethargy, and will be treated with antiviral medication to limit the symptoms they experience due to the infection. Any ferret displaying neurological clinical signs, which may include symptoms such as ataxia or seizures will be culled immediately

Avian eggs - all Mild;
Turkeys - all Mild;
Rabbits - all Mild;
Sheep - all Mild

What will happen to animals at the end of this project?

Killed
Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Specific antibodies are required for use in tests to characterise viruses and evaluate viral vaccines. These are complex and need to have a broad activity against the viruses and vaccines candidates that can mimic what might be observed in higher vertebrates - humans. Because of the complexity of the mammalian immune system, these can only be generated in protected animals. The same complexity and quality cannot be achieved in a non-animal system currently.

Research into technologies such as phage display may ultimately be able to replace the use of animals. For the studies outlined in this licence, however, the application of alternative methodologies is still in development. The validation of a method is complex since it needs to involve generation of antibodies that can effectively mimic the polyclonal ("broad") response that is generated by animals to various influenza proteins and candidate vaccine viruses.

These then need to be in volumes sufficiently large that global laboratories and vaccine developers can use them to the volumes required in their processes. The approach would then need to be validated in other laboratories to ensure a harmonised approach globally. Thus the projects are still very much in a research phase and the use of protected animals to provide the required antibodies will need to be continued for the foreseeable future. If a new technology looks to become a viable alternative, the use of this will need to be tested alongside the current methods to prove its validity before the use of animals can be replaced.

The use of antibodies produced by in vitro methods is under investigation for use in influenza vaccine potency assays. If validated this would remove the need to produce antibodies in sheep for new influenza vaccine strains.

Which non-animal alternatives did you consider for use in this project?

The use of reverse genetics (RG) to prepare reassortant viruses allows for precise engineering of desired reassortants. This is an alternative to classical reassortants produced in eggs. Reassortants prepared by RG do not require rabbit antisera to eliminate undesirable reassortants, although the use of ferret sera for antigenic characterisation of the resulting viruses is still a requirement, and the RG viruses are still grown in embryonated eggs. However, use of these viruses for vaccine manufacture is hampered by restrictions associated with intellectual property rights (IP) unrelated to the Establishment

– it is unable to force manufacturers to use viruses generated by reverse genetics as this would be a conflict of interest, due to promoting the use of a patented technology which is owned by one particular company.

Materials prepared for vaccine manufacture and standardisation of vaccines must be prepared on the same substrate as vaccines. Propagation of virus in embryonated eggs is currently the most common way by which vaccines against influenza are manufactured. While the use of cell lines is increasing, there is still limited use for generation of standard reagents. However, with an increase in the number of cell lines approved for isolating viruses, vaccine development and production there exists the possibility of removing the need to use embryonated eggs in the future.

Turkey red blood cells are critical components of haemagglutination (HA) and haemagglutination inhibition (HI) assays used to assess viruses and viral vaccines and the immune responses they elicit. There is no reliable commercial supply of turkey blood of

suitable quality. In order to be able to isolate red blood cells of appropriate quality it is essential that blood is drawn from live turkeys, blood obtained post-mortem is not suitable. To kill a turkey each time red blood cells are required would be an extreme measure. Birds are monitored for adverse events as a result of blood sampling (such as haematoma formation) and only bled again under re-use authority if they are fit and healthy with no sign of adverse reaction to previous blood sampling.

As above, cell lines might be used in the future, depending on the wider vaccine production field.

Why were they not suitable?

Tissue culture is not a commonly used substrate for influenza vaccine production, limiting its use at the establishment for generation of standard reagents. However, more recently cell lines have been approved for isolating viruses, vaccine development and production and this affords the possibility of removing the need to use embryonated eggs in the future. These have limited utility currently until the wider vaccine field moves away from egg-based vaccines completely.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers reflect previous years' use and allows for flexibility should a number of influenza strains need to be changed in any one season - typically this would be 1, perhaps 2, but there may be instances where additional changes are made or replacement reagents (particularly serological) are essential to ensure vaccine supply.

The number of eggs required is predictable and is regarded as the minimum to assess the material needed to test vaccines. The volumes of blood from turkeys are those required based on years of experience of undertaking the specific laboratory tests.

Few animals are required to generate the sera that are needed, but experience has shown over the years that several animals must be immunised or infected to be sure that there are sufficient suitable sera. Typically, up to six ferrets will be used in infection experiments and the same number of sheep for immunisation with non-replicating antigens. The numbers of animals proposed is regarded as the minimum necessary to produce the desired result, based on the experience of many years.

Influenza viruses are sufficiently different that it is not easy to predict how good an immune response an individual animal will make - we pool sera collected from multiple animals to ensure supply and homogeneity of the samples.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The numbers are based on previous experience. The experiments do not change substantially between iterations of this project licence since they are linked into the global approach to influenza vaccine production.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers of animals used under the Protocols will be the minimum required to obtain sufficient biological materials – viruses, antiserum – as based on historical scientific data and experience with the species.

The individual project plans will include a pre-study meeting to identify the number of animals required per group, in cases where the experiment has not been previously undertaken.

We maintain dialogue with vaccine manufacturers to determine if (and when) they can use less volume of sera to test their products, and if so we will be able to reduce the amount we provide and thus reduce the number of sheep used to make sera.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Embryonated eggs - this is the least sentient species; monitoring of eggs in which virus is propagating in the allantoic fluid will minimise suffering of embryos which can be terminated early should there be signs of infection of the embryo itself. The use of eggs at or past the two-thirds gestation will only be necessary should the virus under investigation be empirically shown not grow to the titre in eggs of less than two-thirds gestation needed for onward use. If eggs at or beyond two-thirds gestation are required, the eggs will be inoculated after setting, and allantoic fluid will be harvested by or at Day 17. The use of

eggs past the two-thirds gestation period is a rare requirement and was not needed in the previous PPL.

Ferrets - infection with influenza viruses and generation of small volumes of antiserum. In order for the ferrets to seroconvert they must be actually infected with the influenza virus, which can lead to clinical signs, and be kept alive long enough for antibodies to be produced by B cells. For animals infected with virulent influenza we will use antivirals to reduce the clinical effects of infection: animals will be given antivirals by the oral route twice daily for 7 days beginning 2 days following an initial intranasal administration of antigenic material. It is recognised that group housing is preferable for optimum well- being of ferrets and wherever possible they will be group housed. The use of remote measurement of body temperature will minimise the amount of animal handling required and thus keep stress levels to a minimum.

Rabbits - generation of antiserum; we have refined the method of delivery of adjuvanted antigen during the course of a parallel and current PPL to minimise the risk of granuloma. The use of a specific adjuvant in rabbits has been reported to be associated with the risk of developing granulomas approximately 1 week post inoculation. To minimise this risk, the inoculum will be spread over 4 inoculation sites to to minimise the inoculum volume at any one site. The areas of inoculation are depilated by shaving to improve accuracy of inoculation.

Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin. By adapting the inoculation process the likelihood of granuloma is reduced and thus the potential for lasting harm is likewise minimised. Should granuloma form, it is possible to pause the protocol until the animal recovers sufficiently, and then select an alternate site for inoculation if needed.

Rabbits will be housed in socially compatible groups whenever possible and always in floor pens.

Sheep - required to generate the large volume of serum required for a reference antiserum reagent for global use. The effectiveness of alternative adjuvants has been and will continue to be explored with the aim of minimising or removing the need to use Freund's adjuvant while achieving the required quality of the antiserum in vaccine manufacture. Currently, Freund's complete adjuvant is required for the initial (prime) inoculation only, whereas Freund's Incomplete adjuvant is used for the subsequent (boost) inoculations. The inoculations in sheep are managed by expert staff to minimise distress of the animal through the inoculation and blood collection procedures; there is availability of food and/or grazing after the procedure for the animals. The sheep are habituated and maintained together as a group. The procedures are not anticipated to result in lasting harm over the duration of the study.

Mice are too small and the response too variable to make them a practical alternative to the sheep.

Turkeys - fresh red blood cell supply is critical for accurate and reproducible in vitro tests. The availability of the blood from the second establishment close to the primary establishment allows for such supply. As blood ages post collection, critical red blood cells can lyse resulting in more variable scientific data which may require additional samples to be used. Here, blood is collected from a bird from a flock which is habituated and kept together over the period of many months. To minimise the impact of blood withdrawal on any one bird, the birds are selected on a cycle system to allow sufficient periods of rest in between blood collections and minimise lasting harm. No single bird is used more than once every 21 days and typically it is at an interval of 42 days.

For rabbits, ferrets and sheep: analgesics will be administered where needed and where their effect will not interfere with the scientific outcome of the study.

All animals will be killed humanely at the end of the experimental protocol / study by the method in the relevant Protocol.

Why can’t you use animals that are less sentient?

Embryonated eggs are the least sentient animal available: the use of eggs at or greater than two-thirds gestation is for those exceptional, though not readily predictable, influenza viruses that do not propagate to usable titres in eggs of less than two-thirds gestation.

Ferrets are among the few animals other than primates whose response to infection with influenza reflects that of humans: both the immune response and the clinical signs closely resemble that seen in humans. Methods for more frequent observation of clinical signs have been developed for earlier recognition of onset of disease allowing earlier intervention with the use of medication to relieve symptoms or termination as appropriate. Data accumulated over the years indicate that the specific immune response is highly predictive for when a strain is sufficiently different from those that have gone before to warrant a strain change in the vaccine. The relationship is far less clear-cut for other species such as mice where infection is usually more restricted.

Rabbits are suitable for small volumes of polyclonal antisera. To generate the same amount of serum in rodents would require substantially more animals.

Sheep are required to generate the large amount of serum required for a reagent for global use. Mice are too small and the response too variable to make them a practical alternative.

Most studies last a number of weeks therefore terminally anaesthetised animals are not a practicable option.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals are habituated prior to commencement of study.

The use of remote telemetry (microchip) of ferrets is based on previous experience to minimise impact of regular temperature monitoring.

Inoculation volumes are based on those recommended by LASA and others; they are the minimum required at any administration site. These have been shown to be appropriate over the previous licence.

We have made changes to practices under the previous PPL such as refinement of inoculation of rabbits to minimise the risk of granuloma formation. To minimise this risk, the inoculum will be spread over 4 inoculation sites to to minimise the inoculum volume at any one site. The areas of inoculation are depilated by shaving to improve accuracy of inoculation. Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin. Reinoculation (boost) of rabbits that do develop granuloma can be paused until the animal is considered recovered.

Freund's complete adjuvant is used for the initial inoculation of a sheep only. This is currently the 'gold standard' for generating anti-influenza hyperimmune serum in sheep. In line with published scientific literature we employ a schedule in which FCA is used for the first inoculation, but not subsequently, since it has been reported that no increase in immune response was seen with continued use of FCA.

Neither Freund's Complete nor Incomplete adjuvant is used in other species in this project. We will continue to review the scientific literature around adjuvants used, and communications with scientific and veterinary groups to determine whether there could be suitable alternatives to FCA (and others) that can be immunogenic but reduce the reactogenicity in animals. Should credible candidates be identified, a comparative study of these against existing adjuvants (particularly FCA in sheep) can be considered with suitable amendment to the Licence to ensure good experimental design and statistical power.

We have a programme of continual improvement to animal housing, husbandry and handling aimed at minimising stress in animals and encouraging natural behaviours.

Animals undergo thorough pre- and during-study checks. Analgesics will be administered where needed and where their effect will not interfere with the scientific outcome of the study. Clinical signs can be ameliorated by the use of antivirals (ferrets) or analgesia (ferrets, rabbits, sheep), for example.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance is available through Home Office including newsletters via the ASRU.

LASA and FELASA guidelines will be applied to guide dose volume/route per laboratory animal subject and surgical procedures.

NC3Rs documents on husbandry, housing and procedural work will be met or exceeded.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment's AWERB circulates up to date information on the 3Rs through the Named Information Officer (NIO). Similarly, the licence applicant is on the email circulation list for the NC3Rs bulletins.

The PPL holder will work closely with the NACWOs and NVS to ensure that changes to the animal studies are improved wherever possible. This may be reflected in changes to husbandry and animal handling practices, refined procedural activities, and advances reported in the scientific literature or at scientific conferences/meetings that could result in use of a less sentient species, fewer animals in experimental groups, or non-animal alternatives.

Information exchange will be used to refine the work programmes as necessary.

117. Ecology and epidemiology of infectious disease in wildlife

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - (Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Wildlife, Epidemiology, Demography, Management, Disease

Animal types	Life stages
European Badgers	juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The over-arching aims of the study for the next five years are to collect demographic, behavioural and epidemiological data from wildlife populations, in order to construct mathematical models and conduct statistical analyses to identify trends in the dynamics of infectious diseases and responses to management interventions. The involvement of wildlife in the persistence of infectious disease in livestock presents a serious challenge to its control. The findings of this study will be used to inform the evidence base available to develop options for the sustainable management of the risks of onward transmission of infectious disease from wildlife to livestock.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many pathogens of wildlife can cause serious disease in humans and domestic animals. Effective management of transmission risks and control of disease outbreaks requires an understanding of the ecology of the wildlife host and the epidemiology of infection in host populations. This study will focus on infectious disease of UK livestock and a major animal welfare issue which imposes significant costs on the taxpayer. Data from this project will inform the development and implementation of sustainable approaches to manage risks of transmission between wildlife and livestock. The study will also provide opportunities to investigate other infectious diseases that may circulate in wildlife and/or transmit to humans and domestic animals (e.g. coronaviruses, tick-borne diseases and salmonella).

What outputs do you think you will see at the end of this project?

Pathogens of wildlife can infect humans, domestic and companion animals, imposing a significant financial and social burden on UK society. In the past, data from our studies has provided important insights into the dynamics of infectious disease in wildlife and livestock and has been instrumental in influencing policies for the management of infectious disease. Data from our studies will continue to be used to further develop mathematical models used to assess different control strategies and will continue to be used to inform disease management approaches. Specific outputs expected during the lifetime of this project will include evaluation of methods of marking vaccinated wild animals and taking blood samples for trap-side diagnosis, and detailed observations on the effects of culling on badger behaviour and disease transmission. This information will be particularly valuable when embarking on a policy of vaccinating animal populations that have previously been subject to culling.

Who or what will benefit from these outputs, and how?

Over the course of the next 5 years this project will provide information of particular relevance in the control of infectious disease risks from wildlife. In addition to furthering our broad understanding of the drivers of the spread and persistence of this disease, we also anticipate specific outputs that will inform plans to roll out wildlife vaccination in areas previously subjected to culling. Our studies will therefore contribute to the ongoing control of a disease of livestock which is a substantial burden on farmers, the UK taxpayer and a welfare issue for livestock and wildlife. Being a zoonotic infection and is therefore of concern for public health.

In the short-term the outputs of this study will inform development of approaches to implement vaccinating wildlife in post cull areas, and in the longer-term will contribute to the wider goal of disease eradication in UK livestock.

How will you look to maximise the outputs of this work?

Outputs from the project will be maximised through communication with policy-makers (so they may inform policy development), collaboration with academia, joint publication in scientific journals, presentations at national and international meetings, and dissemination of findings to key stakeholders including the farming industry and their representatives, and conservation groups.

Species and numbers of animals expected to be used

- : 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Wild animals of all age groups can be infected with disease and can be involved in the persistence of infection in livestock. During our field studies we will collect fine scale information on the dynamics of this disease, the demographics of wild populations, and their social behaviour (contact patterns in particular) and how these relate to disease transmission and attempts to manage disease spread.

Typically, what will be done to an animal used in your project?

Under this licence an animal will typically experience being captured in a trap and transported to a sampling facility where it will be anaesthetised for examination and sampling. On first capture each animal is given a number and letter combination tattoo on the belly for future identification and a hair sample is taken to provide a unique genetic identifier. At each capture animals will be visually examined to assess their age, sex, condition and reproductive status, they will be weighed and their body length measured. A series of samples will be taken to establish whether they are infected with disease, including blood, sputum, urine, faeces and swabs of any wounds or abscesses. Some captured animals may have skin scrapings, additional nasal, oropharyngeal or anal swabs taken or ticks removed, in order to investigate other parasites and diseases. A small number of animals will have tissue biopsies taken from the ear to investigate ageing and whiskers may be collected from animals to investigate foraging behaviour. Collars carrying tracking devices will be fitted to some animals to allow their movements and contact behaviour to be tracked. After sampling all animals will be allowed to recover fully from anaesthesia. Animals will typically be held for up to 24 hours (up to a maximum of 36 hours if required) prior to release back into the wild. Once deemed fit for release each animal will be transported back to where it was caught and set free. Animals may experience this process several times in their life.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected level of severity of procedures is mild. No lasting adverse effects are expected as a result of capture, examination or monitoring of wild animals. Nevertheless, we have detailed procedures in place to address any welfare issues arising from unexpected outcomes. At the end of the study animals will be set free into the wild. We observe a closed season when animal trapping is suspended (Feb – Apr) to avoid catching lactating females and dependent young. As all captured animals are only away from their social group for a short period of time we do not anticipate any significant impacts on their social position. The observed social stability of the population we have been studying since the 1970s indicates that our activities have not caused any noticeable social disruption.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild for all procedures.

What will happen to animals at the end of this project?

Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Complete replacement of the use of live animals is impossible as the purpose of the research described here is to investigate their role in the persistence of infectious disease and options for managing disease risks to livestock. However, the data available from our studies can be used in simulation models to investigate the likely effects of different management scenarios and the dynamics of disease under other conditions, which may reduce or obviate the need for the use of live animals in the future.

Which non-animal alternatives did you consider for use in this project?

Disease modelling was considered.

Why were they not suitable?

This is a study of disease in wildlife which provides basic biological data that can be used to build models that simulate disease dynamics and responses to management interventions. However, these models can only provide limited information on the relative outcomes of different management approaches and cannot answer fundamental questions about the disease in wildlife and their behavioural responses to infection and management interventions. It is also necessary to use live animals in order to field test new management techniques (e.g. trap-side blood sampling) and diagnostics. Hence, at present no non-animal alternatives exist for collecting the data required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is a study of wild animals and so it is not possible accurately forecast numbers that may be captured as this will vary between populations and according to weather and local circumstances. In addition, as this study adapts to the requirements for evidence to inform disease control policies, it is not clear in advance how many animals might need to be captured to answer specific questions. However, the figure of 750 animals is based on numbers that have been captured in recent years working under the previous project licence, as this provides the best estimate of numbers likely to be required over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

These studies are largely observational, involving long-term monitoring and sampling of wildlife populations, and so there is no formal experimental design as such. However, where sub samples of animals are required to test new methods or answer specific research questions then we will take statistical advice on experimental design and use power analyses to determine how many animals to recruit into these studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers of animals in this work will be optimised through the use of highly skilled field staff and very effective means of capturing wild animals, which ensures that our field operations are efficient (under a range of environmental conditions) and that we do not lose any captured animals. Also, the skilled personnel who carry out anaesthesia and all procedures ensure that we obtain a full set of samples from virtually every animal. The use of highly experienced staff and standard operating procedures results in very few adverse

effects being observed and allows us to obtain high quality samples. Our in-house expertise in mammal ecology and infectious diseases, and collaborations with specialists from academia maximise the value of the data obtained from the captured animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The study requires capture, examination, sampling and monitoring of wild animals in which infectious pathogens circulate. The research team have considerable experience in the trapping and handling of wildlife, they have continued to develop and improve field and sampling methodology in the interests of minimising animal suffering. In the light of experience, trap design has been refined to reduce the likelihood of injuries. The team includes a veterinarian and full time NACWO. All methods are described in operating procedures and all staff undertake extensive training, including annual refreshers on techniques and direct supervision. Trapping is carried out under licence and each study within this wider programme of work is subject to scrutiny by the AWERB Panel.

Why can’t you use animals that are less sentient?

Replacement of animals with a less sentient species is not an option as the purpose of the research described here is to investigate natural ecological and epidemiological processes in wildlife populations.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our working practices have been refined over many years but are the subject of continual improvement. Procedures have been refined on the basis of emerging evidence and at our annual refresher session we run through existing procedures with all staff involved and provide an opportunity for all to raise any issues/suggestions for improvement. We encourage a culture of shared responsibility for animal welfare in the team and an openness to discuss any concerns or ideas for improvement.

Some recent refinements are,

1. The gradual replacement of traps with a mesh size that is associated with a lower likelihood of injuries during trapping. This was achieved by systematically monitoring injuries (most of which are very minor, e.g. skin abrasions) associated with different types of trap over time.

2. The introduction of additional measures to monitor body temperature of animals under anaesthesia so we can pick up departures from normality and take appropriate action when required.

3. Completely emptying drinkers immediately prior to the administration of anaesthesia of animals in holding cages, so as to avoid any animal becoming unconscious with its snout in the water.

4. As part of work involving deploying radio/GPS/proximity logger collars on animals, we implemented a procedure of getting each newly fitted collar double checked by another experienced person.

5. The use of camera traps to locate collared animals in order to target trapping effort and so maximize chances of recapturing them and removing the collar.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In my role as PPL holder I stay up to date on innovations in wildlife research to identify opportunities to improve our working practices. This involves staying informed about the latest literature and in particular any best practice guidance. Our AWERB Panel also pass on any published best practice guidance that may be relevant.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I undertake ongoing CPD (often identified by our local AWERB panel) that is relevant to the 3Rs and my role as a PPL holder. In addition, close liaison with the NACWO, NVS and NIO provide further opportunities. I also personally stay informed about advances in the 3Rs in wildlife research through my regular access to the scientific literature. I am able to consider the implementation of any advances through discussion with the team involved in the study, the NACWO, NVS and NIO. Our annual refresher session provides a useful forum for this and allows all staff working on the project to raise any issues. I am able to authorise changes to the working practices on the project as I am the lead scientist for this area of work in addition to being the PPL holder.

118. Mechanisms of metabolic regulation in health and disease

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary goals of this project are to study how tumours change the metabolism of the host organism, and how, in turn, metabolic changes in both tumour and the host support tumour development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite significant progress in understanding the molecular basis of how tumours emerge and develop, cancer remains a significant cause of death worldwide. In particular, liver cancer, a major focus of this project, is the fifth most deadly tumour type, with no substantial improvement in patient mortality rates over the past three decades, in contrast

to most other tumour types. The rise in liver cancer cases is, partly, due to an alarming increase in obesity-induced liver disease, which is typically associated with accumulation of fat and subsequent injury in the liver. Chronic liver injury, in turn, promotes cancer - almost all liver cancer patients have had some form of liver disease earlier in life and about 20% of patients with cirrhosis (an advanced form of liver disease, also associated with excessive alcohol consumption) will develop liver cancer. However, there are no clear indicators that predict which patients with liver disease will go on to develop liver cancer. Furthermore, there are limited therapeutic options and, even then, it is unclear which patients will respond to these therapies. Therefore, clinicians need to observe patients with liver disease over long periods of time in order to capture those that do develop cancer early, when surgical resection still offers hope for survival. Beyond the cost in human lives, such long-term patient monitoring adds a significant cost to health systems.

A common feature of cancer cells is that they change their metabolism, compared to normal cells, in order to survive and proliferate. Targeting cancer metabolism offers significant therapeutic potential as evidenced by the fact that the first chemotherapy, methotrexate, targets a metabolic pathway and is still successfully used today in the clinic. However, there is a high failure rate in producing effective drugs that target metabolism, in part because there are many gaps in our knowledge about basic metabolic processes. Specifically, it is unclear how changes in metabolism of the host organism, which are often found in patients with various types of cancer, help tumour initiation, maintenance and dissemination (metastasis). Alterations in the metabolism of the host, such as loss of fatty (adipose) tissue and muscle mass, also have profound effects on the quality-of-life of cancer patients and, in part, contribute to mortality.

The proposed work brings these two challenges under one umbrella by aiming to provide mechanistic insights into how tumours change host metabolism and how host metabolism, in turn, supports cancer formation, in order to identify new therapeutic strategies; and apply these insights into testing new therapeutic approaches for liver cancer. Some of the metabolic pathways we study play important roles in normal physiology and our studies will also provide insights into these normal functions. Finally, by using models other than liver cancer, such as mammary gland cancer, we also aim to explore whether our findings have broader relevance for oncology.

What outputs do you think you will see at the end of this project?

Broadly, we expect to produce new knowledge about the role of specific metabolic processes in normal body physiology and tumorigenesis, and to generate new genetic, chemical and computational tools that will accelerate mechanistic understanding of the functions of metabolism in health and disease. More specifically:

- We will elucidate the mechanisms that tumours employ to alter the metabolism of the host organism and will assess whether and how these pathways can be targeted for cancer therapy.

- We will generate new genetically altered mouse lines that harbour knockouts of metabolic enzymes to assess the role of these enzymes in normal physiology, in metabolic disease and tumorigenesis.
- We will develop new small animal imaging methods to measure dynamically metabolic pathway activities in living animals and validate their usefulness as a tool to monitor disease progression and response to therapy.
- We will validate small molecules that alter the function of metabolic enzymes to assess their value as potential therapeutics against cancer.

- We will use our data from animal experiments to generate and train new computational models of animal physiology and metabolism that have improved predictive capacity.

The new knowledge acquired from our work will be distributed through a wide range of channels including presentations and posters at relevant conferences, and publications in relevant journals. In addition, we will also announce breakthroughs and updates through social media channels such as Twitter and the institutional website.

Who or what will benefit from these outputs, and how?

- Basic science and the scientific community: Metabolism underlies all aspects of life and is linked to the biggest killers of human society, incl. diabetes, infectious diseases and cancer. Research into the metabolic basis of disease is rife and our work will provide important insights into the fundamental mechanisms mammals use to maintain a healthy metabolism, how these mechanisms are perturbed in disease and how we can intervene to restore a healthy outcome. Our work will also generate new genetic, chemical and computational tools that can be used to interfere with metabolic processes. In the short term, both the knowledge and tools generated from our work will be available to other researchers to be used and inform their work.

- 3Rs: In the longer term, our work holds great promise for helping to reduce the number of animals required for future metabolic research. Our proposed work will help us train computational models of mouse metabolism to improve their ability to predict which metabolic processes to target in order to stop tumour growth. In turn, better computational models will help us refine our hypotheses and design more targeted experiments that will enable us to achieve our scientific objectives using a smaller number of animals. Similarly, once validated, our imaging methodologies have the potential to either decrease the numbers of animals needed to obtain similar insights, or obtain more data-rich results from each animal without repeated sampling.

- Clinical translation/patients: Ultimately, we envision that our work will benefit human patients by improving our understanding of cancer’s impact on whole body metabolism. Liver cancer patient mortality has not improved for decades, in contrast to other tumour types. Patients with cancer of diverse primary origin suffer both due to perturbation in the affected tissue’s function but also due to disturbance of systemic metabolism, which leads to frailty and poor quality-of-life. Our work on the metabolic consequences of

tumorigenesis, will illuminate new strategies towards ameliorating whole- body physiology and to halt tumour growth. Beyond our focus on liver cancer, our work will also test whether whole-body metabolic changes are also relevant in other cancers, such as breast cancer, and in metabolic disease.

How will you look to maximise the outputs of this work?

A major goal of this project is to understand how tumour-induced changes in host metabolism occur and their role in tumorigenesis. Host metabolism alterations have been reported in patients with tumours of various tissue origins. So, although most of the planned work focuses on liver cancer, we are also proposing targeted experiments in other mouse cancer models to assess how our findings apply to other cancers, thereby expanding the scope of our work's translational applications.

Dissemination of newly acquired knowledge and experimental tools will also help maximise our work's outputs. We will report our findings to the broader scientific and clinical community through publications in scientific journals and presentations in national and international conferences. Newly generated tools, such as imaging protocols, genetic knockouts and computational models of mouse physiology will also be made available through appropriate channels, such as mouse and software depositories.

These tools will catalyse further research by other researchers world-wide.

The proposed work will also facilitate existing, or instil new collaborations both with academic and industrial partners. For example, our mouse metabolism data will help to improve computational models by mathematical biologists that would, otherwise, not be able to readily test their models' capabilities. In turn, computational models will help us process large amounts of data and generate new, testable hypotheses. Furthermore, our newly discovered metabolite analogues with improved pharmacokinetics may be of interest to other academic or industrial partners who seek to use in vivo validated chemical tools to study the consequences of perturbing metabolic pathways in mice.

Species and numbers of animals expected to be used

- Mice: 48450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Most human metabolic pathways and the processes that regulate them are highly conserved in rodents making the mouse the lowest animal in the evolutionary tree that is appropriate as a model species to study metabolic disease and cancer, the main focus of our work. In practice, mice have proven invaluable in elucidating mechanisms that

maintain an organism in a healthy state. Consequently, mice have also been a cornerstone of preclinical drug evaluation for most successful therapies. Furthermore, there are numerous available genetically modified mouse lines and refined procedures that can significantly accelerate testing new hypotheses into molecular mechanisms and alleviate the need to re-develop experimental approaches that would necessitate additional animals.

Given that cancer significantly affects ageing populations, most experiments will be performed in adult mice (typically up to 40 weeks of age). Metabolic deterioration during ageing (e.g. age-induced inflammation and diabetes) may contribute to higher tumour incidence in older individuals. Therefore, to assess whether metabolic pathways in the host that support tumorigenesis change as mice age, we will also perform metabolic analyses in older adults (typically approx. 1-1.5 years old). Conversely, some of the metabolic enzymes we study have been implicated in inborn errors of metabolism affecting neonates and children. Therefore, mice harbouring genetic deletion of these genes will be valuable models of these metabolic diseases. In such cases, in a small number or animals, some metabolic measurements will be performed in a small number of neonate or juvenile animals.

Typically, what will be done to an animal used in your project?

1) Generation of mouse models of cancer and metabolic disease.

In general, we will generate mice that develop tumours by various genetic or chemical methods. In most cases, mice will also be fed diets high in sugar and fat, which are known to cause obesity and are linked to increased human cancer incidence. In some cases, mice will undergo surgical procedures,

e.g. to remove an endocrine organ that is implicated in producing tumour-promoting signals. All surgical procedures are relatively short (up to 30 minutes).

2) Monitoring metabolic body parameters and tumour growth.

Most animals will be scanned by non-invasive imaging methods (primarily MRI) to monitor tumour development, metabolic parameters or response to therapy. Imaging will be done at regular intervals throughout tumour development, and up to the time that tumours approach the humane end point. In cases where response to therapy is assessed, tumour monitoring may be extended for up to a time required to confirm no re-emergence of therapy-resistant tumours.

3) Measurement of metabolic activities in vivo.

To measure metabolic activities in tissues of living mice, most experimental animals will be fasted between 6-18 h and then administered with labelled metabolites. The metabolic state of some experimental animals will be assessed by administering a single dose

(bolus) of a metabolite (e.g. glucose) or hormones (e.g. insulin) followed by sampling of a small volume of blood.

4) Testing effects of pharmacological or genetic modulation of target pathway upon tumour development.

In some cases, to test whether a metabolic process is needed for tumour emergence or development, an agent that alters the activity of such a process will be administered over a period of time that is long enough to observe an effect upon tumour growth. Suitable compound doses, administration routes and frequencies will first be determined in pilot experiments. Substance administration will not exceed predetermined volume and frequency limits that are approved in this licence.

What are the expected impacts and/or adverse effects for the animals during your project?

Experimental procedures proposed for this project have either been established or will be refined to minimise the possibility of adverse effects. Animals that develop tumours may experience weight loss, appetite loss, hunching, or temporary shivering. Animals will be monitored daily and weighted weekly, and any animals experiencing more than 15% weight loss between these measurements will then be weighed daily and killed if approaching the humane endpoint. Notably, in some cases weight loss during therapeutic treatment regimens may be associated with improving, rather than deteriorating, overall health, e.g. when animals are switched from an obesity-promoting to a normal chow diet.

Objective assessment of whether weight loss is a cause of concern will be aided by assessing the overall body condition and behaviour of animals (e.g. for signs of distress or piloerection).

Surgical or chemical damage to the liver is reversible and full liver mass and function are expected to recover within 6-7 days after treatment. Surgical procedures and cell injections can cause internal bleeding. Animals are closely monitored during procedures and directly after recovery and any animal showing evidence of bleeding will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Moderate (60-70%)
- Mild (30-40%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To identify mechanisms of growth and metabolism that are relevant in the context of the whole intact animal and are therefore meaningful for human clinical studies, it is necessary to utilise animal experiments. This is because, organ- and cancer-specific metabolic pathways are highly influenced by the complex physiological processes inside the body, the local tissue microenvironment, and metabolic crosstalk between different organs and tumours; none of these features are yet possible to faithfully recapitulate in vitro.

Which non-animal alternatives did you consider for use in this project?

Our current and future research makes extensive use of alternatives to animals. In vitro cultures of mammalian cells/tissues, under conditions made more physiologically relevant as informed by the experiments described in this project, can be used for some of our studies that focus on cell- autonomous mechanisms and are undoubtedly an important source of replacement.

We are also making extensive use of computational models of mouse metabolism, whereby, metabolic processes that are predicted to be important for cellular functions related to cancer (such as biomass production to support proliferation). To provide meaningful predictions, these models require input from prior experimental measurements but can be used to test or refine hypotheses before experimental validation in animals.

Why were they not suitable?

The main aim of this project is to understand how organs interact to maintain whole-body metabolic homeostasis, the perturbation of which is a hallmark of many severe diseases such as cancer, infectious disease and metabolic syndrome. It is, therefore, fundamentally impossible to study this problem in any other model than the intact animal. In addition, the effects of manipulations of the diet can only be meaningfully studied in vivo.

Furthermore, cultured cell systems alone are inadequate to address most of this project's aims because they cannot recapitulate the metabolic input from the gut and tissue microbiomes; they cannot mimic circadian effects; they lack the multitude of cell types found within different tissues and overall tissue architecture (known as "zonation" in the liver). All these parameters are known to have profound influence on cell metabolism.

Finally, although our improved computational models are increasingly making better predictions that help refine experiments and reduce animal numbers, they need to be validated experimentally before making any meaningful decisions about the translational potential of our discoveries.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most experimental models proposed in this project have already been established in the lab. We therefore have a clear picture of assay limitations in the context of the expected variability from animal physiology and we can empirically estimate how many animals each experimental group requires for our studies. For new methods, we have consulted the literature and colleagues with relevant experience.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our animal studies design is aided by the NC3Rs Experimental Design Assistant and uses the PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines. We consult with a statistician with regards to the experimental design to minimise the number of animals used whilst ensuring meaningful data can be collected.

We always strive to invent, improve or implement novel technologies to obtain more information from each animal. Then we incorporate those techniques that are suitable to obtain the desired output while minimising animal numbers at strategic points in our experimental plan. For example, when we need to study a specific pathway (rather than the entire metabolic network, which requires specialised measurements in tissues from terminal experiments) we use magnetic resonance spectroscopy (MRS) to obtain dynamic metabolic activity measurements in a tissue-specific manner. This approach provides, from a single mouse, data that would otherwise require dozens of animals. We use MRS to measure lipid content in a spatially resolved manner without killing the animal, which can then be used for other measurements. For therapeutic treatment studies, longitudinal MR imaging (MRI) ensures cohorts have the desired tumour burden, negating the need for increased animal numbers that would otherwise be used to offset therapeutic response variability due to diverse starting tumour size, or to avoid losing animals that unexpectedly reach the humane end point before the completion of the study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Before embarking on any animal experiments, we will collect as much evidence as possible to determine whether a candidate genetic or environmental manipulation has a reasonable chance of regulating mammalian growth and metabolism in vivo. Evidence will

be collected from our own initial studies using cancer cells cultured under physiologically relevant conditions, as well as by surveying the relevant literature. In addition, we will use non-regulated procedures to collect expression data from fixed non-GM mammalian tissues and functional/expression data from genetically and/or environmentally manipulated in vitro mammalian cell lines.

Where possible, mouse lines will be maintained in a homozygous state, thereby obviating the generation of a large excess offspring with inappropriate genotypes. In other cases, homozygotes will be generated from heterozygote inter-crosses, with littermates genotyped as heterozygous or wild type used as age and gender matched controls. In the case of our liver studies, when scientifically justified, we will make use of viral vectors with tropism to the liver (e.g. adeno-associated virus serotype 8 – AAV8), to decrease the need for breeding multiple alleles to obtain tissue-specific genotypes.

For most of the quantitative experiments, design will be based on PREPARE guidelines. Otherwise, we will use the minimum number of animals to provide an adequate description of the projected outcome, determined on the basis of previous experience (our own, or from the literature).

This programme of work will make optimal use of several tissues, fluids and cell types per individual mouse. We will aim to collect organ samples from multiple body sites and to provide other affected tissues to appropriate scientists, so that they do not have to breed mice specifically for their experiments. This highly integrative approach will maximise the information obtained from the minimum resources. Cryopreservation of gametes, embryos, tissues and cells is routine at our establishment and will ensure that the minimum number of mice is bred.

We also expect that, as we gain better understanding of the metabolic processes involved in biological systems under study, we will be able to define more tailored methods to investigate metabolism while maximizing the amount of information derived from each animal, e.g. by defining new biomarkers or in vivo imaging probes that would allow longitudinal observations of metabolic functions and thereby reduce animal numbers. This is likely to have application not only for this project but also for the broader research community.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mice to study inter-organ communication in health and disease because, although relatively low in the evolutionary tree, their overall anatomical distribution of metabolic functions and metabolic network organisation are highly similar to those in humans. Furthermore, there are many genetic tools and highly refined techniques available for mice, which aid scientific discovery.

The genetic and chemical carcinogenesis models of liver and mammary gland cancer are well established, are known to have relatively minimal adverse effects and have been extensively characterised in many labs around the world. Furthermore, the selected liver cancer and tissue damage models, alongside diet manipulation, recapitulate specific aspects of human disease, that, collectively, contribute to morbidity.

Why can't you use animals that are less sentient?

One of our primary scientific goals is to understand how organs communicate to achieve whole-body homeostasis, and less sentient species, such as the fly, do not recapitulate the overall anatomical and functional distribution of metabolic activities across organs (e.g. the fly tissue that is thought to be the liver equivalent only performs some of the mammalian liver functions, in addition to other functions that are performed by the mammalian adipose tissue). Most of our measurements with metabolic tracers are done under terminal anaesthesia. However, for studies on cancer growth and metabolic disease development, both of which are intimately linked to ageing, and develop over several months, we need to use adult mice as this is the most physiologically relevant life stage.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Wherever appropriate, we will minimise the adverse effects associated with genetic alterations by using inducible or conditional alleles to delete gene activity from specific tissues rather than from the entire mouse. To minimise stress during breeding and maintenance, we will follow best practice guidelines and follow local refinements of husbandry such as cage enrichment and sufficient amounts of nesting material. On receipt or generation of a new line, we will minimize suffering by ensuring increased observation and monitoring until a detailed phenotypic analysis for each line is accomplished. If any welfare implications are identified, they will be acted upon and refinements considered in consultation with the NVS and NACWO.

For all manipulations we will adhere to local or national guidelines that aim to minimize suffering. Many of the genetic, dietary, temperature and oxygen manipulations as well as the administrations of gene inducers/repressors or other agents are standard and previous refinements from the literature will be used. If, however, there is insufficient information available, new manipulations will be pre-screened in small-scale pilot studies to obtain

indications of the minimum dose and exposure time that is likely to be effective, thereby minimising any potential suffering.

In all surgery, analgesia will be provided according to contemporary best practice and advice from the NVS/NACWO. In work done under a previous licence, we have optimised surgical techniques, such as partial hepatectomy, to accelerate the procedure, minimise incision size and reduce the probability of collateral tissue damage. Good aseptic surgical techniques, heat & fluid therapy will be provided. In the case of cancer models for example, we will follow the guidelines in Workman et al, British Journal of Cancer (2010) 102, 1555 – 1577. For each protocol where there are a number of optional steps, the maximum number of steps is clearly defined within the adverse effects section.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidance given in the NC3Rs 'Resource Hub' (https://nc3rs.org.uk/resource-hubs) for example on blood sampling (https://www.nc3rs.org.uk/blood-sampling-mouse) and effective use of genetically altered mice (https://www.nc3rs.org.uk/GAmice). We will also refer to the National Cancer Research Institute guidelines on using animals in cancer research published by Workman et al. 2010 (British Journal of Cancer 102, 1555 – 1577).

For surgery, we will follow the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (https://www.lasa.co.uk/wp-content/uploads/2018/05/Aseptic-Surgery.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date with the latest developments on refining animal research methods via the NC3Rs website (https://www.nc3rs.org.uk), also complemented by information we obtain from regular newsletters prepared by our animal facility. Animal house staff will ensure that any advances are fully implemented throughout the facility.

119. Neural circuits in health and disease

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Behaviour, Depression, Neural circuits, Neuronal cell types, Opto- and chemogenetics

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to study connections between nerve cells (neurons) using mice under normal healthy conditions and in an animal model of depression. Neurons make connections with each other and our aim is to access these connections between nerve cells in various brain regions that are shown to be altered in depression. These neuronal connections will subsequently be manipulated using state- of-the-art chemo- and optogenetic methods that are modern neuroscience techniques in which genes for chemical- and light-sensitive proteins are introduced into specific types of brain cells in order to monitor and control their activity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The brain is the most complex and least understood organ in the brain. Brain diseases include a wide spectrum of disorders including depression. More than 20 million people in Europe suffer from depressive disorders and overall costs that comprise of both direct costs (including medication and hospitalisation) and indirect costs (that are (i) morbidity costs that include wages lost by people who are suffering from depression and are thus unable to work and (ii) mortality costs that incorporates costs due to lost life-years after premature death) were calculated to nearly 120 billion Euros in 2004 (Sobocki et al., 2006).

Scandalously, over 30 percent of patients are considered to be treatment-resistant (Otte et al., 2016) underpinning the urgent need to develop novel treatment options. Of note, the female:male ratio of patients suffering from major depressive disorder is approximately 2:1 (Albert, 2015). The latter stresses the need to perform basic and translational research taking the gender into account (Schiebinger, 2014).

In order to develop novel treatments, it is further important to better understand the role of various peculiar subtypes of neurons including excitatory pyramidal neurons and inhibitory GABAergic interneurons in both health and disease.

With this work we will gain (1) insight into the neuronal connectivity between different brain regions known to be involved in depression, and (2) how these connections are altered during depression in a gender-specific fashion.

This will not only lead to additional information on how neurons communicate with each other, but also on the mechanisms of depression that will be useful for other researchers working on depression. Our findings might provide an avenue of developing new targets for treating this devastating disease.

What outputs do you think you will see at the end of this project?

The major output of this project will be new information on the mechanism of how depressive-like behaviour emerges and a better understanding of the brain areas and neuronal cell types being involved.

Findings will be published in academic journals and presented on conferences to disseminate our research results. The data will be made available in public databases to increase accessibility and reproducibility.

Who or what will benefit from these outputs, and how?

This work will contribute to generating novel knowledge on the structure and function of the healthy brain and how neuronal networks are changed in models of depression.

Although a new treatment might not be the direct result of this study we will provide valuable information that can be used to guide the development of new treatments long-term and help patients suffering from depression in the future.

How will you look to maximise the outputs of this work?

We will disseminate our findings by presenting them at national and international conferences and by publishing scientific research articles. We aim to publish the data in open-access journals, which has been shown to widen the audience.

We will also report negative results and try to explain why these experiments may have failed as it is generally agreed on that other scientists can still learn from negative results studies.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mouse models. The primary reason for using mice is the ease of genetic manipulation of this species and the ability to obtain relevant mouse models from appropriate repositories. In addition, there is an extensive literature using this species to investigate underlying causes of neurological and psychiatric disorders. The use of genetically altered animals (GAAs) allows us to study cell-type diversity and the role of specific cell types in neural circuits in health and disease. There are currently no feasible alternatives that would replace GAAs in order to perform these investigations.

Typically, what will be done to an animal used in your project?

Some mice will be exposed to a depression-inducing protocol known as maternal separation with early weaning. Mice of this group, and also of an age-matched control group, will undergo surgery to inject viruses into specific areas of the brain. Injected mice recover well from the surgery. Subsequently, mice be tested for depressive-like and reward-seeking behaviour in behavioural tests such as the sucrose preference test, the splash test or the open field test.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice might experience pain after surgery. They will be closely monitored. To minimize adverse effects local analgesics will be given perioperatively.

The depression protocol might have adverse effects, both during maternal separation, and following weaning. Possible adverse effects that may be encountered during maternal separation include hypothermia, and rejection by the mother upon return to the home cage. To avoid hypothermia, mice are isolated in a cage on top of a heat mat and provided with plenty of bedding. To avoid rejection by the mother, mice are handled with gloves to mask experimenter odour and rubbed with bedding from the home cage to re-familiarise them to the mother. The main adverse effect that may be encountered in mice exposed to maternal separation is that they might not gain weight as they would otherwise. To ensure that pups are strong enough to undergo the separation, litters of no more than 8 pups will be used. Litters will be provided with baby food from the last two days of maternal separation till a week after weaning. Littermates will be kept together for first week of weaning to allow them to share body heat and keep each other warm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Stereotactic surgery: moderate

Maternal separation: moderate

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Brain connectivity and the effect of stress on brain development needs to be studied in a living animal. There are currently no in-vitro alternatives to study these objectives.

Which non-animal alternatives did you consider for use in this project?

We are constantly reading the relevant scientific literature to look for relevant alternatives and also check relevant databases. At the current state of knowledge, the most promising technology is in vitro brain organoids. These are groups of cultured neurons that can be encouraged to develop into the rough organisational formation of a brain in a Petri dish. However, this technology is currently very primitive, and while we hope to utilise this in the future, this currently does not recreate the level of organisational complexity required to reproduce and study psychiatric symptoms such as depression.

Why were they not suitable?

The human brain contains nearly 100 billion nerve cells and even in small animals the central nervous system is comprised of millions of neurons that are precisely wired together. Proper neuronal wiring is achieved during development under optimal conditions that involves coordinated steps from neuronal growth to accurate matching of neural connections. To date, mimicking these conditions in a dish has not been accomplished making it difficult to study neuronal circuits both under normal conditions, but also in disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated, with the help of the institutional biostatistician, based on statistics from preliminary experiments, statistics from our own published and similar works, and experience from the previous PPL.

A maximum 500 animals will be used over the two-year application. They will be bred under Protocol 1 and then either be kept for replacement breeders or move to other protocols within the licence for use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have performed power calculations based on data previously generated in our lab, which gives an indication of the potential effect size between control and test groups. The numbers included in this application are the minimum numbers required to reach statistical significance for each experimental group, and as such the minimum numbers required to detect an effect.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Taking our experience from the previous project into account we consider efficient and well-planned breeding as a crucial measure to optimize and reduce the number of animals in this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using the maternal separation model of depression. Separating mice from their mothers from day 6 until day 16 for 6 hours a day into individually isolated compartments with early weaning at day 17 cause stress and has been shown to result in a depressive phenotype. After weaning mice will be group housed where possible to reduce further harm and they will only briefly be separated for tests that need the mouse to be single housed such as sucrose preference testing. During this time mice will have nesting material and a little house in their cage at all times to minimize distress to the animals.

Why can't you use animals that are less sentient?

It is not possible to study higher integrated processes such neuronal information processing using cell- based assays, or simple model organisms (e.g. yeast) that lack the required neuronal pathways to allow a detailed understanding that can be translated to human physiology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice exposed to maternal separation are at risk of hypothermia during maternal separation, and being rejected by the mother upon return to the home cage. Additionally, they might not gain enough weight to thrive after early weaning. To avoid these possible adverse effects during maternal separation, pups are kept in a cage with a heat mat and lots of bedding, and are handled with gloves and rubbed with home cage bedding upon returning to the home cage. To ensure the pups thrive following weaning, litters of no more than 8 pups will be used. Litters will be provided with baby food from the last two days of maternal separation till a week after weaning. Littermates will be kept together for first week of weaning to allow them to share body heat and keep each other warm.

All animals in recovery experiments may experience some post-operative pain or discomfort because of surgery. Animals will be monitored on showing signs of adverse effects, like their coat state and how they are behaving. We will use post-operative analgesia to reduce surgical post-operative discomfort.

Health condition including body weight, spontaneous movement, head/face swelling, and appearance will be monitored and scored in the first several days after surgery, and

treatment interventions (such as analgesia or food/heat support) and/or humane endpoints will be applied as per conditions in the licence.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the appropriate websites such as NC3Rs refinements, NORINA, relevant literature and breeding information.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will receive email newsletters from the 3Rs websites and we will discuss these issues with colleagues regularly to stay informed. We will also receive relevant information from our NIO and regularly liaise with NACWO and NVS.

120. Tau pathology in alzheimer's disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Tau tangles, Selective cellular vulnerability, Genetic modifiers and risk factors, Clearance pathways, Alzheimers disease

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged
Rats	embryo, adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify why tangles form and dementia occurs, and how to prevent or treat it.

Dementia caused by clumps of the protein tau is seen in several dementias including Alzheimer's disease (AD) and FrontoTemporal Lobe Dementia (FTD-tau). The tau clumps have been termed Neurofibrillary Tangles ('tangles') by pathologists. Tangles are therefore a significant contributor to neurodegenerative disease and dementia. The overarching aim of my research programme is to understand the mechanisms that cause tangles to form, especially in AD and FTD-tau, focusing on mechanisms involved in what goes wrong in the brain, why there are so many different diseases that have tangles as the root cause, and the impact of tangles on brain function, including the type of memory and learning

problems ('cognitive impairment') that we associate with dementia. All aspects of the work are attuned to the potential for therapeutic targeting and intervention. Our work aims to identify how the genetic make-up of the mouse (in parallel with studies on humans) influences whether you will get tangles and dementia, and how severely; mechanisms driving the formation of tangles and dementia and potential therapeutic interventions; why certain brain cells are more vulnerable than others to the harmful effects of tangles. It is hoped that deeper understanding in these research areas will drive the development of therapeutics for people living with dementia.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tangles form in the vast majority of people who have dementia as they are a major factor causing both Alzheimer's disease (AD) and frontotemporal lobe dementia (FTD-tau), and more than 20 other diseases or syndromes that present with dementia. AD accounts for 60-80% of all dementias and FTD- tau accounts for approximately 50% of all FTD cases which in turn accounts for 10-20% of all dementias. Tangles are also seen in patients with traumatic brain injury and following certain microbial infections. Alzheimer’s disease is characterised by the accumulation of two types of proteins - tangles made of tau and also plaques made of a protein called amyloid. Although amyloid seems to occur first and drive tangle formation, loss of neurons and memory decline is linked to tangles forming. Over the past decade, it has emerged that after tangles first form, the tau protein that causes them spreads across the brain from neuron to neuron, causing worsening of the dementia that accompanies it. As part of my new research programme and using a series of sophisticated methods, I hope to find ways in which to stop tau accumulating in tangles and spreading across the brain and thereby prevent or slow disease development in people.

What outputs do you think you will see at the end of this project?

This project will result in new data for the science community to use, publications, presentations and possibly new drug therapies to combat dementia.

Who or what will benefit from these outputs, and how?

People with dementia, especially those caused by Alzheimer's disease or Frontotemporal dementia (FTD-tau) will benefit from these outputs. The research proposed aims to identify what causes these diseases by focusing on one of the causative proteins, tau, which can accumulate in brain cells and kill them. Our research aims to identify why the toxic protein tau accumulates in the brain, how it injures and kills brain cells and how this leads to the memory loss and ultimate death of people with this diseases. We also aim to test whether we can treat the disease in mice that have engineered to develop the diseases. Outputs

such as presented or published data will be beneficial to the scientific community in the short term; therapies or new targets are not expected to be fully realised until completion of the project.

How will you look to maximise the outputs of this work?

My lab has a long history of collaboration to accelerate and streamline research and through rapid dissemination of new knowledge through presentation and publication and through the provision of resources (eg. intellectual knowledge, lab resources) to others. This includes the deposition of new mouse models to repositories such as Jackson Labs.

Species and numbers of animals expected to be used

- Mice: 30,000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use rodents for the research, especially genetically altered rodents that mimic Alzheimer's disease and FTD-tau. New developments in the field have generated good models of dementia that can be used to test hypotheses as to why people get dementia, and ultimately to test therapies. There are no suitable alternative animal models for the disease that reproduce dementia. We will examine rodents at young and old life stages to ensure we reproduce the life stages relevant to dementia.

Typically, what will be done to an animal used in your project?

Many of the mice on this licence will be used for breeding. This will allow us to achieve aim to understand how particular genes cause neurodegenerative diseases. Several steps of breeding are required to get to a cohort with the necessary combination of genes that can be studied.

In order to understand specific pathways implicated in tau pathology and the aetiology of Alzheimer's Disease, some animals will undergo short (5 min-maximum 1 h) procedures where either expression of specific genes and/or proteins will be altered or certain substances that will modulate synaptic and/or cellular function will be applied at appropriate life stages of the animal. These procedures may be minimally invasive (eg. dosing of drugs via injection or oral gavage to test how interventions achieve our aims to identify disease causing mechanisms, or possible treatment) or more invasive (eg. intracranial injection to directly measure brain functionality). Tissues may then be harvested from the animal at a designated point of pathology development.

Animals may additionally or alternatively undergo surgeries to implant cranial apparatus permitting in- vivo brain imaging, or direct stimulation of specific brain regions. This will allow us to measure brain function and test whether normal brain function can be rescued. Anaesthesia and analgesics will be given as appropriate to the procedure, and careful monitoring and humane endpoints will be applied to all animals. The maximum number of cranial surgeries experienced by an animal within its lifetime is limited to 3 procedures.

A subset of mice will undergo a combination of phenotyping and/or behavioural tests to characterise preclinical models and for hypothesis testing. This is important as the diseases we are studying cause dementia and severe behavioural problems therefore we need to be able monitor cognitive performance in the mice.

At the end of an experiment, typically animals are deeply anaesthetised and a terminal bleed or perfusion carried out.

What are the expected impacts and/or adverse effects for the animals during your project?

Genetic alterations in the mice used in this project may lead to the development of dementia-relevant phenotypes. In mice, these changes may lead to effects such as: abnormal behaviour including increased aggression/fighting activity, mild motor impairment, seizure-like activity, or decreased food intake leading to weight loss or altered response to some procedures.

For most animals, the duration of these effects will be limited. Animals displaying moderate severity of their phenotype that is detrimental to their welfare such as seizure behaviours, weight loss, or significantly abnormal behaviour, will typically be used for an experiment within 1-2 weeks of onset of these moderate effects, or sooner if so advised in consultation with the NACWO and NVS. Where animals show a milder phenotype that causes little impairment to their well-being, the duration of these mild effects may be prolonged (eg. 6 months - 1 year). Care will be taken to use animals at the soonest timepoint where the desired phenotype is expressed, to limit the duration of any suffering.

For some tests, mice will need to undergo anaesthesia. All surgery and anaesthetic use in mice carry a risk of mortality and a risk of pain (short and long term), which may differ between genetically altered lines. Appropriate analgesia will be applied to all animals undergoing surgical procedures (or other non-surgical, painful procedures) to minimise any acute suffering.

Mice undergoing cognitive testing using a food reward for motivation will have reduced access to food to reduce their body weight by ~10% from their free feeding weight. Studies have shown that in some mouse models that are genetically modified to have dementia-causing disease, food restriction increases survival, consistent with data for C57BL/6 mice in general. Thus, we do not anticipate adverse welfare outcomes associated with food restriction. To improve the validity of our results we will monitor long-term effects of food

restriction by assessment of blood glucose before and after food restriction and body mass composition.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 5% of animals may experience 'non-recovery' severity, as they will only be subject to procedures under terminal anaesthesia. This is limited to wild-type animals undergoing terminal cardiac perfusion. They will therefore be returned under a 'non-recovery' category.

A further 20-30% of animals will experience only sub-threshold severity, as their genetic alterations will not cause any adverse phenotype.

Approximately 25% of animals may experience mild severity, either through the severity of the phenotype caused by their genetic alteration, or due to the nature of the procedures applied to them (such as non-invasive injections of non-harmful substances).

The remaining 40% of animals may experience moderate severity. These animals will typically be those entered onto protocols involving a surgical procedure, or may be animals that have been bred to exhibit a moderate phenotype and display adverse effects such as seizure behaviours, abnormal behaviour, or decreased body weight.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Alzheimer's disease and FTD-tau afflict a very large number of people, especially the elderly, and they manifest as dementia. While some research in this field can, and will be done on cell models, ultimately the only way to test whether we have really understood what causes dementia, and how we should treat it will need experiments to be performed in animals as they have a complex brain that can replicate the memory aspects of humans. For example, people in the earliest stages of Alzheimer's disease get lost easily, even in familiar environments. They have problems with spatial navigation.

Using mice that have been genetically altered to develop Alzheimer's disease, and sophisticated within-brain recording and behaviour testing techniques, we are working on identifying particular cell populations in the brain that are responsible for the problems in spatial navigation. We are also working on rescuing the deficits in brain circuitry that are linked to these problems in a way that could be impactful for AD patients. These experiments would not be possible in humans, or animals with less complex brains.

The primary objectives of this project are to:

- Link molecular and cellular changes of dementia-causing diseases to dementia-relevant phenotypes (including changes to cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole-body physiology).

- Understand how environmental changes and pharmacological interventions can modulate dementia- relevant phenotypes. It would be unethical (and not possible) to test humans with dementia with interventions that have not been approved by regulatory agencies.

It is not possible to manipulate the molecular and cellular pathways in people who have dementia in order to determine how these processes impact cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole-body physiology. Thus, an animal model must be used. We need to use an animal model to manipulate pathways and we cannot observe humans directly as we need to begin before obvious symptoms manifest, and throughout the course of the disease, taking many different measurements (some invasive) to see how they relate to each other. The wider research community is undertaking significant work analysing clinical and human post-mortem datasets from people who had dementia-causing diseases, but these only give a 'snap-shot' of what is happening in the brain, and it is usually only performed post-mortem, reflecting the very end stage of disease. We also perform preclinical work in cell, organoid and invertebrate model systems of dementia-causing diseases.

However, to fully understand all the factors causing dementia we need to use well defined and reproducible animal models, and manipulate specific factors associated with the disease to tease apart how they interact with the complex environment of the brain.

This project will link with and draw on these experiments to minimise animal use and maximise translational value of the preclinical mouse work in this project. The work in this project cannot be addressed elsewhere using alternative approaches.

Which non-animal alternatives did you consider for use in this project?

Clinical longitudinal studies of people who have dementia (biomarkers including blood, CSF and neuroimaging), genetic and cognitive/behavioural/clinical scoring.

Human post-mortem and brain biopsy studies.

Induced pluripotent stem cells (iPSCs) and direct conversion induced neurons from human patient fibroblasts, brain organoids, transfected HEK cells

Computational models

Why were they not suitable?

Clinical longitudinal studies of people who have dementia, provide correlative data between an individual's genetics, environment, biomarker (blood or cerebrospinal fluid biochemistry, or brain imaging data) and cognitive and behavioural outcomes. These datasets can be used to generate hypotheses of the molecular and cellular causes of dementia-associated biology but cannot be used to test how specific factors influence dementia outcome. For example, we cannot look at people pre- clinically (before symptoms of disease) and monitor the disease as it starts and progresses. We cannot genetically manipulate people and see how different genes impact disease. We cannot administer different pharmacological or neuromodulation interventions that are not approved for human use, and test which work, and how. We cannot record how well individual cells and brain circuits are functioning while the person is alive.

Human post-mortem and brain biopsy studies comparing people who had dementia (early and late in disease course) with people who did not have dementia, can be used to determine which cellular and molecular changes occurred in the brain. In some cases (especially AD which is more prevalent, but not FTD which is a relatively rare disease), clinical and biomarker data from life will also be available for these individuals and this observational data can be used to hypothesise which cellular and molecular changes resulted in clinical disease. However, these samples cannot be used to directly test hypotheses, and work out which hypothesis is correct without testing in animal models. For example we cannot tell whether neurones or immune cells are responsible for dementia, or which cellular pathway causes degeneration, and whether that is responsible for dementia.

Similarly, iPSCs and brain organoids cannot currently be used to study cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole body physiology.

In addition to non-animal models, we also considered using invertebrate models of disease. Invertebrate (fly) models can be used to study the response of neurons to some cellular pathways, for example, the proteins that misfold and aggregate in dementia-causing diseases. However, flies do not have complex brains capable of sophisticated behavioural and cognitive abilities, thus it is not possible to study how the cellular and molecular processes that result from an event such as protein misfolding impact the brain cell populations and circuitry leading to the executive function or subtypes of memory that go awry in dementia. For example, it is not possible to quantify working memory, motivation or apathy in a fly. Flies also lack key brain-resident immune cells (microglia) and a closed circulatory system (veins and arteries), which play key roles in the development of neurodegenerative disease.

These aspects, and many others involved in the biology of dementia cannot be modelled in flies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The programme leader has more than 25 years of experience with AD or FTD-relevant mouse models and has published more than 70 papers describing experiments in mice similar to those proposed here.

Current estimates are based on our prior knowledge of the fecundity and attrition, timing and robustness of disease characteristics and variability seen in the type of mouse models proposed. Factors driving the speed at which pathology develops include transgene expression levels. Variability is impacted by genetic background. Based on pilot and

published date, we estimate that we will need a sample size of 10 per sex and genotype for each phenotyping experiment.

In view of the total number of animals used under in previous animal projects, the new plan of work and expected size of my team (10-15 researchers), we estimate that we will require approximately 10,000 mice for transgenic breeding, maintenance of colonies, and animals subject to no procedural interventions where post-mortem tissue is used in experiments. It is estimated that multiple rounds of breeding may be required to generate animals carrying multiple genetic alterations for experiments, and we anticipate providing other researchers with cohorts of mice matched to those studied for collaborative phenotyping projects

We estimate that approximately 1000 rats are to be used as pups or embryos for phenotypic analysis at specific stages of developments.

We anticipate that a further 20,000 mice may be entered on to the subsequent phenotyping protocols: current estimates are that we will need a sample size of 10 per sex and genotype for each experiment.

No reuse of animals is planned.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power equation calculator will be used for group size calculations for all experiments plus attrition rate calculation will also be used to ensure sufficient power is maintained until the end of longitudinal studies.

We have additionally used the NC3Rs Experimental Design Assistant within the planning process of our upcoming experiments, to inform our expected cohort numbers and ensure that sufficient power is maintained.

The combination of tests in each experiment will be designed to gather the most meaningful data. Tests which can inform each other will be carried out on the same mouse to remove inter-animal variability and increase the power, thereby decreasing the overall sample size and the scientific utility of generated data. This approach will also provide novel scientific insight into the relationship between dementia-relevant phenotypes and help validate new testing approaches such as home cage assessment.

SOPs have been written and used routinely for previous projects. This standardises the way the data is collected and reduces the variability and therefore the sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have selected to use state-of-the-art animal models that best replicate human dementia so that our data will be valid, relevant and reproducible in the future.

Where possible we have selected models that require the least breeding (genetically homozygous mouse models) to generate sufficient animals for studies, and ones that reproduce the disease in a shortened timespan. Lines will be bred efficiently and holding lines as frozen-down embryos and sperm will be used to minimise the number of mice being produced for these studies.

Before undertaking experiments in animals, we will have performed as much of the work in cell and computational models as possible.

We have coordinated with other researchers to share tissue resources and results so that we will limit the number of animals used as much as possible. Any excess stock will be offered to other researchers to minimise wastage.

Genetically modified lines will be sourced from repositories to avoid remaking of lines whenever possible.

Pilot studies will be undertaken to generate means and standard deviations for work using background strains for which data is not available. Tissues sampled from the animals used in this project will be shared with other researchers and the data produced linked to that generated by the project, to maximise long term utility.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will largely use transgenic or otherwise genetically altered (eg. knock-in, knock-out) models of Alzheimer's disease or fronto-temporal dementia. Additional reporter lines (eg. Cre-ERT2 models, fluorescent protein models) that do not display any adverse phenotype will be interbred with AD mice.

We have selected to use state-of-the-art animal models that best replicate human dementia so that our data will be valid, relevant and reproducible in the future.

All animals models used are ones that reproduce the disease phenotype in as short a timespan as possible to limit the suffering of the animal. Wherever possible, we propose to principally use preclinical models that have a reduced welfare burden and provide a more refined scientific tool.

Why can't you use animals that are less sentient?

Experiments have been designed to use animals that are less sentient as much as possible. For example, we will be able to perform some of the research in brains from mouse embryos.

Where possible, terminal procedures will be performed preferentially to recovery procedures. However, some animals will be required to undergo chronic procedures (eg. repeated procedures of in-vivo brain imaging), or procedures wherein time is then required for pathology to develop or be characterised.

Moreover, we will assess how neuroimmune pathways lead to dementia-relevant diseases (including cognitive and behavioural changes); this will focus on the molecular and cellular biology that underlies these changes to cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole body physiology.

Invertebrate (fly models) can be used to study the response of neurons to the proteins that misfold and aggregate in dementia causing diseases and to screen for genetic modifiers of these processes.

However, they do not have complex behavioural and memory biology or complex neuroimmune system and thus it is not possible to study the cellular and molecular processes that result in altered executive function or subtypes of memory in dementia, as in this project. For example, it is not possible to quantify working memory, motivation or apathy in a fly. The fly cardiovascular system significantly differs from that in mammals (being open without veins or arteries) thus the effect alterations to cardiovascular biology on dementia cannot be readily modelled in a fly. This work needs to be undertaken in an adult model organism with an intact nervous system, blood-brain-barrier and robust immune response without anaesthesia to assess disease-causing pathology in their brains.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experiments will be designed to balance the overall experience of the mouse and the number or type of tests undergone by any one animal against the value of a full understanding of the biology of individual animals and why phenotypes are altered in order to maximise utility of the research data obtained.

Mice undergoing phenotyping tests have increased monitoring (defined per protocol) and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests.

When general anaesthetics are necessary, the combinations with least potential for adverse effects will be used. Mice which have undergone anaesthesia have extra monitoring until fully recovered and extra checks when back in the holding rooms. Peri-operative analgesia will always be provided, and animals will be checked post-operatively by the responsible PIL and the animal facility technicians (see protocols for defined schedules of checking per procedure step). In case of any post-surgical complications, or any unexpected adverse effects, NVS advice will be sought.

For any experiments that may induce stress in the animals, care will be taken to reduce stress through gentle handling, habituation to equipment or behavioural arena, or training according to best-practise guidelines.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from Laboratory Animal Science Association good practice administration of substances guidelines 1998 (http://www.procedureswithcare.org.uk/lasa_administration.pdf).

Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at https://www.mousephenotype.org/impress.

ARRIVE and PREPARE guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We (lab and PI) will attend the NC3R annual conference; we will also attend international meetings focusing on animal models of dementia causing disease and webinars run by the MODEL-AD consortium. In addition we will attend local 3Rs seminars and events, as the NC3Rs liaises closely with the Institute and University.

121. Supply of materials to develop and maintain tests for transmissible spongiform encephalopathies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Testing, Diagnosis, TSEs, Material, Collection

Animals Types	Life Stages
Cattle	juvenile, adult, aged
Sheep	juvenile, adult, aged
Goats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To support diagnosis and eradication of naturally occurring transmissible spongiform encephalopathies (TSEs) in ruminants by ensuring that material is available for test development and validation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

TSEs are notifiable diseases in the UK, which include scrapie in sheep and goats, bovine spongiform encephalopathy (BSE, "mad cow disease") in cattle and chronic wasting disease in deer. The BSE agent is the cause of variant Creutzfeldt-Jakob Disease in humans, which has so far affected more than 170 people in the UK. Eradication of TSEs in farmed animals is a global objective as it impacts on human and animal health and affects trade. There is a legal requirement to monitor susceptible animals for TSEs. Detection of disease relies on reporting of suspect cases or active monitoring of a subset of slaughtered or found dead animals, which then need to be diagnosed and confirmed by postmortem tests. These tests need to be validated, and testing laboratories need to be regularly quality assessed to ensure adequate diagnosis, which requires appropriate testing material. In addition, material may also be required to develop further tests or inform on the level of infectious agent contained within the tissue, which may be important for food safety if the tissue is edible. Furthermore, there is the legal requirement to maintain familiarisation with the clinical presentation to aid in the education of livestock owners. This work aims to fulfil these requirements by either acquiring animals suspected of having naturally occurring TSEs or exposed to naturally occurring TSEs or by experimentally infecting animals if naturally occurring case numbers are too low or not suitable to acquire the necessary material.

What outputs do you think you will see at the end of this project?

The output will be the generation of material needed for TSE test development and validation, for distribution to other diagnostic laboratories for external quality assessment (EQA) so that they can continue providing a diagnostic service, and to address research questions requiring study of th disease in the natural host. Depending on the research questions, this may result in publications or data input into risk assessments. In addition, it may generate training material about the clinical presentation to aid in the reporting of clinical suspects in the field.

Who or what will benefit from these outputs, and how?

It is a legal requirement to carry out TSE surveillance, and all processes in relation to the diagnosis need to adhere to quality standards. TSE tests require validation, and laboratories require regular validation and quality control to be able to carry out surveillance. Training material generated through observation and examination of animals will support passive surveillance. Without surveillance, the United Kingdom will be unable to trade in ruminant livestock and their products with other countries.

TSE studies in the natural host using material from these animals will aid in addressing important policy questions, e.g. assessing distribution of the infectious agent may inform on safety of edible tissues for human consumption and potential spread of the infectious

agent in the environment. This is beneficial to consumers and policy makers to protect human and animal health.

How will you look to maximise the outputs of this work?

Although material generated through this licence is to be used for domestic purposes, various tissues will be archived for future use or research requests from other countries. In the past, tissues have been distributed to various research institutes, which often require positive control tissues.

The output of any research addressing policy question will be beneficial both nationally and internationally, e.g. EU-wide if included in opinions of the European Food Safety Authority working groups.

Species and numbers of animals expected to be used

- Cattle: 22
- Sheep: 250
- Goats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All animals used will be the natural host for these diseases since tests have to be carried out and validated in tissues from the relevant species. Due to the long incubation period, the majority of animals will be adults or reaching adulthood when developing clinical disease if experimentally inoculated or naturally exposed.

Typically, what will be done to an animal used in your project?

Blood will be collected from all animals prior to euthanasia and tissues collected post mortem.

Naturally infected animals will be acquired and transported to the research establishment for clinical examination, which may include additional clinical tests to support the clinical diagnosis or rule out alternative diseases. Due to statutory requirements and restrictions to the source farm it is not expected that clinical suspects will be kept longer than a week.

Animals naturally exposed through contact with infected animals but without clinical disease and confirmation of disease status will be kept for longer to study disease development, which may include examination of a rectal biopsy taken under local anaesthesia to inform on disease status.

Experimentally infected animals will usually be inoculated with TSE brain homogenate under general anaesthesia and analgesia and monitored for disease development, which could take months or years.

What are the expected impacts and/or adverse effects for the animals during your project?

Study end-point is clinical disease, which may include nervousness, over-reactivity to external stimuli, incoordination, difficulty getting up and loss of weight. A scoring system will ensure that animals are culled when they reach clinical end-stage where clinical disease is highly suspicious of a TSE but the welfare of the animals is not severely

affected. For animals that need to be transported, fitness for transport will be confirmed prior to any transport.

For experimental infection, inoculation is performed through the skull into the brain under general anaesthesia, with possible adverse effects being haemorrhage, inflammation and cardiac or respiratory problems, potentially leading to death, although this has not happened in the past and measures are in place to prevent this from happening.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild for all naturally infected clinical suspects (all species) but moderate for the majority of exposed or experimentally infected animals regardless of species since they need to be kept until development of clinical disease unless exposed animals do not develop disease because of older age at exposure or genetic resistance (mild severity for these).

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tests validation and quality control can only be achieved with tissues from the natural host.

The majority of animals are clinical field suspects or exposed on farms with known confirmed TSE cases, which are subject to cull as per legislation.

Experimentally infection is necessary to reproduce natural disease for those disease types where cases of natural disease are too rare or material is limited or unsuitable, for example due to autolysis.

Which non-animal alternatives did you consider for use in this project?

None. There are no suitable non-animal alternatives.

Why were they not suitable?

Cell cultures are not available to replicate prions from various species, and brain is needed for test validation and EQA purposes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on historical material demand and availability of naturally infected or exposed animals; the latter may be from farms that are subject to herd or flock cull as per legislation, which depends on farm size. As scrapie infection in sheep and goats is influenced by genetic predisposition (the prion protein genotype) and other factors, such as age at exposure, which is not usually known, the number of sheep and goats to be used is comparatively large but only a small number (less than 10%) in a flock or herd cull may be infected and able to provide scrapie-positive material.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Material requirements for test validation and EQA are discussed with the relevant stakeholders, including the biological archive manager, to estimate demand.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When possible, archived material will be used or material obtained from animals culled as part of an eradication measure of TSE as notifiable disease or found dead on farms and subsequently confirmed as TSE positive through active TSE monitoring. If experimental infection is required, the intracerebral instead of the oral route will be used to achieve a higher success rate of infection with shorter incubation period and thus reducing the number of animals needed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The natural host, i.e. ruminants, will be used. Most will be naturally infected and must be culled as per legislation, and experimental disease will only be generated for those disease types where naturally occurring cases will not provide adequate material. For experimental infection, intracerebral inoculations will be used as it most closely resembles naturally acquired spontaneous disease and reduces the time period that animals need to be housed indoors.

Why can't you use animals that are less sentient?

Tests have to be validated in the natural host.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All of the TSEs studied are naturally occurring and procedures to monitor animal clinically are well established. Clinical monitoring methods include regular clinical examinations and passive observations, including CCTV monitoring, in addition to daily observations during normal husbandry to determine onset of clinical disease and clinical end-point. Inoculations into the brain are carried out under general anaesthesia and analgesia with material that has been screened for microbial contamination prior to use to minimise post-operative adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance is obtained from NC3Rs, ARRIVE, IAT and the RSPCA. Publications and articles are also reviewed during the approval process prior to each individual study. Where specialist training is required, inter-institutional exchanges and training visits are organised.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment is a signatory to the Concordat on openness on animal research and applies the Culture of Care in animal studies as well as the ARRIVE guidelines. Staff from the Establishment frequently attend or organise external symposia on laboratory animal welfare e.g. RSPCA and IAT meetings. Staff attending these meetings provide meeting feedback reports locally. In addition, the Establishment has a Species Group Care and Use Committee where all personal licensees are invited to attend. Specialist topics are presented and refinements, such as environmental enrichment, are communicated and opportunities are used for implementation. In addition, specialist knowledge exchange is organised by field and lab exchanges with other research organisations.

122. Immunotherapy and vaccine development for cancer and sars-cov-2

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, vaccine, immunotherapy, SARS-CoV-2/COVID-19

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify and validate targets for immunotherapy, develop vaccines and immunotherapy strategies to treat melanoma, breast, lung, ovarian, pancreatic, colorectal and gastric cancers and SARS-CoV-2 and to progress at least two products to clinical testing.

To investigate the influence of microbiota on responses to vaccination/therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer directly affects 1 in 2 of the population during their lifetimes and although significant progress has been made in the last two decades cancer still remains a major cause of mortality and improved therapies are required.

SARS-CoV-2 emerged as an international public health emergency and since first detection has led to 128,000 deaths in the UK. Emerging virus variants result in continued infections and fatalities. Vaccine treatments and therapies are showing promise although the efficacy of these against emerging variant strains remains unclear. It is therefore essential to develop new treatments to prevent and contain this virus. These will benefit the worldwide population to reduce the severity of this disease.

What outputs do you think you will see at the end of this project?

Development of novel immunotherapy products and combinations for cancer treatment and translation of these into clinical studies

Increase in understanding of the effects of immunotherapy on the immune system
Significant data publication in high quality peer reviewed journals

The translation of SARS-CoV-2 vaccine into clinical studies as a booster vaccine against emerging virus variants

Who or what will benefit from these outputs, and how?

In the shorter term, we expect to discover more about immune responses to cancer antigens and how best to harness these for cancer therapy. This will be of interest to both clinicians and research community interested in immunology and tumour immunobiology and will be made available through publication in peer reviewed journals.

The primary expected long term benefit will be the development of new therapies for treatment of melanoma, ovarian, lung, breast, colorectal, gastric and pancreatic cancers that are effective in causing tumour regression and prolonging patient survival.

The world wide population will benefit from SARS-CoV-2 vaccines that can be used as boosters to existing vaccines and help protect against emerging SARS-CoV-2 variants.

How will you look to maximise the outputs of this work?

Outputs will be maximised through ongoing and new collaboration with groups at research institutions, universities and biotech companies.

New knowledge will be formulated into scientific papers published in peer review journals and presented at national and international conferences.

Species and numbers of animals expected to be used

- Mice: 13490
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Currently rodent models are the most widely used models with physiological relevance to humans. Mice and rats aged over 6 weeks are chosen as models of mature immune systems and suitable for study of the interplay between the immune system and tumour growth. Mice genetically modified to express components of the human immune system enable better assessment of vaccines and immunotherapies for translation to human use. Immune deficient mice permit the assessment of immunotherapies using human tumour models or human immune cells in an in vivo setting.

Typically, what will be done to an animal used in your project?

Typical actions:

In this project, mice will be bred to have specific genetic modifications which are not expected to be harmful and will be bred using natural mating and maintained for use in this or other project licences.

The animals in this project may be injected multiple times with the candidate items that will be tested (by one or more of the following routes -subcutaneous, intravenous, intraperitoneal,

intradermal, intramuscular, gene gun, topical, drinking water, or diet) to assess whether the therapeutics are immunogenic.

Implantation of tumour cells subcutaneously or in the mammary fat pad will be performed and immunotherapies tested for prevention of tumour growth using pre-determined dosing strategies.

Luminescent imaging under anaesthesia may occur in some studies on typically up to 4 occasions.

Blood sampling, taken from a superficial vessel, will occur in some studies and an optional sample taken under terminal anaesthesia.

Animals may be transported to labs at the site of secondary availability for S1 killing and tissue harvest.

The typical duration of a study will vary from between 3-12 weeks and beyond, depending on the study design. Animals will be humanely killed at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

It is anticipated that some animals may experience minor transient discomfort during this project resulting from the implantation of tumour cells, administration of substances, in vivo imaging and blood withdrawal. During the tumour growth phase some animals may show signs of skin change over the tumour which will be monitored for up to 7 days with recovery. This will cause the animal moderate discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The techniques that may be used under this protocol are not expected to result in an animal experiencing clinical symptoms beyond mild to moderate transient discomfort.

Expected severities for mice in on breeding program is subthreshold. Mice on other protocols are expected to be 90% mild and 10% moderate.

Expected severities for rats are 97-98% mild and 2-3% moderate.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vitro assays cannot adequately model the complete array of events involved in tumour growth, or the generation of an immune response, both of which are essential to our understanding of tumour immunology and anti-viral responses. In vivo studies using rodent models are therefore crucial.

Which non-animal alternatives did you consider for use in this project?

Whenever possible, a variety of in silico and in vitro experimental techniques to identify potential immunogenic peptides/proteins will be used to minimise animal use prior to in vivo studies.

Why were they not suitable?

The in silico and in vitro models fail to truly represent the complexity of the immune system and the establishment of immune responses. In vitro tumour culture fails to truly mimic the

in vivo growth of a tumour and does not efficiently replicate the complex tumour environment that is established in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals have been estimated based on previous usage and expected usage based on progress using our experimental therapies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Studies will be designed to use the minimum number of animals required for statistical significance.

We will ensure that we use the minimum number of animals required to answer the scientific question by performing power calculation studies. We will consult qualified statisticians about experimental design and statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All experiments using live animals will adhere to the ARRIVE guidelines on design and reporting. Good principles of experimental design will be applied to ensure sufficient group sizes will be used to adequately test the hypothesis. Sample sizes are estimated from pilot studies and previous data using power analysis

Breeding will be performed to reduce any surplus mice and both sexes will be used in studies. Consideration may be given to the use of ex-breeders for the use of tissue collection and analysis.

Candidate vaccines will be designed and assessed for their suitability with the use of in silico and in vitro techniques before the possibility of moving into an animal setting.

Mice with multiple rather than single relevant genetic modifications will be used whenever possible.

Tumour cell lines will be maintained in vitro and stored frozen to negate the need to use additional animals for maintenance in vivo.

Pilot tumour growth studies will be performed where appropriate to establish tumour growth prior to use in therapy studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered mice of a non harmful phenotype will be bred and maintained.

All cells prior to implantation are prepared in a sterile environment and are administered using sterile techniques and the lowest volume of cells.

Substances are prepared and administered using sterile technique. The route of administration is via the least invasive method appropriate to the model. The volume of substances to be used will be in accordance with the Laboratory Animal Science Association (LASA) good practice guidelines.

The assessment of tumour development will be performed using an appropriate measuring device.

The delivery of some therapies will be assessed using the in vivo imager which will require transient anaesthesia to immobilise them while an image is acquired. Once completed, the animals are expected to make a full recovery within 30 minutes.

Blood sampling will be performed using sterile techniques and the volumes collected will be in accordance with the LASA / NC3Rs guidelines. We will aim to take the smallest volume which will allow for adequate analysis.

All animals will be humanely killed by a Schedule 1 method.

Why can’t you use animals that are less sentient?

To efficiently assess the proposed project animals need to have a fully functional mature immune system. Animals younger than 6weeks old or at an early gestational stage of life are not sufficient to model a fully functional immune system. Mice and rats are the lowest sentient organisms appropriate to use to model the interplay of the immune system and tumour development.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The route, volume and frequency of the administration of substances is reviewed and selected in order to ensure the scientific question can be answered with the least impact on the welfare of the animal.

Where a procedure has an unexpected impact on the welfare of animal the frequency of monitoring clinical signs, bodyweight and/or tumour development will be increased.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines published by the Workman Group on welfare and use of animals in cancer research published in 2010, The ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments) and LASA Good Practice Guidelines.

I will also take note of publications relating to improving the reproducibility of animal research such as Frommlet, F. Improving reproducibility in animal research. Sci Rep 10, 19239 (2020). https://doi.org/10.1038/s41598-020-76398-3.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will maintain close interactions with the NACWO, NTCO and NIO as they oversee and perform in vivo studies. The PPL holder will stay informed of advances in the 3Rs by regularly checking the NC3Rs webpages (https://nc3rs.org.uk/the-3rs) and the newsletters which are circulated monthly by the NIO.

Moreover, the PPL holder will attend appropriate seminars, symposiums and conferences deemed suitable.

123. Studying host interactions in tumour and metastasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, microenvironment, metastasis, immune cells, inflammation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This Project licence aims to support the work of the laboratory in performing mechanistic studies on the interaction between tumour cells and the healthy host tissue cells. We have a particular interest in the relationship between tumour and inflammation and its relation with the rest of the cellular environment of cancer cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One out of two people will get cancer in their lifetime, making cancer one of the most common diseases. Over the last 40 years, cancer survival has doubled largely thanks to better treatments but despite this more than 1 in 4 deaths in the UK is still caused by cancer. The fundamental understanding of cancer complexity is instrumental for the development of new and refined therapies. The studies on the synergistic cooperation

between tumour cells and the host tissue cells holds the potential for novel and more effective anti-cancer therapies. Indeed, the interaction of cancer cells with their microenvironment is implicated in every aspect of tumourigenesis, from onset to metastasis as well as in resistance to chemotherapy. Understanding the inflammatory component of the microenvironment is of particular interest for the enhancement of efficacy of host-dependent anti-cancer treatment like immunotherapy.

However, this complex physiology needs to be addressed within an mammalian system. Mice have a comparable physiology and the tumour disease trigger the same cascade of events as in humans. In particular, the human immune-system's reactions to cancer are highly recapitulated in mice, which are fundamental part of any therapeutic intervention and an essential focus of our work.

What outputs do you think you will see at the end of this project?

The expected benefits of the work will be mechanistic understanding in the immediate future and therapeutic benefit in the longer period. They can be summarized as follows:

1. To assist in the design of future anti-cancer therapies. We aim to discover novel molecules and proteins involved in the tumour microenvironment that can be efficiently targeted to weaken tumours making them more sensitive to standard therapies and reduce the risks of recurrence.

2. We aim to understand the impact of environment and lifestyle (for example; diet, inflammatory reaction, microbiota) on the tumour microenvironment and the impact on spread (metastasis) and cancer cell reactivation (dormancy). This will help the management of cancer patients and potentially help identify patients at higher risk of recurrence.

3. By studying the involvement of certain inflammatory components and systemic signals in cancer, we aim to clarify the mechanism of disseminated dormant cancer cell re-activation.

4. We also aim to better understand novel relation between cells of the tumour microenvironment and particularly the relation between the nervous system, inflammation, and cancer initiation.

5. Finally, this work will benefit the basic research community by increasing our knowledge of tumour biology.

Who or what will benefit from these outputs, and how?

The output of this work will initially be mechanistic information on cancer progression, identifying new potential drug targets, which will be used by the pharmaceutical industry to guide future potential treatments. The work will also provide valuable information to guide

doctors in the clinic for the management of cancer patients with disease that may have spread to other sites in the body.

The short-term benefit will include presenting at scientific conferences and supporting other in vitro findings followed up with the publication of novel discoveries in international scientific journals. In the mid and long term the benefit will reach the pharmaceutical industry and clinicians, resulting in improvement of care for patients.

How will you look to maximise the outputs of this work?

We will look to maximise the outputs of any significant findings through interactions with the scientific community through presenting at seminars and conferences. We also aim, where possible, to present unsuccessful data to prevent repetition by other labs. We also work alongside the Translation team who support collaborations with industrial and clinical partners that would reduce the bench-to-bedside time and enable possible changes in clinical practice (use of new drugs/screening tools) to be trialled sooner.

Species and numbers of animals expected to be used

- Mice: 45000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

My area of research is cancer; therefore, mice are for me the species of choice.

The reasons why mice are the best choice as cancer experimental models, can be summarized as follows:

- the physiology of cancer in mice is consistent with the human disease,

- The genome of a mouse is easy to modify allowing the study of particular genes in the cancer process. Mice can also be modified to be genetically prone to cancer (spontaneous genetically engineered mouse models) and this can allow a less experimentally engineered approach to studying the development and spread of cancer.

- In mice, there are many models that are commercially available, as well as well-defined techniques for production. There are also many scientific tools like genomic libraries, antibodies etc that are largely available.•

In most cases where tumours will be induced, adult mice will be used, but there will be instances where juvenile animals may be used, for example; in order to pre-condition with dietary changes.

Typically, what will be done to an animal used in your project?

Typically, animals will develop tumours (either spontaneously through genetic modification or through transplantation of tumour cells by injection methods). In some cases, we will transplant tracer cancer cells (created by our lab) that can label the cells neighbouring the tumour, therefore tissue will be collected to allow further analysis.

Treatments (chemo/radiotherapy) could be employed in this setting. Drugs or antibodies will be used to study the roles of different host cell types on the tumour disease, generally by depleting or boosting them and looking at how the tumour develops, spreads and responds to treatments such as chemo or radiotherapy.

As we are interested in how environmental changes also impact cancer progression, we may use other interventions, such as; changes to the diet, infections with respiratory viruses, changes in gut bacteria (using antibiotic treatments). These interventions will have impacts on the host and we are interested as to how the changes caused by these will impact on the tumour and it's response to therapy.

The animals might have their disease monitored over time using non-invasive imaging techniques, particularly if they have internal disease. The duration of the experiments will vary depending on the model and will consider many features of the disease specific to the experiment, including the nature of the cancer cells, if transplanted (slow or fast growing, local disease or prone to spread) or the known timeframes in genetically engineered mice that form spontaneous tumours. We always aim to maintain duration of experiments to the minimum required to address the scientific need.

What are the expected impacts and/or adverse effects for the animals during your project?

In most cases animals used in this license will form tumours. The size and impact of these tumours on the animal will differ due to model and method. For example, poorly aggressive tumour cells might grow well within the transplantation site but spreading to other areas of the body is poor and therefore the impact on the animal is low. However, with a more aggressive line tumours may spread early meaning that even though growth at the transplant site is not particularly high, the impact on the animal due to spreading to other areas of the body may produce more suffering for the animal.

We have much knowledge and experience of all the models that we use, both transplantation and spontaneous and are able to predict well the time frame over which the animals will not show adverse effects. The use of certain interventions can make this slightly less predictable, but the animals are monitored closely in this case to minimise any suffering and we aim to terminate experiments before the onset of undesirable adverse effects. Undesirable affects could be limited to the locality of the tumour (for example- ulceration) or be general signs of poor health, such as; weight loss, piloerection, hunching, increase breathing rate (especially when tumours have spread to the lungs).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities predicted by this proposal are both mild and moderate.

For those protocols that involve tumour growth it is expected that a greater proportion (50%) will reach a moderate severity, due to repeated procedures, tumour burden or possible surgery.

When working with animal models it is essential to minimise any possible adverse effects of the experimental procedure. We closely monitor the animal's reaction to specific experimental procedures and pay attention to any sign of suffering that may occur. Cancer is a complex disease, however the knowledge of all the tumour models used will allow a good prediction of the time frame of the disease progression. Therefore, mice will be likely killed on the basis of a time period rather than based on their clinical signs. An experimental end point (time controlled) will most likely occur before a humane endpoint (as determined by deterioration of heath conditions) and result in only mild suffering for the animal.

When performing our metastatic studies, it will not be an experimental requirement for animals to reach a late stage of disease, but metastatic progression must occur. We will pay particular attention to mouse behaviour and monitoring specific to the organ targeted by the disease, and will in most cases, aim to terminate experiments before obvious signs of health deterioration appear. For example, in cases where tumours spread to the lungs, particular attention will be paid to the breathing behaviour of the mice both in resting condition and after a small physical challenge, however, some mice can drop in condition very quickly without many prior signs and may show more of a moderate suffering.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In contrast to other tumour studies, here, a tumour is analysed in the context of its local tissue environment, as well as within the scope of the systemic changes induced in the

host organism affected by the disease. Therefore, these studies must mainly be performed within the animal as the complexity of these changes and the number of players involved cannot be modelled in the laboratory.

Which non-animal alternatives did you consider for use in this project?

Targeted lab-based assays using 3D scaffolds and organoid cultures will be designed accordingly with the gained information used to reduce mouse workload. For instance, in order to assess specific interactions between tumour cells and certain components of the microenvironment or of the immune system. This approach will also have the advantage of identifying the impact of these components on each other in a “clean” system where all the players are known and better controlled.

Why were they not suitable?

Even the most sophisticated lab-based model systems cannot convey the complexity of the tumour microenvironment or the impact that tumour disease can have systemically on an animal. In order to investigate the impact of infiltrating cell types alongside both the local and systemic response of tumour we can only do this within the complexity of the animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used have been estimated on the basis of the previous 10 years of work of my lab and the current landscape of projects of the lab going forward.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We employ several strategies to try to limit the number of mice in the study:

- Firstly, we will always aim to maximise the amount of data we get from each mouse and when possible, we will use it for the study of both primary tumour and metastasis.
- Also, we will limit the use of genetic models (that often require many generations breeding) using orthotopic transplants of labelled cells and treating the mice with chemical agents either to block immune-system components or to generate tumours.

- We also use the minimal number of mice needed for statistical significance when testing the experimental hypothesis based upon pilot experiments to inform on numbers required. We can always relay on our in house statistician for any additional advise whenever we need.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever possible, we will share animal tissue from experiments to enable multiple studies-ex vivo.

We are committed to improving education and training for those working under this project license.

We breed many of the genetically altered animals ourselves in order to promptly and, often transitory, adapt colony sizes to respond to the experimental need and reduce wastage from overbreeding.

We also take lead from HO efficient breeding of GA animals (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773 553/GAA_Framework_Oct_18.pdf) and take decisions to archive lines by cryopreservation when not required over a period of time.

Obtaining wildtype mice from in house facility-shared breeding allows better efficiency for larger colonies.

We we also always run pilot study to estimate the effect size and the directions for future experimental settings.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use spontaneous genetically engineered models of cancer alongside more controlled experimental models of inducing cancer, including transplantation techniques. Our work at present is mainly focussed on breast cancer and pancreatic cancer but it is not limited to this. We minimise the use of surgical methods, wherever possible, by

employing ultrasound guided injection techniques which drastically reduces the suffering experiences by the animals.

Why can't you use animals that are less sentient?

Other animals that are suitable for these types of studies lack the organ and physiological complexity needed for translation to humans. This complexity needs to be recapitulated to make the investigation of tumour microenvironment possible. The requirement here is to have a physiology which is as close as possible to humans, and only mammalian organism have the same complex immune system, hormonal infrastructure and basic metabolism as humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have access to cutting edge techniques and experts within various fields of medical research. We actively share refinement and improvements in techniques and seek to constantly improve our models to ensure that we are minimising any harms to the animals, as this also helps to improve the accuracy of our study and reduce artefacts caused by stress. For example; the use of imaging guided techniques to reduce surgery as a means of transplanting cancer cells to internal sites. We also follow local NVS policy on post-operative care and pain management to minimise any harms to the animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Unless otherwise specified, the work in this project will be designed using the principle outlined in PREPARE guidelines for planning animal research and testing (2017) and in the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.

With regards to cancer models we take advice from the "Guidelines for the welfare and use of animals in cancer research".(Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Guidelines for the welfare and use of animals in cancer research. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642. PMID: 20502460)

LASA Guidelines will be followed for Administration of substances.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly receive updates on advances in the 3Rs from within our establishment from NC3Rs and NORECOPA. Where we are placed to refine techniques without impacting the scientific validity of our work we aim to implement advances.

124. Developing treatments for huntington's disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Huntington's disease, Neurodegeneration, Therapy

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This projects aims (1) to understand the first steps in the process by which the faulty gene in Huntington's disease causes brain cells to become dysfunctional and die and (2) to test treatments designed to correct these early stages of the disease process. It is by targeting these first steps that we might develop the most effective medicines to delay or slow down the course of the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

HD is a devastating disease of the nervous system. On average, symptoms start at around 40 years of age, but this can vary widely from early childhood to very old age. Affected individuals develop psychiatric illnesses, an inability to control their movements, difficulty in

reasoning and solving problems and lose weight. In the latter stages, HD patients are often bedridden and unable to talk or swallow (being fed via a feeding tube). The disease progresses for 15-20 years until death. Children of affected individuals have a 50% chance of inheriting the faulty gene and have often witnessed the effects of this devastating disease in their relatives. There are no treatments that will delay or slow down the course of the disease and most of the symptoms do not have effective medicines.

What outputs do you think you will see at the end of this project?

1. An in depth understanding of which of the products of the faulty Huntington's disease (HD) gene are the most damaging to brain cells.

2. A detailed characterization of the effects of the faulty HD gene in the brains of HD mouse models.

3. A understanding of which treatments are most successful at decreasing the damaging HD gene products and have the most beneficial effects.

Who or what will benefit from these outputs, and how?

The Huntington's disease research community will benefit. We will gain a better understanding of how the faulty HD gene causes brain cells to become dysfunctional. Other researchers will build on this information to further our collective understanding of the disease. These benefits will occur during the course of this project.

Biotechnology companies and pharmaceutical companies will benefit. In order to develop treatments for Huntington's disease, researchers in universities and in industry must work together. Our research into the cause of the disease will help industry decide on which are the best treatment options to follow. We shall use our very detailed knowledge of presymptomatic disease in HD mouse models to collaborate with colleagues from academia, industry and he HD Foundations to test potential therapies in mice. This will help companies determine which are the best treatments to develop as medicines that can be given to people. These benefits will occur during the course of this project.

Huntington's disease patients and families will benefit. We shall target the first stages by which the faulty HD gene causes brain cells to dysfunction. This has the potential to produce the most effective medicines to delay or slow down the disease process. Our collaborative research program will help to decide which are the best approaches to test in clinical trials. The tolerability of such treatments could be tested in HD patients during the course of this project and large-scale clinical trials could be initiated.

How will you look to maximise the outputs of this work?

To accelerate progress, we shall work with collaborative networks of scientists in academia and industry that are coordinated through Huntington's Disease Charitable Foundations. We will share results informally and formally at workshops and conferences.

We will publish completed projects in open access journals (that are free for anyone to read) and share them before publication on an appropriate website.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We cannot learn about the early stages of Huntington's disease in brain cells by studying HD patient tissue. We only have access to this as post-mortem brain by which time so many things have gone wrong that we cannot unravel the first steps in the disease process. We need to target these first steps to develop the most effective medicines.

Mice have a nervous system of comparable complexity to humans and we can use them to study degenerative conditions of the brain. We know that mouse models of Huntington's disease are good models of the human disease. Over the past 25 years, we have learnt about many important aspects of the disease, from studying the mouse models, of which we were previously unaware. HD is a late-onset disease and therefore, we shall usually work with adult mice, although we may also use younger mice to study the first changes in the brain.

Typically, what will be done to an animal used in your project?

We shall use many of the animals in this project for breeding.

We shall breed HD mouse models to provide tissues and brain sections to map out changes in the brain before symptoms begin and during the course of the disease.

We shall breed HD mouse models to other genetically altered mice (which do not themselves have symptoms). This will be to ask whether these genetic alterations delay or slow down the presymptomatic brain changes, or symptoms of the disease.

We shall treat HD mice with potential medicines to find out whether they delay or slow down the presymptomatic brain changes, or symptoms of the disease.

We may be able to give these treatments in the food or drinking water. However, some of the treatments that are being developed for HD need to be given directly to the brain. In patients, these therapies are delivered to the fluid that surrounds the brain (CSF) by a lumbar puncture or into the brain tissue. In mice, they are delivered into the CSF in a space in the brain by injection. Therefore, some mice will undergo surgery under anesthesia.

In most cases, we will collect tissues to study brain cells before symptoms begin. In some cases, we will monitor symptoms with tests to measure e.g. weight, changes in gait, balance and coordination, anxiety, memory and grip strength. These are short non-invasive tests that are repeated at appropriate intervals. Gait measurements may take a few minutes, monitoring exploratory activity may take 30 minutes.

At the end of a study, we will collect tissues for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

HD mouse models develop symptoms that are similar to those seen in the human disease and include changes in gait, problems with thinking and a failure to gain weight.

Most of the HD mouse models that we use do not develop these symptoms until after one year of age and we do most of our work before they develop symptoms. We sometimes keep mice after symptoms appear. One of our mouse models develops symptoms at a younger age and we may use this model to find out how much a treatment improves symptoms.

Some of the treatments that are being developed for HD require administration into the fluid that surrounds the brain. Therefore mice receiving these treatments will require surgery under anesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The level of severity associated with the symptoms of Huntington's disease is moderate. However, the vast majority of our work is performed using mice that are in the presymptomatic phase of the disease. Some of the treatments that we shall test need to be administered directly into the brain under anaesthesia. We anticipate that approximately 20% of our mice will have a moderate level of severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to study the earliest stages of the disease in order to develop effective medicines for Huntington's disease. As HD is mainly a disease of the brain, patient tissue is not available for this purpose.

Our work is part of a large international research program. The processes that we study often follow on from work in cultured cells or invertebrate HD models (flies and worms). However, in the past, we have tested many potential treatments that have been suggested by work with these simple systems and have usually obtained negative results in our HD mice.

Clinical trials for HD are extremely expensive. This is because several hundred patients must be studied over a period of two to three years to give a good chance of detecting a beneficial effect. Therefore, potential treatments suggested by work with the simple systems cannot be tested directly in clinical trials.

We use HD mouse models to provide an important intermediary resource to test potential therapies and prioritize those that should be advanced for clinical trials.

Which non-animal alternatives did you consider for use in this project?

The only possible non-animal alternatives might be HD brain cells that have been made by reprogramming the skin or blood cells from an HD patient to generate stem cells. Over a period of a few months, these stem cells can be turned into brain cells in a dish.

Why were they not suitable?

Huntington's disease is a slowly progressing brain disease with an average age of onset of 40 years. Brain cells that have been generated from stem cells and grown in a dish cannot model the course of the disease. At present, these cell-based systems cannot reproduce the complexity of the mammalian brain.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our experimental design is based upon on extensive knowledge of HD mouse models. Through our experience in planning these studies and consultation with statistical experts we use the minimum number of animals required to obtain scientifically valid and robust results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. We are aware of the minimum number of animals required to obtain valid results in our tests. We design our studies to limit the number of experiments required.

2. We have developed tests that can be performed on tissues at early stages of disease. Therefore younger mice that have not developed symptoms can be used. These tests require less mice than those that measure neurological symptoms in symptomatic mice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. We have developed approaches that could, in some cases, replace complex breeding programs thereby reducing the number of mice required.

2. We have found that one of the products of the HD gene, that initiates the disease process, is produced in skin cells from HD mice. We have immortalized skin cells from our mouse models to provide a continuous supply of this resource. We are using these to investigate the disease process and for screening potential therapeutics. The most suitable therapeutic can then be tested in mice to study their effect on the disease process in the brain.

3. Breeding mice can produce more animals than are needed. We take tissues from these additional mice and maintain an HD model tissue bank. This means that we often have a ready source of tissues available for analysis without the need to breed mice. We can also provide the HD scientific community with a tissue resource, removing the need for some labs to keep HD mice.

4. We freeze embryos or sperm for all of our mouse lines, so that we do not need to breed live mice unnecessarily.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We shall use mouse models of Huntington's disease. We shall age mice to provide tissues for biochemical or histological techniques. In most cases the tissues will be collected before the mice show symptoms of the disease. Sometimes, we will monitor the mice by observational tests or tests of strength, gait or memory. These are non-invasive and we will halt the test if a mouse shows signs of fatigue. In other cases, we will study the brains of the mice by imaging techniques under anaesthesia, from which mice will make a full recovery. Mice will be tested with potential medicines to see if they have beneficial effects.

Why can’t you use animals that are less sentient?

We are studying the earliest stages of the process that causes brain cells to become dysfunctional in Huntington's disease. To do this, we are studying the way in which the HD mutation alters the processing of the HD gene and its products. The structure of the HD gene is conserved between human and mouse and so we can use HD mouse models for this purpose. The structure of the HD gene is not the same in other possible animal models e.g. flies and worms.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have adopted best practice with respect to housing e.g. the use of environmental enrichment, and of cylinders to pick up mice. In most cases we study our mouse models of HD before they develop symptoms, by performing tests on tissue samples. These tests need less mice to give a conclusive result than the tests that monitor symptoms e.g. changes in gait. If we do need to measure clinical symptoms, we do not use tests that would cause pain or distress. We monitor symptomatic HD mice with a scoring system to ensure that they always have access to food and water and never become immobile or unresponsive. We will review and update these procedures following guidance on the NC3Rs Resource Hub.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will access the experimental design resources available through the NC3Rs Resource Hub. This provides access to a wealth of guidelines e.g. ARRIVE and information on the design and analysis of experiments at all stages.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our NC3Rs representative is a member of our Biomedical Services Users group and will keep us informed of advances at these meetings. We shall use the NC3Rs Resource Hub to keep up with best practice. We subscribe to the NC3Rs newsletter and will access NC3R E-learning modules and webinars.

125. Mouse models of chronic inflammatory clinical conditions. Word document missing

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

inflammation, immunology, immunotherapy

Animal types	Life stages
Mice	neonate, adult, aged, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify pathways that contribute to chronic inflammatory conditions that underly clinical diseases afflicting many people and to use this information to develop and validate new treatments to prevent, control or cure these conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic inflammatory conditions are clinical diseases that reduce patient quality of life slowly as disease symptoms become worse. These conditions include persistent infections, cancer, autoimmune, allergic, neuroinflammatory and cardio-vascular diseases, as well as rejection of transplanted cells, tissues and organs. Many people, particularly the elderly, succumb to one or more of these conditions. For example, in the UK, 85% of people over the age of 85 currently suffer from more than one chronic condition. Comorbidities complicate treatment options and medical management for many elderly people but chronic conditions such as cancers, chronic infections and autoimmune syndromes also afflict many younger people. Despite the diversity of these clinical conditions, sustained tissue inflammation is a common underlying factor. The purpose of inflammation is to activate immune responses but when sustained inflammation may cause tissue injury and symptoms that get worse over time, including pain, fatigue and behavioural disorders. Collectively, chronic clinical conditions present a huge and growing burden on health care systems worldwide as disease incidence and severity increase with age, complete cure is rare, and relapse is common. As mice and humans are mammals their immune systems share many common features, and mouse models of chronic clinical conditions replicate clinical conditions experienced by patients. Hence, mouse models offer powerful ways to gain new insights into physiologic processes driving chronic inflammatory disease progression and resistance to therapy, and to develop and test new immunotherapies to treat these debilitating clinical conditions.

What outputs do you think you will see at the end of this project?

Outputs from this project will include new information about underlying physiologic processes that incite and sustain chronic inflammatory conditions. Information generated will identify potential new targets to prevent, control or cure these conditions by manipulating inflammatory and immune responses (immunotherapy) for clinical benefit. New reagents showing therapeutic promise in mouse models of chronic conditions will be developed for future clinical applications in partnership with clinicians and corporate partners. Outputs will also include publications and scholarly reviews in scientific journals, as well as presentations at scientific meetings nationally and internationally. Outputs will also include engagement with the wider public, healthcare professionals, patients and patient support groups, and charitable foundations supporting biomedical research on human diseases.

Who or what will benefit from these outputs, and how?

Over the 5 year period of the project, short-term project outputs will benefit the scientific and medical communities interested in preventing or treating chronic inflammatory conditions. Outputs will be communicated to these beneficiaries via publications, meeting

presentations and research seminars. In the longer term (5-10 years) expected project benefits are development and validation of new treatments to prevent, control or cure chronic inflammatory conditions in partnership with other scientists, clinicians and corporate partners.

How will you look to maximise the outputs of this work?

Outputs will be maximised by publishing project data in a timely fashion in scientific journals and scholarly reviews, and by presenting research talks at meetings and seminars. Collaborations with other scientists, clinicians and corporate partners will be sought to enhance project scope, quality and productivity. New knowledge dissemination will include unsuccessful, as well as successful outputs to ensure that new insights into disease processes generated from the use of mouse models of chronic inflammatory conditions are distributed effectively and efficiently.

Species and numbers of animals expected to be used

- Mice: 15,300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

As mammalian species, mice and humans share multiple features arising from a long period of co- evolution, including an immune system composed of many common cell types and functions. In addition, mice breed relatively quickly, can be bred to generate new strains with defined genetic backgrounds, and mouse genes can be manipulated to create new strains used to study disease mechanisms. Consequently, over many decades multiple mouse models of human disease have been developed and used to study clinical disease processes. To date, mouse models have generated key insights into physiologic processes driving many clinical diseases, including (but not limited to) cancers, infections, allergies, autoimmune syndromes and transplant rejection. In this project, adult and aged adult mice will be used to study how chronic inflammatory conditions arise and develop in mice with mature immune systems, and to study how age impacts these disease processes and treatments.

Typically, what will be done to an animal used in your project?

The project uses several different mouse models of chronic inflammatory conditions. The overall project rationale is that sustained tissue inflammation is a common physiologic process driving chronic activation of the immune system, leading to disease progression and common co-morbidities experienced by patients with such clinical conditions. Some

mice will be bred in house (under SPF conditions) to generate standard and GA strains needed for experimental research (Protocols 1, 2).

Protocol 3 allows healthy adult mice to be treated with reagents that stimulate or suppress inflammatory and/or immune responses (Protocol 3). Sustained inflammatory and immune responses may incite disease progression and onset of clinical symptoms specific to each disease such as persistent (Protocol 4) infection, tumour growth (Protocols 5,6), or immune-mediated tissue injury and gradual loss of tissue function (Protocol 7). As the current Covid-19 pandemic has shown, pre-existing chronic inflammatory conditions such as chronic infections may increase risk of potentially lethal respiratory infections. To address this important clinical complication, this project includes a comorbidity model to study how established chronic infection impacts host immune responses to treatments for cancer (Protocol 4).

Experimental duration depends on the particular disease model under scrutiny. Mice infected with murine retrovirus (MuLV) develop persistent infections and may be kept for up to 6 months (Protocol 4). Most mice with transplantable tumours are kept for up to 2 months after engrafting tumour cells (Protocols 5). Some mice that clear primary tumour burdens following effective therapy, and mice with prior MuLV infections may be kept for longer (up to 9 months) to allow research questions to be fully addressed; for example, mice may be re-challenged with tumour cells to assess if anti-tumour immunity induced after primary challenge and therapy is stable and durable. Mice prone to developing intestinal (colon) tumours (APCmin/+ mice) may be kept for up to 15 weeks (Protocol 6). Most mice used to study arthritis (Protocol 7) are kept for 4-6 weeks after initiating disease, unless therapies are effective when mice may be kept for up to 6 months to assess therapy efficacy.

Several procedures may be applied to mice, including (a) treatments to initiate disease, which may include booster treatments, (b) treatments to manipulate inflammatory or immune response pathways (given before, during or after disease initiation) and (c) potential new immunotherapies to prevent control or cure disease (given after disease initiation, at disease onset or when disease peaks). In some cases treatments or therapies may be applied daily over periods of up to 20 days.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts and clinical symptoms differ according to the disease model under scrutiny as follows;

Protocols 1 & 2: GA mice with harmless (Protocol 1) or harmful (Protocol 2) effects are bred locally to generate mice used for experimental work in other Protocols.

Protocol 3: Treatments to incite, inhibit or manipulate inflammatory and/or immune responses may cause transient mild discomfort that resolves in 1-2 days in most cases. Most reagents have been used for decades (e.g. Complete Freund's Adjuvant, CFA) and

adverse effects are well documented, though some novel reagents (e.g. hydrogels, DNA nanoparticles) may induce unanticipated adverse effects.

Our group is highly experienced in monitoring mice treated with such reagents to detect any unanticipated adverse effects and minimise them, as described under '3Rs'.

Protocol 4: Persistent MuLV infections cause increasing immune dysfunction manifesting as progressive splenomegaly, lymphadenopathy and immune suppression by 6-8 weeks post infection (99% incidence in susceptible strains). Infected mice are monitored regularly to assess general health and condition (activity, behaviour, appearance, body weight). In rare cases (<5%) swollen lymph nodes cause breathing difficulties, necessitating humane killing.

Protocols 5: Transplantable dermal or lung tumours are not expected to cause more than mild discomfort or interfere with the ability to access food and water or incite abnormal behaviours for several days (typically 7-12 days) after tumour cell transfer. Over time, increasing tumour burdens may cause general deterioration in health status, unless effective therapy is applied to slow tumour growth. Treatments that modulate inflammatory and/or immune responses may lead to stable control of tumour growth and some treatments may promote long-term survival (curative therapy). Some untreated dermal tumours may cause reddening or scabbing of skin (up to 10%), and some mice may develop skin ulceration (up to 1% for untreated mice and higher for some treatments).

Protocol 6: Most APCmin/+ mice (>90%) develop intestinal (colon) neoplasias causing moderate discomfort due to progressive loss of colon function and morbidities caused by loss of digestive functions by age 4-5 months, as documented in published studies using this model. Humane endpoints are set at age 15 weeks in this project to ensure that mice do not experience severe discomfort.

Protocol 7: Most mice (>70%) treated to induce inflammatory arthritis develop limb joint swelling that leads to increasing lameness (from mild to moderate) and local pain as disease progresses. These adverse effects do not impair access to food and water or ability to nest and interact with other mice. In monoarthritis models (induced by local challenge), most mice (>70%) develop swollen joints after ~24- 48h, which then declines over a 14d period (100%). Sustained inflammation may lead to skin ulceration in some WT mice (<10%) and incidence may be higher in some GA strains with defective immune regulatory pathways. Systemic polyarthritis models are as for local monoarthritis models, exept that all limb joints may become inflamed and joint swelling is progressive if no treatment is applied (50-100%).

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

Expected maximum severities and proportions (%) of animals in each severity category are as follows; Protocol 1: sub-threshold (~50%) or mild (~50%)

Protocol 2: mild (~80%) or moderate (~20%) Protocol 3: mild (~90%) or moderate (~10%) Protocol 4-7: mild (~5%) or moderate (~95%)

Note: Humane endpoints defined in each protocol ensure that severity and incidence do not exceed the proportions stated above.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Underlying physiologic processes that cause and sustain chronic inflammatory conditions are poorly defined, largely because disease progression (a) occurs long before clinical presentation and (b) is driven by interactions between small numbers of distinct cell types, many of which cannot be cultured ex vivo. Studies in mice preserve tissue architecture and physiologic complexity, allowing the effects of defined genetic or physical manipulations on complex responses to be evaluated over time starting from tissue homeostasis. New insights into disease processes and drugs targeting such processes identified using alternative approaches must be validated in vivo because the complexity of the immune system cannot be replicated ex vivo and the potential for misleading and potentially fatal responses to interventions is therefore high. These considerations mean that it is impossible to discern critical pathways that cause or prevent disease without recourse to in vivo disease models. Hence, studies on mice are essential to discover new drug targets for immunotherapy and validate new reagents as potential immunotherapeutic drugs to treat disease. Immunotherapy offers novel ways to improve treatments for syndromes that afflict many people, including those addressed in this project; cancer, infectious and autoimmune diseases. These opportunities arise from novel insights generated from fundamental research using animal models to identify physiologic pathways that initiate sustain, inhibit disease progression or alleviate established disease. For example, our past research using animal models of pregnancy and cancer identified the metabolic enzyme indoleamine 2,3 dioxygenase (IDO) as a process that protects developing foetal or malignant tissues due to suppression of maternal or anti- tumour immunity, respectively. Elevated IDO activity also manifests in other chronic inflammatory conditions because IDO is induced by interferons made in inflamed tissues. By analogy to cancer, elevated IDO activity may protect infected tissues from host immunity to promote pathogen persistence. On the other hand, interventions to boost IDO activity may protect healthy tissue subjected to immune- mediated injury in autoimmune diseases or transplant rejection.

Which non-animal alternatives did you consider for use in this project?

Alternative approaches considered include studies on;

(a) immortalized human or mouse cell lines,

(b) primary hematopoietic (bone marrow) cells

(c) studies on cells or tissues from healthy human subjects or patients.

Such approaches can generate mechanistic insights into underlying molecular pathways that contribute to disease or therapeutic responses.

Why were they not suitable?

The alternative non-animal based approaches considered exclude potentially critical contributions from other cell types (e.g. immune cells in cancer development and therapy) and distort, oversimplify and therefore devalue data generated. Historically, it has proven difficult to model complex physiologic processes that regulate (suppress) immunity using non-animal based approaches, largely (but not exclusively) because (a) small numbers of immune regulatory cells may control much larger cohorts of immune effector cells and (b) the difficulty of culturing immune regulatory cells, while preserving their regulatory functions and measuring regulatory functions ex vivo. Moreover, samples from patients provide few hints about underlying causes of inflammatory diseases that develop over many years because it is not possible to access tissues where early disease development is initiated and progresses long before clinical presentation. A further complication is that identical ligands and signal pathways may incite opposing effects (immunogenic or tolerogenic) in distinct physiologic cell types.

For example, inflammatory insults co-activate parallel pathways that stimulate and suppress immunity, and the balance between opposing responses is elaborated in physiologic systems to incite or inhibit disease processes or therapeutic responses. Without recourse to in vivo disease models to verify particular outcomes there is substantial danger that potential new reagents to treat disease may instead exacerbate disease in clinical settings. In summary, in vitro approaches do not replicate the complexities of tissue microenvironments, and data generated in vitro must be validated for relevance in vivo due to the high risk that extrapolations from alternative (in vitro) approaches may result in misleading (at best) or fatal (at worst) responses in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of mice required for this project were estimated based on the following criteria:

1. Prospects to fund specific avenues of research on particular models of clinical disease described in this application.

2. The need to breed standard mouse strains and GA strains in house to generate mice required for this project (up to 7,500 GA mice in Protocols 1 & 2 over 5 years).

3. Experimental group size necessary to test scientific hypotheses rigorously.

4. Control groups required to test scientific hypotheses rigorously.

5. Replicate experiments (at least 2) necessary to validate study outcomes and minimise variables in order to test scientific hypotheses rigorously.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Measures to minimise numbers of mice required for this project include the use of well-defined interventions and parameters (readouts) appropriate to the research questions posed. Studies will involve the minimum number of mice per experimental group and experimental replicates (2) to generate unequivocal outcomes. Measures to minimise numbers of mice required for this project include use of the following guiding principles;

1. Using standard interventions developed over many years, and/or used in many laboratories, that induce well-defined and/or unequivocal inflammatory and/or immune responses

2. Applying outcome measures (readout parameters) with robust effect sizes to assess inflammatory and immune responses that permit group numbers to be minimised

3. Limiting control and experimental groups to the minimum needed to generate unequivocal tests of specific research questions

4. Applying multiple readouts in individual experiments to assess inflammatory and immune responses.

These principles will be applied whenever possible to reduce the number of mice required to conduct unequivocal tests of research questions.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding programmes will be designed to ensure maximum usage of mice generated. Pilot studies will be conducted to estimate effect sizes will be conducted if no published information on a specific approach is available. Advice from bioinformatics/statistics experts will be sought if larger scale studies are undertaken. For initial pilot studies to test novel scientific hypotheses group sizes will be 3-5, or will be based on comparable published studies (if available). Multiple parameters will be measured using the same mice when feasible, providing that this incurs minimal increase to health burdens. Some assays can be applied multiple times to the same mice without increasing health burdens excessively, including non-invasive imaging methods to detect tumour growth (CT scans) and mechanical nociception assessments. All data generated will be made available to the research community in a timely fashion to reduce the need for other groups to repeat the studies. Published outcomes from the program of work will follow the ARRIVE guidelines to facilitate subsequent studies by other research groups using these models.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Humans and mice are mammalian species with long periods of shared evolutionary history. As a consequence, humans and mice have highly evolved immune systems with many shared immune cell types with equivalent functional attributes. Murine models of many clinical diseases have been developed and are widely accepted and widely used in the research community. The ability to manipulate specific biological pathways in selective cells is a key factor making mice a suitable species for the proposed research on disease progression and treatment. Moreover a large array of established reagents and databases applicable to mice are other factors promoting their suitability for research on clinical diseases and developing new therapies.

Mouse models selected are suitable to address the four Research Objectives in this project for the reasons described below. Figure 2 indicates how each model is integrated into the four Research Objectives and the overall Project Work Plan.

Inflammation and immune response models (Research Objective 1, Protocol 3): Reagents that incite or modulate inflammatory and immune responses are used to identify pathways driving disease progression, therapeutic responses, and/or therapy resistance. Many reagents (chemicals, toxins, adjuvants, antigens, etc.), environmental factors (infections, allergens, food, exercise, microbiome) and manipulations (wounds, transplants, cells)

cause tissue inflammation. Inflammation activates immune cells but in vivo outcomes (immunity or tolerance) depend on complex physiologic interactions in tissues that cannot be fully reproduced ex vivo. Inflammation stimulates immune responses but often incites immune regulatory (suppressive) processes in parallel and/or in sequence. Regulatory responses may protect tissues from immune-mediated injury but may allow pathogen-infected or malignant tissues to evade protective immunity, leading to persistent infections or cancer, respectively. On the other hand, defective immune regulation may lead to immune-mediated injury of healthy tissues and donor-specific immune responses destroy healthy transplanted organs and tissues, unless immune responses are suppressed by therapy. Inflammation also enhances local pain sensitivity and sustained inflammation causes neurologic and metabolic dysfunction, leading to fatigue and behavioural disorders. Relative to immunogenic responses, immune regulatory (tolerogenic) responses remain poorly defined and are difficult to model using non-animal based approaches due to the complexity of tolerogenic processes and the need to measure immune inhibitory responses. Hence, a major research objective in this project is to identify regulatory pathways that suppress inflammatory and immune responses, which may contribute to disease prevention, progression, resolution, or therapy resistance.

Chronic Infection Model (Research Objective 2, Protocol 4): A natural mouse leukaemia virus (MuLV) chronic infection model was selected because MuLV infections replicate multiple clinical features of retroviral infections in humans (e.g HIV-1 infections that cause AIDS). In recent preliminary work, we found that mice with pre-existing chronic infections (MuLV) are highly resistant to effective treatments that eliminate dermal tumours. As many patients with cancer have pre-existing inflammatory conditions, this finding prompts the need for further research to evaluate how MuLV infection causes resistance to effective cancer treatments.

Cancer Models (Research Objective 3, Protocols 5 & 6): Cancer models were selected because they replicate multiple clinical features of cancer in patients. In recent published studies, (Lemos et al., 2016 Cancer Research and Lemos et al., 2020 J Immunotherapy of Cancer) we described refinements to standard mouse dermal models that better replicate key clinical barriers to effective cancer immunotherapy observed in patients, including late cancer diagnosis, robust immune checkpoints and adaptive therapy resistance. These experimental refinements improve the clinical relevance of mouse dermal models for research on how immune responses that protect developing tumours and how to reduce therapy resistance. In the course of this project, laboratory staff worked closely with local technical and veterinary staff and the Home Office Inspector to improve detection and management of unanticipated adverse effects. For example, we found that novel treatments with STING agonists eliminated tumours but caused transient ulceration at sites of tumour growth due to robust inflammatory and immune responses required to eliminate tumours. In cooperation with technical, veterinary and Home Office staff we developed a novel scoring system to detect and manage adverse effects experienced by tumour-bearing mice subjected to effective (curative) treatments. Aging APCmin mice

develop spontaneous colon carcinomas that replicate multiple features of clinical colon cancer (Protocol 6).

Autoimmune Disease (AD) Model (Research Objective 4, Protocol 7): AD models were selected because they replicate multiple clinical features of equivalent clinical syndromes that manifest in AD patients. The collagen-induced arthritis (CIA) model is the preferred model to study rheumatoid arthritis (RA) and test/validate novel therapies for RA, as the CIA model replicates clinical RA more accurately than other antigen-induced arthritis (AIA) models. However, AIA models may be refined to induce monoarthritis (not polyarthritis seen in clinical disease and the CIA model). and are also useful for discerning disease mechanisms because B6 mice (and hence many GA strains) may be used in AIA models, while the CIA model is confined to susceptible strains such as DBA/1 mice.

Why can't you use animals that are less sentient?

Less sentient, non-mammalian species and immature mice do not have highly evolved or mature immune systems with immune cells and functional attributes that replicate how the human immune system works. Terminal anaesthesia is not appropriate to study inflammatory and immune responses driving chronic inflammatory diseases or therapeutic responses because these processes develop over long periods (weeks to months).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all models, general refinements to minimise suffering (harms) are listed below:

1. Severity will be limited using experimental endpoints based on defined scoring criteria including general health status and disease specific parameters. Goals are to restrict suffering to the minimum necessary to (a) replicate clinical symptoms experienced by patients and, (b) generate high quality outputs that allow rigorous testing of scientific hypotheses under investigation.

2. Treatments and study durations are restricted to the minimum needed to address stated research objectives and to ensure scientific rigour.

3. Low stress handling techniques are used, including tunnel handling during cage change and observations whenever possible.

4. Mice are monitored regularly to identify distressed animals. Supportive care is provided to mice that lose significant body weight or exhibit other adverse effects indicative of distress and suffering. Supportive care includes providing access to moist food and regular observation. The NVS and/or NACWO will be notified if mice approach the maximum permitted weight loss specified in each Protocol (range 20%-30%). Mice will be killed humanely if weight loss does not reverse in reasonable timeframes, based on model-specific criteria and other general health status scores, as specified weight loss limits are approached. On rare occasions, it may be necessary for some control groups to reach the

upper weight loss limit to document effective therapeutic responses in vehicle control groups.

5. Humane endpoints, adverse effects and control measures are described for each Protocol. Mice are killed by a Schedule 1 or non-Schedule 1 method if humane endpoints are reached. Specific justification for the need to allow some mice to reach humane endpoints are as follows. First, on rare occasions it may be necessary for control mice with disease that do not receive therapy to reach humane endpoints in order to document effective therapeutic responses in experimental mice with disease that are given therapy. Second, it may be necessary for some mice that receive novel experimental therapies to reach humane endpoints to validate therapeutic responses rigorously. This is more likely when therapies are applied at later stages in disease progression to model clinical situations accurately. For example, numerous therapies block tumour growth and promote remission and full recovery if therapy is initiated before overt dermal tumours form following engraftment of tumour cells. In many cases, the same therapies fail to control tumour growth if applied after overt tumours form, or when tumours are more developed. Hence, delaying treatments may be necessary to model challenges faced when treating patients due to late diagnosis of cancer when tumours are well developed and more resistant to therapy. Laboratory staff are highly experienced in detecting and managing unanticipated adverse effects arising from complex disease induction and therapy procedures, as illustrated by our effective cooperation with local technical and veterinary staff to develop a novel scoring system to monitor mice with dermal tumours given curative treatments that induced transient ulceration at sites of tumour growth.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on best practices will be sought from the scientific literature and agencies promoting the 3Rs such as NC3R and ARRIVE.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Updating and implementing advances in the 3Rs will be conducted by reading relevant scientific literature and monitoring sites that provide information about advances in the 3Rs, including the UKRI National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs; www.nc3rs.org.uk) and Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines (www.arriveguidelines.org)

126. Colorectal cancer initiation and progression

Project duration

5 years 0 months

Project purpose

Basic research

Translational or applied research with one of the following aims:

- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Colorectal cancer, Stem cells, RNA metabolism, Cancer driver genes, Cancer metastasis

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Colorectal cancer is the second commonest cause of cancer related mortality and there is a pressing unmet need for the delivery of new therapies for its treatment. Determining how tumours initiate and progress is critical for understanding tumourigenesis and guiding therapeutic development. The aim of this research programme is to identify potential therapeutic targets by determining the mechanisms important for tumour initiation and progression.

During this research programme we will use appropriate, well-defined mouse models to address 2 aims:

1) The role of changes in how RNA is processed in cancer

2) The identification of novel cancer driver genes

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Expected benefits for objective 1.

My research has the potential to define novel cancer mechanisms. This will increase our understanding of how tumours form and spread and open new therapeutically exploitable opportunities.

Expected Benefits for objective 2.

The identification of novel mutations that drive cancer will provide great benefit to the understanding of how tumours form and spread. It has the potential to identify mechanisms important for tumourigenesis. This in turn may lead to the development of novel therapeutic strategies for targeting colorectal cancer.

What outputs do you think you will see at the end of this project?

The main outputs of this project will be in peer reviewed publications describing the results of our work. These will describe cancer promoting mechanisms and the genetic drivers of colorectal cancer. In addition, the results of this work may lead to additional work developing therapeutics that target the mechanisms we identify. We will also communicate our work more broadly to a wider audience via science communication events, traditional media and social media outputs.

Who or what will benefit from these outputs, and how?

This work will broaden our understanding of cancer driving mutations and mechanisms. In the short term this will benefit the scientific community, who will be able to incorporate and build on our research in their own research programmes. In the longer term, our work has the potential to inform and direct new therapeutic development for the treatment of colorectal cancer. This may lead to patient benefit and wider economic benefits.

How will you look to maximise the outputs of this work?

All work carried out during this project will be published in open access, peer reviewed journals. All data produced during the project will be made freely available to other research groups to help inform their own research. We will also collaborate with other groups to ensure our work is carried out in the most effective way. We will discuss our work during scientific conferences and in public engagement events open to the wider public. Upon publication, we will communicate our findings more broadly using social media and traditional media.

Species and numbers of animals expected to be used

Mice: 15,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

As colorectal tumours are very complex and have a variety of different components e.g. tumour cells, immune cells, supporting cells (stroma) and blood supply, it is not possible to mimic these processes outside of the body. Experiments in animals better recapitulate these effects on how tumours grow and as such it is important to study it in this context. The involvement of the tumour support system and the immune system on cancer cell development and response to therapy is well documented and highlights the need to use mouse models for these studies.

We will use primarily adult mice for our experiments as the genetic models we will utilise can be induced at the adult stage.

Typically, what will be done to an animal used in your project?

In a typical experiment mice will be bred to carry an inducible genetic allele that causes cancer development and additional alleles that we wish to test for a role in cancer development. When the mice reach 6-8 weeks old the genetic mutations are 'induced' by injecting with an agent such as tamoxifen. Mice are then aged until symptoms of tumourigenesis arise and then humanely culled. Samples are taken and analysed to determine the function of the gene of interest in tumourigenesis.

What are the expected impacts and/or adverse effects for the animals during your project?

The primary adverse effects on the mice in this research programme are the development of intestinal/colonic tumours.

When intestinal tumour burden is high in mice, mice become anaemic (as shown through paling of the feet) and begin to lose weight. In around 10-20% of mice rectal bleeding is expected. This occurs due to the presence of small colonic/rectal tumours and is well tolerated by the animals (they show no other obvious signs of distress). Close monitoring will occur after the observance of anaemia and/or bleeding and mice will be humanely culled when they show signs of moderate discomfort. This is described as three of the following symptoms - weight loss over 20%, subdued behaviour, stop interacting with their cage mates, anaemia, sustained rectal bleeding with visible blood on fur and sustained diarrhoea for over 72h. Other mice will be culled at pre-defined time points according to the experimental protocol at which time tissues will be taken for analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity (75%)
Moderate severity (25%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Colorectal tumours are very complex and have a variety of different components e.g. epithelial tumour cells, immune cells, supporting cells (stroma) and blood supply it is not possible to mimic these processes outside of the body. Only in vivo approaches recapitulate micro environmental effects on tumourigenesis and as such it is necessary to study it in this context. The involvement of the tumour microenvironment and the immune system on cancer cell development and response to therapy is well documented and highlights the need to use mouse models for these studies.

Which non-animal alternatives did you consider for use in this project?

We, and others, have developed a number of ex vivo tumour and tissue organoid culture techniques that will be used in parallel to these studies. These alternative models complement the use of animals and can be used for initial target identification and mechanistic analyses. In particular we have developed models for CRISPR/Cas9 screening in these ex vivo models in order to refine targets for in vivo testing. For example, we routinely use CRISPR/Cas9 to screen for candidate genes that impact on tumour organoid growth but do not impair normal intestinal organoid growth. This approach allows us to determine candidate genes that not only are likely to suppress tumour growth in vivo but not detrimentally impact on normal mouse physiology. We also routinely carry out bioinformatics approaches, for example mining human gene expression datasets to help determine human disease relevance to selected target genes. These approaches reduce the number of animals used by focusing their use on addressing the key questions throughout the proposal. We have utilised this approach under our current PPL to successfully stratify candidate genes for analysis. This has led to the identification of a number of cancer driver genes with reduced animal usage than would have occured without these ex vivo approaches.

Why were they not suitable?

Despite acting as disease relevant models and being useful for initial target identification experiments organoid models fall short of fully recapitulating the complex environment found within tumours. In particular, they lack immune, stromal and vasculature involvement and cannot be used to model more complex tumour phenotypes such as tumour initiation and metastasis. For these reasons these models fall short of replacing the need to carry out these experiments in animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Power analyses, based on our past experience, have been performed to estimate the number of mice required to generate significant results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals used in this project we took a number of steps:

1) Power analyses were performed to ensure that we use the minimum number of mice to generate significant results. These were based on our past experience.

2) Embryos/sperm are frozen from lines not immediately required for experimental studies.

3) Tumour metastasis is a highly complex process that occurs following the acquisition of multiple genetic mutations. The only reliable autochthonous genetically-engineered mouse model that gives rise to liver metastasis carries 4 separate genetic alleles (VilCreERT2 P53fl/fl KrasG12D Notch-ICD). Therefore, the complex breeding to generate such models and add additional alleles to test effects carries a large animal usage burden (over 1000 mice would be required to generate cohorts for analysis). Organoids from these mice can be genetically altered using CRISPR/Cas9 and successfully re transplant at high efficiency (~80%). Therefore, the use of orthotopic transplantation models in syngeneic mice is a viable, disease relevant alternative with a small fraction of the animal usage.

4) By developing a model for in vivo genome editing using CRISPR/Cas9 in adult mice we can significantly reduce animal numbers compared to the use of traditional breeding programmes to generate mouse lines carrying multiple genetic mutations. Similar to the orthotopic model outlined above a large animal breeding burden is needed to generate mouse cohorts for testing the function of genes in tumour initiation. Our standard tumour

initiation model (VilCreERT2 Apcfl/+) requires over 100 mice to cross another allele to homozygosity and generate cohorts for analysis. By generating colonies of VilCreERT2 Apcfl/+ Cas9 mice we can reduce this as all mice generated can be used in experiments.

Throughout our experimental design we have utilised information derived from experiments carried out under our current PPL to inform this process.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1) Breeding plans are optimised for efficiency

2) Any tissues generated from previous experiments are archived and stored appropriately therefore ensuring that repetition of experiments is not necessary.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically engineered mouse models will be used throughout this project. In addition, orthotopic transplantation of organoids into syngeneic recipients and direct in vivo CRISPR/Cas9 editing of the colon will be carried out. Procedures will include injection or feeding with inducing agents (eg tamoxifen, doxycyclin), injection with labelling agents (eg BrdU), induction of colitis (DSS) and treatment with candidate therapeutic agents.

Why can’t you use animals that are less sentient?

These models have been chosen because the mutations that they carry are those associated with the human disease allowing us to recapitulate the same genetic mutations observed in human cancer. No other models are currently available to perform this analysis and lower species such as fish or flies do not accurately recapitulate the human disease. Indeed, a number of studies in fish have demonstrated fundamental differences in the mechanisms of Wnt signalling activation following loss of Apc so this model is inappropriate for modelling human colorectal cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where possible cre-loxP systems will be used to specifically target the tissue of interest thereby reducing off-target adverse effects in the animal. The group will ensure that all animals receive the highest standard of care and appropriate social, environmental and behavioural enrichment such as bedding, tubing and group housing and will be provided. Close monitoring of tumour development will ensure animal suffering is kept to a minimum. We have vast experience of these cancer models and the clinical signs that develop and can therefore ensure that suffering is kept to a minimum. For the genetically engineered mouse colorectal tumour models animals will be euthanized when they reach the clinical endpoints outlined in Appendix A. Reaching these clinical endpoints is extremely important to allow disease progression to a stage where it reasonably mimics the human disease and to ensure all animals with different genetic alterations are taken at an equivalent disease stage thus allowing accurate comparisons between them. Additionally work carried out to date under our current PPL has shown that sacrifice of the animals at this stage allows us to obtain statistically significant results when studying the role of key proteins in colorectal tumour development.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all our studies we will refer to the Guidelines for the Welfare and use of animals in Cancer Research (Workman et al, 2010) and ensure best working practice. We will use all the refinements (1-

10) recommended in this document. We will also refer to PREPARE and ARRIVE guidelines: https://journals.sagepub.com/doi/10.1177/0023677217724823
https://journals.plos.org/plosbiology/article?id=10.1371/journal.pbio.1000412

and the following resources: https://www.nc3rs.org.uk/experimental-design
https://acmedsci.ac.uk/policy/uk-policy/animals-in-research

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Via the 3Rs website: https://www.nc3rs.org.uk and communication from animal facility management.

Staff in my lab will be kept informed of any advances in 3Rs and will implement them. Changes to protocols as a result of these advances will be implemented via license amendments.

127. Tuberculosis immunity and vaccine development

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

vaccines, infectious diseases, immunology, diabetes

Animal types	Life stages
Mice	juvenile, adult, pregnant, aged, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project are to:

a) understand the complex interaction between Mycobacterium tuberculosis, the causative agent of tuberculosis (TB), and the host immune system, and how diabetes and co-infections e.g. cytomegalovirus (CMV), affect these interactions

b) develop and evaluate vaccines against TB and other pathogens, for which there are currently ineffective vaccines or no vaccines at all.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tuberculosis (TB) is the leading cause of death from a single infectious agent, killing more than a million people a year. There is an urgent need for better control measures and the most cost effective way to control any infectious epidemic is with effective vaccination.

There is only one available vaccine against TB, but it is able to prevent only 5% of all vaccine preventable deaths. For this reason a more effective vaccine is urgently required that will also target an increasing diabetic population and people with co-infections.

What outputs do you think you will see at the end of this project?

Detailed understanding of immune responses to tuberculosis and identify responses that correlate with protection

Understand how protective immune responses are altered by diabetes and co-infections

Develop more efficient vaccines against tuberculosis and related diseases, and understand how these vaccines interact with the immune system.

Who or what will benefit from these outputs, and how?

It is estimated that one-quarter of the world's population is currently infected with Mycobacterium tuberculosis. The majority of infections are in the developing world, where co-infections with HIV, cytomegalovirus (CMV) and the prevalence of diabetes result in worse disease outcomes. The long- term aim of this work is to develop a vaccine that is effective in all populations and in all risk-groups, and will help control the TB epidemic.

Our short-term aim, is to identify immune responses that correlate with protection, and evaluate a number of vaccines for their immunogenicity and protection. These findings will help the scientific community, and in particular the TB vaccine field, by ensuring that vaccines in development are able to induce these protective immune responses. In addition, information about how immune responses are altered when diabetes is present and when there is an underlying co-infection, will inform all vaccines in development. This was emphasised in the current COVID-19 pandemic, where people with hyperglycaemia/diabetes, had worst disease outcomes. For this reason, vaccines should be equally effective in these populations.

How will you look to maximise the outputs of this work?

We will publish our findings, both positive and negative, in peer-reviewed journals and we will present in meetings and consortia.

We have a number of on-going clinical trials, and a large number of stored samples and there will be a constant feedback between the two sides to maximise the impact and confirm the relevance of our findings. In addition, we have a number of collaborations (human and veterinary) that we will be sharing our results and techniques with.

Species and numbers of animals expected to be used

- Mice: 16,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used for this work as they are similar to humans in the main features of the innate and adaptive responses to TB. Just like in humans, TB primarily infects the lungs. In addition, there is an abundance of immunological reagents and assays that allow extensive characterisation of any aspect of TB pathogenesis, much more than in any other animal species. In some instances, we will be using genetically altered mice, that lack parts of the immune system, in order to help understand what is their role in vaccination and in protection.

We will use juvenile and adult mice as they have a fully developed immune system.

Typically, what will be done to an animal used in your project?

Immunogenicity experiments: Mice will be typically immunised on up 3 occasions and immune responses will be measured at pre-defined end points. Hyperglycaemic mice will also be immunised with promising vaccines to understand if and how immune responses differ. Similarly, mice will be

inoculated with MCMV before immunisation to explore the impact on vaccine immunogenicity and efficacy.

Efficacy experiments: To investigate the protective capacity of vaccines, animals will be first immunised with our vaccines and then challenged with Mycobacterium tuberculosis. We will be comparing the bacterial load of the vaccinated compared to unvaccinated control animals. On rare occasions we will challenge vaccinated hyperglycaemic mice, to ensure that promising vaccines are still protective.

On rare occasions, we will be using genetically-altered mice, that lack parts of the immune system, to understand what is their importance in infection and vaccination.

What are the expected impacts and/or adverse effects for the animals during your project?

Our immunisation experiments are expected to have only mild effects that are transient, similarly to human vaccination. In the majority of cases, animals will be sedated to avoid stress and pain associated with the procedure.

For challenge experiments, animals will be monitored for signs that are associated with disease progression, such as weight loss, loss of activity. Typically challenge experiments are completed before any signs of systemic disease, but animals will be closely monitored throughout these experiments to ensure that humane endpoints are not exceeded

Hyperglycaemic mice will have a higher blood glucose level compared to animals with normal levels. Adverse effects include increased urination, higher water intake and weight loss. These animals will be monitored for both blood glucose levels and weight.

Infection with MCMV results in latent infection that is held in check by the immune system. MCMV might cause short-term transient, non-specific illness and therefore animals will be closely monitored after infection, and in the days following infection, to ensure complete recovery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 10% subthreshold
- 60% mild
- 30 % moderate

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although human challenge models do exist for other diseases such as malaria, safety and ethical concerns over human TB challenges have limited their development. Moreover there are currently no immune responses that correlate with protection, and for this reason the efficacy of vaccines needs to be assessed in animals. Mice are similar to humans in the main features of the innate and adaptive responses to TB. Just like in humans, TB primarily infects the lungs. There is currently no in vitro system that can mimic the complexity of the immune response.

Which non-animal alternatives did you consider for use in this project?

Human challenge studies:

a) We have performed a human challenge study, using BCG vaccine, as a surrogate for M.tuberculosis challenge,

b) on-going challenge study using aerosolised BCG as surrogate for M.tuberculosis challenge.

In vitro assays: human cell samples and blood post-infection and post-vaccination, in vitro infections such as mycobacterial growth inhibition assays (MGIA) to test the efficacy of vaccines, in vitro infections to identify promising antigens vaccine preparations

In silico modelling e.g. bioinformatics, to identify promising antigens to include in vaccines.

Less sentient animals such as Drosophila melanogaster, amoeba Dictyostelium discoideum and zebrafish

Why were they not suitable?

Human challenge studies: a) although this study was able to show the protective ability of some vaccines, the route of infection was different to the natural aerosol route of M.tuberculosis. For this reason, the following study (b) is investigating the aerosol route of infection. Although these studies are very informative, they will not be able to replace animal challenge experiments that aim to compare different vaccine candidates

In vitro and in silico assays: we use human cell samples post-vaccination and pre and post- infection to identify promising antigens to include in our vaccines. This reduces the number of vaccines to be evaluated in animals but there is still the need for vaccination and evaluation of vaccine efficacy in animals

Less sentient animals: the lack of an adaptive response, a key part of the immune system induced by vaccination, is absent in these animals. In addition, although the zebrafish is more similar to humans in their immune system, they do not have lungs, the primary organ that is infected by M.tuberculosis

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

To generate some transgenic mice for our experiments, we need to perform complex genetic crosses; in addition we will need to backcross genetically modified animals to parental strains to minimise genetic drift.

For the animals to be used in our experimental protocols, we estimated our number on past experience and on the number of projects that we have on-going. We have performed

power calculations based on past data to identify the minimum number of animals to observe differences in our experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use in vitro assays to screen promising antigens to include in our vaccines. For example, we screen antigens on human blood from TB infected individuals, and perform in vitro infection experiments, followed by mass-spectrometry. This step minimises the number of vaccines that need to be tested in mice.

Rigorous statistical calculation to identify the appropriate number size to ensure that the minimum number of animals are used but at the same time ensure that each study is sufficiently powered to provide a meaningful result.

Minimise variation by controlling for cofounding factors such as sex, age, environment. Lower variation means that less animals are required per group.

Trying to address multiple questions within one experiment. For example, assess immunogenicity and protective efficacy of a vaccine by performing an in vitro challenge when possible

We will be conducting our experiments to comply with the ARRIVE guidelines when publishing

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cryopreservation of mouse strains when not in use

Pilot studies with small number of animals, when a new vaccine regime or animal strain is used for example, to understand the variability within each group

We will use in silico modelling to select antigens to be included in our vaccines

We will be sharing samples with collaborating groups who investigate different aspects of the same immune responses e.g. metabolomics, epigenetics

We will use good colony management to ensure that only those cohorts required for experiments are produced. Breeding data is available from our mouse database to enable effective breeding calculations to be conducted.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse strains that are commonly used for TB research will be also be used for this project. We will use non-genetically modified strains such as C57BL/6, BALB/c, CB6F1, all of which are quite resistant to TB infections. Challenge experiments with these strains allow us to detect the effect of vaccination before any systemic signs of disease develop. In some instances, genetically modified animals will be used to explore the role of particular aspects of the immune system in vaccination and TB protection.

The methods that we will be using are: immunisations and challenge experiments.

To investigate the effect of hyperglycaemia on vaccine immunogenicity and efficacy, we selected two mouse models that best represent human type 2 diabetes. One is an altered diet model where mice are fed on high fat/sugar diet and one a transgenic mouse model. We will not be inducing diabetes in these mice, but moderate levels of hyperglycaemia to mimic subclinical diabetes. Methods will include the induction of hyperglycaemia, immunisations and in some instances challenge experiments.

Why can't you use animals that are less sentient?

The mouse model is the least sentient model with a similar immune system to humans. Just like in humans, TB primarily infects the lungs. In addition, there is an abundance of immunological reagents and assays that allow extensive characterisation of any aspect of TB pathogenesis, much more than in any other animal species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Particularly when testing the susceptibility to TB infection of new animals strains, co-infections or in hyperglycaemic mice, we will perform pilot challenge experiments with the non-pathogenic BCG mycobacterial strain.

Our state of the art aerosol challenge equipment, allows us to perform infection experiments with really low M.tuberculosis doses, which a) are more relevant to the human situation and b) cause infection with a lower bacterial burden

In vitro challenge assay, is currently optimised and used in our laboratory. This assay, referred to as mycobacterial growth inhibition assay (MGIA), has the potential to replace in vivo challenge experiments. We will use this assay as a first step for screening new vaccines or investigating the impact of mycobacterial infection on new genotypes.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the ARRIVE guidelines and the NC3Rs Experimental design assistant when setting up new experiments. The Design of animal experiments, 2nd edition, by Michael Festing et al will be used to help us design our experiments and online statistical tools such as G*power will be used to calculate group sizes. In addition, The Handbook of Laboratory Animal Management and Welfare, Sarah Wolfensohn and Maggie Lloyd, Blackwell publishing, for guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have members of our team that are part of the local ethics committee and members that are funded by the NC3Rs to develop assays that are a significant refinement to the standard protocols. We regularly attend internal 3R's meetings and use the NC3Rs website to keep up to date with the more recent advances in the 3R's

128. Impact of hormones and inflammation on reproductive health and disease

Project duration

5 years 0 months

Project purpose

Basic research
Key words

hormone, reproduction, inflammation

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to understand how signalling molecules called hormones control the function of immune cells in order to understand how this affects women's reproductive health and to find out if this could be targeted in new therapies for women's health disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One in three women in the UK will suffer from a reproductive health problem such as endometriosis or heavy menstrual bleeding. These common disorders cause life-changing symptoms. Reproductive disorders impact on the health and wellbeing of individuals and carry a high cost to both women and society.

Despite its clear importance, lack of funding has hampered research into women's reproductive health, and this has prevented development of new treatments. Current treatments for conditions such as endometriosis or heavy menstrual bleeding include fertility-ending surgery or medical therapies that have unwanted side effects.

The womb must repair as part of each monthly cycle (menstruation) in order to maintain healthy function. This is essential for ongoing fertility and reproductive health. Repair is abnormal in reproductive health disorders and this may be caused by unbalanced hormones and increased inflammation caused by immune cells. Hormones are a type of messenger signal that is released into the blood and travels to different organs to change their function. Specific types of hormone are required for reproductive function; these are known as sex steroids. In females, the womb changes its function in response to sex steroid hormones that stimulate growth (estrogens) and remodelling (progestogens) as part of normal reproductive function. Androgens are a type of sex steroid hormone that are usually associated with male reproductive function but we have found that androgens are also important for normal function of the womb. Androgens can alter wound repair in other tissues such as the skin and some studies suggest this is because they can change the function of immune cells. We do not fully understand how hormones can affect immune cells and this has not been investigated in the context of womb repair or women's reproductive health. We know that unbalanced sex steroid hormones are associated with abnormal immune cell function and reproductive health disorders.

We want to understand how hormones control immune cells in order to understand how this could contribute to women's reproductive health. If we can understand this we believe it could help us to develop new therapies for women's reproductive health disorders.

What outputs do you think you will see at the end of this project?

This project will assess how hormones and immune cells control womb function in health and disease. This work will develop new understanding that will be shared with other researchers by presenting our findings at meetings and by publishing our results in journals and online via social media/websites.

This research will help us to better understand how the womb works, which will help us to develop new ways to improve women's reproductive health. New treatments will be developed by testing targets found from this project in human cells/tissues.

Who or what will benefit from these outputs, and how?

This project will benefit clinical doctors and scientists with an interest in women's health who will gain new knowledge relevant to their research.

The results will also be of interest to the pharmaceutical industry, clinicians and scientists who are keen to develop new treatments for women's health problems. One key opportunity involves using drugs already developed for treatment of inflammatory and hormonal disorders but as a treatment for women's reproductive health disorders. This

approach may be of particular interest to patients as these drugs could be developed into new treatments more quickly than entirely new drugs. These long-term benefits may come from the research conducted as part of this project.

How will you look to maximise the outputs of this work?

Research outputs will be shared broadly with other researchers by presenting research findings at meetings and publication of research findings in academic journals and online via social media and websites. This approach will help to ensure the benefits of the research can reach key stakeholders.

The research outputs in this project may benefit other researchers both locally and internationally and help to shape research assessing the role of hormones and immune cells in other contexts. Relevant information will be shared with collaborators and colleagues through departmental research meetings where formative/unsuccessful aspects of research can be shared and improved, local/national research meetings and via publication in journals. Research, including data from unsuccessful approaches will be made available at the earliest opportunity via preprint servers such as Biorxiv (https://www.biorxiv.org/).

Species and numbers of animals expected to be used

- Mice: 7950

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Normal functioning of the womb (endometrium) is essential for reproductive health. The endometrium is a complex organ and a full understanding of the how different cell types interact and how signals called hormones control these cells requires the use of animal models. Importantly, our studies, and those of others, have demonstrated that the endometrium in adult female mice is strikingly similar to human tissue and they share the same cellular compartments. Important for this proposal is the ability to model features of human menstruation (period) which involves endometrial tissue breakdown, inflammation and repair. We have developed a mouse model that can mimic this in a consistent manner and the mouse model of endometrial repair shares similar key features to human.

The process of endometrial repair is linked to fertility and pregnancy and therefore can only be modelled in adult mice. Moreover, the immune system and particularly the part of the immune system we wish to focus on (macrophages) is well defined in mice and shares similarities with human in health and disease. Powerful research tools are available if you use mouse models including the ability to change expression of key factors or to label

specific cell types using genetic approaches. Studies in mice therefore provide the ideal platform for our investigations for which we have well validated models of endometrial repair that are appropriate for the aims of this project.

Typically, what will be done to an animal used in your project?

The experimental work will involve some minor surgical procedures and delivery of hormones by injection or slow releasing capsules placed under the skin. Procedures are classified as either moderate or mild in severity. These procedures will allow modelling of endometrial breakdown and repair as well as modulation of hormonal and inflammatory processes. Pain will be controlled during surgery by general anaesthesia and post surgically by painkillers (analgesics). Animals will be monitored during the post-surgical period and further analgesia will be administered if animals exhibit signs of discomfort. Surgical procedures have short duration, typically less than 10 minutes. Typically, an experiment will involve up to three short surgeries within a three-week protocol.

There are two main types of surgery; removal of ovaries (ovariectomy) and placing capsules under the skin that release hormones, which are performed under general anaesthesia. Ovariectomy involves making a small incision in the skin, making a small hole on the body wall, holding the uterus with forceps and removing the ovaries. The opening in the skin is then closed using surgical clips. This procedure takes 7 minutes on average and mice have actively recovered (awake and moving freely) within around 10 minutes. Insertion or removal of capsules involves making a small incision in the skin and placing or removing the capsule under the skin. This takes less than 5 minutes and recovery within 10 minutes. In each case, animals recover quickly and return to normal behaviour after procedure and anaesthesia. These procedures allow hormone signalling to be changed in order to mimic changes that take place in the menstrual cycle in women that allows us to better understand endometrial function and repair.

Endometriosis is the presence of endometrial cells/tissue at sites other than the uterus, usually on organs or tissue inside the pelvic abdominal cavity. In women, these deposits form lesions and this is associated with symptoms of infertility or pelvic pain. We have developed a mouse model that mimics some features of endometriosis in order to help us to understand the factors that allow lesions to become established and to grow in the pelvic cavity. Our model generates endometrial deposits, that establish in the pelvic cavity and have a similar architecture to endometriosis lesions found in women. This procedure involves transferring endometrial cells/tissue by injection into the pelvic cavity of the mouse and allowing these deposits to attach to the peritoneal wall over a period of 2-3 weeks. This procedure is associated with changes in immune cells, particularly macrophages, which are similar to changes that are seen in women. The procedure is well tolerated with no obvious adverse effects.

We will monitor behaviour of mice on this protocol to ensure that model or any interventions do not have a negative impact on behaviour. Our previous studies have used

state-of-the-art movement monitoring techniques and found that mice with endometriosis lesions behave no differently from control mice.

Thus, although this model is useful for understanding the role of inflammatory cells and hormones in establishment of lesions it does not recreate pain symptoms that are seen in women.

Some previous studies suggest that experimentally-induced endometriosis can cause animals to become more sensitive to unharmful stimuli, which can be considered a 'pain-like' behaviour. Although we have not seen this in our experience, we will measure this by using established tests such as von Frey test. Von Frey test uses fine plastic strands of different widths that are applied to the hind paw and if the rodent withdraws, licks or shakes the paw then a positive response is recorded. If an animals sensitivity is increased this response will happen with finer strands (smaller width) than in control animals.

Taken together, the majority of animals in this project will undergo procedures to allow us to mimic events that occur in the menstrual cycle in women in order to investigate the impact of hormones on macrophage function in the endometrium. Endometriosis will be experimentally induced in some animals in this project in order to understand of how hormones and macrophages can contribute to establishment and growth of endometrial deposits as this can help us to better understand what causes disease in women.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected, and appropriate measures have been taken to eliminate the possibility of such complications. However, infections can occur after surgery in approximately 1% of animals. Risk of infection will be minimised by good surgical and aseptic technique. Pain post-surgery may occur and analgesia will be administered following surgical procedures to minimise this impact. Animals will be monitored during the post-surgical period and further analgesia will be given if animals show signs of discomfort. All substances will be given at doses known to be non-toxic based on our experience and reported dosages. At the end of procedure, animals will be humanely terminated and tissues collected for analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The experimental work will involve some minor surgical procedures and administration of hormones via injection or as slow releasing pellets placed under the skin. The procedures are classified as either mild (15%) or moderate severity (85%). Most animals will be classified as moderate.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Menstruation and endometriosis only occur in women and higher primates (apes and some monkeys). Using our understanding of reproductive biology we have been able to develop mouse models of menstruation (endometrial wounding and repair) and endometriosis. Our models have provided an ideal platform for improving our understanding of how the endometrium functions in health and disease.

Complex interactions between different cell types cannot be fully explored without the use of an animal model. This is particularly true of immune cells and in particular macrophages which are controlled by signals from their tissue environment and therefore do not behave the same way when removed from the tissue and studied in isolation in a dish. Also, because hormones act by signalling through the blood their actions need to be investigated in an animal model.

Which non-animal alternatives did you consider for use in this project?

We have used human tissue specimens recovered from women in the adjacent hospital to study behaviour of different cells in the womb that have informed our experimental approach. This allows us to test cells in isolation, or to investigate samples of tissues taken at a single time point. We have tested single populations of cells and developed co-culture systems to identify relevant cell-type markers and to understand some basic cell interactions.

Why were they not suitable?

Although these studies are informative they offer only limited insight. Isolated cells do not behave in the same way as those within tissues and the complex interactions between different cell types cannot be investigated with this approach. Importantly, the processes we wish to investigate are dynamic and complex and cannot be recreated by in vitro experiments or understood by assessing tissue specimens. Animal models allow us to understand how specific cell types in endometrial tissue function and how they respond to different signals that would not be possible using other approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

An expert statistician has been consulted about the experimental design of the studies and statistical calculations have been used to predict the minimum number of mice to be used. These calculations have been informed by our previous experience using the mouse model of endometrial repair and studies we have conducted investigating the impact of hormones on reproductive function.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design has been informed by NC3Rs experimental design hub resources and will adhere to the PREPARE guidelines on how to design conduct experiments (https://norecopa.no/prepare) which have been developed with the involvement and support of the RSPCA. We referenced guidelines for animal colony management to ensure safe, reliable, and efficient animal breeding of genetically altered mice that we will need to conduct the studies in this project (Jackson Laboratory Resource Manual; Breeding Strategies for Maintaining Colonies of Laboratory Mice).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In vitro work and studies on human tissues/cells will be carried out in parallel with all animal experiments to inform choice of targets for analysis and ensure we investigate mechanisms that have the most relevance to human health. Our studies will have broader relevance to researchers investigating the roles of hormones in regulating inflammatory responses in other tissues and as such sharing of tissue will be encouraged as much as possible. Efficient breeding strategies will be informed by NC3R's Breeding and colony management resources (https://nc3rs.org.uk/breeding-and-colony- management) and by completing specific training in mouse genetics/breeding provided by MRC Harwell (https://www.har.mrc.ac.uk/training/).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The architecture of the reproductive system in female mice mirrors that in women and there are close parallels in hormone regulation of womb function between the two species both of which are mammals. We have developed mouse models of menstruation and endometriosis and validated that they recreate key features of tissue recovered from women giving us confidence that they are robust models for studying these processes and their regulation.

Mouse models allow use of animals in which expression of key factors required for immune cell or hormone function can be changed genetically. This approach is more refined than using chemical mediators or drugs which can have off target effects thereby minimising risk of suffering. This approach will allow us to identify key mechanisms unambiguously ensuring results are robust and meaningful thereby minimising animal use.

The surgical procedures used in this project are well validated and have been used in this context since 2014. We are expert in handling and administering the procedures and therefore animal distress is minimised. In using these methods we carefully monitor animals and ensure appropriate anaesthesia and analgesia is used at all times to minimise pain, suffering and distress. The hormones we use in our methods mimic normal changes that occur in the animals and any additional drug treatments used are at doses known to be non-toxic. At the end of procedures animals will be humanely terminated using Home Office approved methods.

Why can’t you use animals that are less sentient?

The architecture of the reproductive system in female mice mirrors that in women and there are close parallels in steroid regulation of endometrial function between the two species both of which are mammals. Species such as worms and flies do not have an endometrium although they do have factors that are the equivalent of steroid hormones.

We cannot fully explore complex cell-cell interactions in the endometrium using cell culture models. Menstruation and endometriosis only occur spontaneously in women and higher primates, however, we have developed mouse models of menstruation (endometrial wounding and repair) and endometriosis which have provided an ideal platform for understanding how hormones, immune cells and progenitors contribute to these complex processes. These methods require adult mice as mice at this stage have a mature hormone, immune and reproductive system which is necessary to see the appropriate changes and responses that are recapitulated by the model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

My group will consult closely with our local expertise and utilise the extensive resources provided by the our website to ensure we are following current best practices. As other

more refined approaches become available during the course of this license either through personal communication, publications or veterinary advice, we will investigate their use following discussion with the NACWO, NVS and Home Office Inspector before incorporating them into our plans.

For example, our facility has adopted improved rodent handling methods that reduce animal stress and now provide environment enrichment as standard which we have adopted.

In addition, we have extensive experience of the surgical procedures and required post-operative care and pain management. In order to improve our monitoring we have introduced digital records to ensure all members of the team and facility staff/NVS can access these throughout procedures.

We also plan to evaluate animal behaviour using new non-invasive in-cage systems. Importantly this system is operator blinded and allows repeated (longitudinal) monitoring of a single animal controlling for intra-animal variability and reduction in animal numbers. This will give refined insight into animal experience on our protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will routinely consult the NC3R's website (https://www.nc3rs.org.uk/) experimental design hub resources and will adhere to the PREPARE guidelines on how to design conduct experiments (https://norecopa.no/prepare) to ensure experiments are conducted in the most refined way.

We will also take full advantage of the local Animal Welfare Committee annual seminar day to find out about pioneering developments in best practice and methods to improve animal welfare.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To ensure our experimental approach minimises welfare costs to animals, we will seek to incorporate any new refined approaches, identified via personal communications, publication or veterinary advice, to our studies.

We will also routinely consult the NC3Rs website (https://www.nc3rs.org.uk/) and take full advantage of the Animal Welfare Committee's annual seminar day to find out about pioneering developments in best practice and methods to improve animal welfare.

Any adaptations will take place following discussion with the NACWO, NVS and Home Office Inspector before incorporating them into our plans.

129. Prevention and treatment of sepsis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Infection, Vaccination, vaccine

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to understand how bacteria cause infections, and will use that knowledge to develop vaccines, and other interventions that might prevent transmission or infection progression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Bacteria can cause mild infections that clear up quickly with antibiotics, but can also cause more serious invasive infections such as bloodstream infections. Although rare, these serious infections can be devastating, with mortalities of around 20% even with modern treatment. A better understanding of how bacteria move from one part of the body to another and from one person to another, combating the immune response, will help us to

develop interventions to prevent these events, and help with vaccine development. In an era where bacteria are increasingly resistant to antibiotics, such knowledge and interventions are much needed.

What outputs do you think you will see at the end of this project?

The project will deliver new information about how infection spreads and help to develop better interventions to prevent transmission and limit the progression of an infection, potentially with new treatments that can act alongside standard antibiotics. The project will increase our understanding about how the immune system responds to infection and is predicted to deliver new vaccines that prevent infection.

Who or what will benefit from these outputs, and how?

Patients and the wider public will benefit the most from such research. Outbreaks of some infections cause huge inconvenience and sometimes deaths. By understanding the scientific factors that influence infection transmission this project will hopefully inform guidance on how to prevent or limit outbreaks. Research might also identify a need to monitor certain strains of infection that are more liable to cause outbreaks.

The proposed work will also assist in development of vaccines, especially noting the increase in bacteria that are no longer responding to antibiotics. For the most common types of bacteria, there are often no vaccines at all. Although vaccines often take at least a decade for development, the recent covid-19 pandemic has demonstrated that it is possible to accelerate vaccine development when necessary.

How will you look to maximise the outputs of this work?

The outputs of this work will be discussed with those who influence policy in public health.

The findings of the work will also be fed back to relevant patient support groups and published in peer reviewed journals. The work will also be presented at national and international meetings, to ensure stakeholders in the wider academic and pharma communities are aware of relevant findings. at an early stage.

Species and numbers of animals expected to be used

- Mice: 4000 although this is a maximum

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Much of our research relies on understanding a normal immune response to infection, and aims to develop vaccines, so it is important to model infection in a mammalian system that has working circulation and immune systems similar to humans. To achieve this, we will use adult mice. Other animals lack the necessary immune cells to make, for example, antibodies and lack the circulation systems of mammals. Furthermore, since many infections affect mucosal membranes and skin, it is important to use a model system that breathes air similar to humans and produces immune responses in surface layers of the body similar to humans. This can only be modelled in mammals and the mouse therefore represents the most conservative and appropriate system to use avoiding use of higher mammals or mammals from the wild. It is possible to use mice that have been modified to better represent humans, or that are deficient in a specific immune factor that is under investigation. Adult mice are required since immune responses and the bacterial living in the gut are fully developed and stable by then, meaning that the outcomes of infection experiments are more reproducible between individuals.

Typically, what will be done to an animal used in your project?

Our project is focussed on infection, therefore all of the protocols include an infection step-other than the preliminary stages of testing a new vaccine or treatment. In all cases we may need to test an animal's baseline level of immunity, and also check what bugs the animal is already carrying; we can do this by taking a small blood or saliva test, and by sampling the nose or mucous membranes beforehand.

In some cases, mice will be infected via the nose, and monitored daily to find out how long the infection is carried in the nose. These infections are usually limited to 7 days as most mice clear infection within a week. Mice are checked daily to see if they are carrying the bacteria. Mice do not get sick or show any symptoms from this infection because the volume administered is tiny.

Some mice may receive an inoculation onto, into or just under the skin, while others might be receive an injection into the muscle in a small volume similar to a vaccination. These mice will usually only be infected for a maximum of 24 hours.

During the infection period, small blood samples may be taken to check for bacteria in the blood. We will weigh animals regularly as this provides an early indication about the infection progression.

Occasionally mice may be anaesthetised during infection to allow us to monitor infection more closely. At the end of any infection model, the bacteria are counted from the site of the original infection and also from as many organs as possible, including the blood.

To understand the effect of novel treatments, or of specific components of the immune response, we will sometimes administer a medicine or antibody to the mice, either before, or during the infection. This might include antibiotics, because it is important to understand how novel treatments work together with routine treatments that patients receive. When we use antibiotics, we choose doses and dosing gaps that are as close as possible to

what is used in humans (the doses are based on weight, therefore we follow doses used for newborns). Most substances are administered intraperitoneally (into the abdomen) or intravenously (into a vein) for easiest rapid spread into the bloodstream. Mice that are infected, are then monitored for progression of infection.

To evaluate vaccines we will need to administer vaccines before any infection. Vaccines are generally made from one or more components of a pathogen, combined with a chemical called an adjuvant, which is a substance that promotes an immune reaction. Vaccines are usually given as injections into muscle or under the skin as in humans and are given on a schedule every 2-3 weeks (usually no more than 3) until immunity develops- this is tested by a blood or saliva test. After the vaccination schedule is completed, mice will be infected and the progress of the infection is monitored, comparing mice that received a test vaccine with those that received a sham (fake) vaccine.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice that experience nasal infection are not expected to undergo any adverse events, although some may experience reduced appetite/eating less for 24-48h; invariably all mice quickly recover from this.

Mice that experience intramuscular infection may experience some pain; although experiments do not normally last more than 24h pain killers will be used if required.

Any mouse that is undergoing a bacterial infection administered into the skin or muscle may show signs of infection, such as eating less, or ruffled fur but these experiments do not last more than 24h.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

Overall for this project, it is estimated that for mice, 40% will undergo mild severity and 60% moderate severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project aims to understand how infection progresses in individuals and between individuals; this can only be modeled in living animals or humans where the circulation is moving, and where breathing is ongoing. Although humans can be used to model infections in so called 'human challenge' models some infections are considered too dangerous for human- while mice appear to tolerate these much better than humans. The project also aims to develop vaccines: Most vaccines being developed aim to protect children early in life. One other problem with human challenge models is that adult humans often have immune responses to the infections being studied, making them poor experimental subjects. Furthermore, having a model system that can reproduce immune responses similar to humans is invaluable. This would not be possible with fish or insects.

Which non-animal alternatives did you consider for use in this project?

To study the immune response to infections, we already use samples from patients with the same infection. We also use human blood cells as a model system although it is necessarily a static system and limited to the cells in a tube- this cannot mimic the dynamic movement of immune cells to an infection site.

Why were they not suitable?

These samples provide very useful information but do not allow us to undertake experiments or test new interventions or vaccines.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use statistics to help us decide the lowest possible number of mice needed to get a meaningful answer to a specific question. The projected number of animals reflects our best estimate of the number necessary to achieve the proposed scientific objectives. We also considered the number of mice funded in our new grants, as well as an estimate of transgenic breeding required to deliver the required numbers. We estimate that a maximum of 700 per year might be used in infection protocols if our vaccine projects are active however this is an upper estimate and the actual number used is likely to be very much less.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experiments incorporate longitudinal monitoring (monitoring of the same mice over a period of time) thereby greatly reducing the number that need to be infected at individual time points by 5-fold, depending on the number of time points.

We also try to identify a suitable fixed single time point to end an experiment; this ensures that we obtain as much quantitative (numeric) data as possible from that final, planned time point. This has largely replaced the practice of waiting for a particular symptom to develop, as the practice is too unpredictable and does not take animal welfare into consideration.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will undertake pilot experiments using a very small number of mice on each occasion where there is a new variable, for example, a new bacterial strain type, as the effect of the new strain will be unknown. This information will be used to undertake statistical tests to ensure the optimum number of mice are used per group, wherever practical.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use intranasal models of infection, and soft tissue models of infection. Some mice will receive treatments by injection, or will receive vaccinations before infection. The models used have been scientifically validated and shown to provide valuable information while emulating the disease features of human infections. The duration of infection, and dosing regimens in these models has been adjusted and improved upon over several years to avoid severe outcomes and to cause least distress.

Why can’t you use animals that are less sentient?

In order to reproduce a mature mammalian adaptive immune response to infection or vaccination, it is necessary to use mature (adult) mice.

We cannot use species that are less sentient, such as insects or fish, because these do not provide the context required to model bacterial infection in humans i.e. being able to breathe air, with a mature adaptive and innate immune response.

For a minority of infections we will use terminal anaesthesia and thus animals are not aware of the procedures.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For any model where there is a risk of systemic illness, the frequency of monitoring will be increased. Where there is a risk of pain, analgesia will be provided in advance, as advised by our veterinary officer.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to guidelines issued by LASA and NC3Rs. Furthermore, we will endeavour to report our findings accurately using ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Institutional seminars and workshops will provide continuing professional development in the 3Rs, while the NC3Rs website provides a readily available resource at all times.

130. Synaptic and circuit mechanisms for neural computation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neuron, Brain, Cognition, Navigation, Autism

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult,pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our first aim is to understand how processing and storage of information by nerve cells contributes to cognitive functions of the brain. Our second aim is to determine how this changes in models of neurological and psychiatric disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

Understanding the biological basis of human and animal behaviour will help to answer centuries old questions about the physical nature of mental processes and may be of general importance for human mental health and disorders of the nervous system, such as depression, anxiety, schizophrenia and memory loss. The general importance of the work in this project will be three fold. First, new fundamental knowledge about how the cells in the brain carry out computations that underlie core cognitive processes will answer long-standing questions about how brains work. Second, new technologies developed during the project will further accelerate progress in understanding brain functions and in investigation of models of brain disorders. Third, advances made during the project may form a basis for new rational therapeutic approaches for brain disorders for which there are at present few effective treatments.

What outputs do you think you will see at the end of this project?

We hope to produce the following outputs:

New knowledge of the connectivity between nerve cells in brain structures important for cognition.

Advances in understanding how information is processed and stored in the brain.
New insights into how new experiences and stored memories influence behaviour.
New technologies that accelerate progress in understanding the brain.
An improved understanding of how changes in information processing and storage lead to symptoms of psychiatric and neurological disorders.

Who or what will benefit from these outputs, and how?

There is a global research effort to understand the workings of the brain and how it goes awry in disorders. The outputs will contribute directly to the effort.

In the medium term we hope that a key beneficiary will be patient populations through development of new therapeutic approaches.

A further potential group of beneficiaries are computer scientists aiming to develop brain like artificial intelligence algorithms.

How will you look to maximise the outputs of this work?

We aim to publish our work in widely read and well respected open access research journals. We will communicate with members of the scientific community at relevant conferences.

We plan to continue collaborations with clinical colleagues to translate our findings to human **patient populations.**

We intend to continue and extend ongoing industrial collaborations to see commercial impacts of our research.

Species and numbers of animals expected to be used

- Mice: 10000
- Rats: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project will use mice and rats. We use these animals as models for several reasons. First, the core cognitive functions we wish to understand and their underlying neural circuitry are well conserved across mammalian species. Therefore, while details may differ in humans, the general operating principles are likely to be similar. By making advances first in rodents, it is then much easier to address whether similar mechanisms arise in the human brain. Second, while similar questions could be addressed in primates, we believe that it is ethically preferable to use less sentient species for experimentation where possible. Third, it is not possible to use simpler established models, for example flies or worms, for the questions we aim to address as these species do not employ the same cognitive functions. Fourth, a remarkable array of experimental tools is available for neuroscience experiments with mice and rats. This enables more rapid progress than would be possible using other similar species.

The project will primarily focus on mature animals as it is cognitive functions in mature animals that we wish to understand. Where development is relevant we may also investigate younger animals, for example when translating our findings to models of developmental disorders, for example autism spectrum disorders.

Typically, what will be done to an animal used in your project?

The project will typically involve two different types of experiment:

To investigate the organisation of connections between neurons, a typical experiment will involve introduction of biomarkers into particular populations of neurons, humanely culling the animal followed by removing the brain from the cadaver and then visualising the connections or assessing functionally how one population of neurons influences other populations.

This experiment requires surgical procedures for injection of biomarkers to targeted brain areas. These procedures are carried out under anesthesia and typically have duration less than 60 minutes.

To investigate information processing and storage by neurons, a typical experiment will involve recording and manipulation of the activity of neurons as animals perform cognitive tests. The recordings of neural activity will tell us what aspects of the test and its solution the neuron represents. The manipulations will enable us to test contributions of neurons to performance on the test. This experiment requires surgical procedures to implant electrodes or optical devices into the animal's brain. The electrodes or optical devices are then used to readout activity of nerve cells in the brain.
The procedures for their implantation are carried out under anesthesia and typically have duration less than 90 minutes.

What are the expected impacts and/or adverse effects for the animals during your project?
The major expected impacts arise from experiments requiring injections of substance into the brain and implantation of devices for recording from the brain. These may include transient pain and weight loss, which will be mitigated with pain relieving medication and supportive care. These procedures can be carried out with refined surgical protocols and are not typically associated with other adverse effects.
They are not expected to cause distress or suffering to the animals.

Animals may be housed singly where there is a concern of aggressive behaviour or increased likelihood of damage to implanted devices, for example for electrophysiology or optical experiments. Single housing is thought to be stressful to rodents and will only occur when scientifically justified. In such cases, the duration will be limited to the minimum period necessary and all cages will be enriched with objects for exploration and play. These methods have been shown to reduce stress in rodents.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity is not expected to be classified above a moderate level. This applies to all animals used for the project. We expect that for 80% animals the severity will be mild or subthreshold since they are only used in breeding and humane killing for tissues, while 20% will experience moderate suffering on the experimental (surgical) protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We want to understand how cells in the brain mediate its cognitive functions. Because these functions of the brain rely on sensory input and manifest as outputs that change behaviour, we can only study how they work using live animals that are able to carry our measurable behaviours.

Which non-animal alternatives did you consider for use in this project?

Computational models can be used to simulate aspects of brain function and to make predictions about how biological substrates can implement cognitive functions.
Cell culture systems can be used to study molecular mechanisms and certain aspects of communication between neurons.

Why were they not suitable?

Computational models are useful as part of an overall refined approach, but it is not possible to use them as alternatives to answer the questions we aim to address. Essentially, the models don't yet explain the cognitive functions we wish to understand. Development of better models requires data that can only be obtained with experiments in which animals use the cognitive functions we aim to understand.

Cell culture systems do not have the organisation of real brains, do not process sensory inputs and do not execute behaviours. They therefore can not be used as alternatives to answer the questions we aim to address.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate of animal numbers takes account of the experimental goals for the period of the project, the number of animals required for experimentation and the numbers required for breeding.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We aim to design experiments that test clear hypotheses and are likely to have large effect sizes and therefore conclusive outcomes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will carefully monitor breeding of animals**.**

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice and rats. We will use methods for investigation of connections between nerves cells, and for recording and manipulation of neurons in animals carrying out behavioural tests.

Why can’t you use animals that are less sentient?

We want to understand cognitive functions such as episodic memory, navigation and decision making. These functions are either absent in less sentient animals or are implemented through mechanisms that diverge substantially from those used by mammals including humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will adopt a number of refinements that minimise welfare costs, which by increasing the precision of experimental tests and manipulations will lead to clearer and increasingly specific answers to the questions we aim to address. These will often involve adopting specific molecular and ex-vivo strategies for precisely targeting single nerve cells or populations of nerve cells instead of invasive and less specific in vivo methods. We will also adopt behavioural assays that give precise control of the experimental animal’s sensory experience and clear read outs of cognitive outputs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow all best practice guidance provided by our institution. We will also follow procedures that we and others have published that establish refined methods for the specific experimental questions we aim to address.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are fortunate to be able to rely on excellent institutional support and training to stay informed about and implement advances in the 3Rs. The Home Office Liason Contact (HOLC) circulates HO guidance notes and welfare organization’s newsletters through emails. The Named Veterinary Surgeon (NVS) team and full time Named Training and Competency Officer (NTCO) work together with PIs to refine procedures and disseminate best practice ideas.

131. Improving prognosis from vascular dementia

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
vascular cognitive impairment, mice, behaviour, vascular dementia, endothelial inflammation

Animal Types	Life Stages
Mice	Adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this research project is to improve our understanding of the pathophysiology of vascular dementia in order to facilitate the development of potential treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vascular dementia is a pressing concern as there are over 150 000 people currently living with vascular dementia in the UK, but also many other types of dementia (like Alzheimer’s disease) co-exist with vascular dementia. Dementia is a global health challenge as the incidence is doubling every 120 years. There are no effective treatments for vascular dementia. Therefore, there is an extreme need to better understand how it develops and to design interventions that can help patients.

What outputs do you think you will see at the end of this project?

The main output of this work will be information. Information will be disseminated at national and international scientific meetings. Information will also be disseminated via science communications and social media. We aim to publish new information in scientific journals with open access policies so information will be accessible to the public.

Who or what will benefit from these outputs, and how?

There will be immediate benefit for the students and fellows that will gain important knowledge and this will continue as they use their skills to continue future work. There will be benefit to the wider scientific community in the mid-term via best practice recommendations surrounding the establishment of new cognitive testing strategies for animal models of vascular dementia. There will also be mid to long term benefit as the information produced will improve our understanding of the pathophysiology of vascular dementia. This knowledge will enable the development of treatment options that could result in benefit to patients and medical practitioners long term.

How will you look to maximise the outputs of this work?

We have successful collaborations with several laboratories that provide access to additional methods and analysis strategies that will allow us to examine data in novel ways. We also collaborate with neurologists that specialise in cerebrovascular research; this helps to focus the projects on tangible translational outcomes. In addition to regular publication of research findings, we have an active social media presence and engage with scientific communication to the public. I have a history of publication of unsuccessful approaches, despite the challenges associated with it.

Species and numbers of animals expected to be used

- Mice: Approximately 400 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The adult mouse is the lowest sentient species suitable to model a progressive condition in which the primary symptom is a decline in cognitive function with age. Mice can be used for a large number of outcome measures, including behavioural testing, imaging and ex vivo tissue analysis. Mice are the only animals that allow for future work that may include genetic manipulation and this would be the next step to confirm new knowledge generated by this project.

Typically, what will be done to an animal used in your project?

Typically, mice will undergo behavioural assessments that mainly focus on testing memory. Most of the tests can be conducted within two weeks. Some mice may undergo

daily testing in an automated chamber that will test decision making and rule learning. These mice will undergo food OR water restriction to motivate performance. This would be the experience for approximately 20% of the mice, but weight will be monitored daily to ensure that animals do not drop below 85% of free feeding weight. Furthermore, the mice would have access to high value food rewards while performing this test.
Typically, mice would undergo a surgical procedure to reduce blood flow to the brain, or a sham surgical procedure. Both procedures involve an incision and implantation of restricting (or non- restricting in the case of sham) devices on both carotid arteries. The animals may lose up to 3% of body weight after surgery, and they would be monitored daily. Typical behavioural assessments would be repeated between 2 and 6 weeks post-surgery, following recovery. During the entire 2 month period, there may be an MRI scan. This would be the experience of approximately one third of the animals. The animals will typically be killed by perfusion fixation at the end of the study and tissue harvested for investigations. A typical mouse would undergo one surgical procedure and behavioural testing, and would be killed after 2 months.

What are the expected impacts and/or adverse effects for the animals during your project?

All animals that undergo food OR water restriction (these procedures will not be performed at the same time) will experience hunger or thirst and this is mildly adverse. Some animals may experience weight loss, but this will not be allowed to drop below 85% of free-feeding body weight. Mice will be without food for a maximum of 23 hours, or water for a maximum of 16 hours per day. The minimal amount of restriction required for motivation will be employed. To minimise stress, mice will be supplemented with extra food/water on the weekends and diet is supplemented with high value rewards in the automated chambers (some mice perform in excess of 200 nose poking trials). There are no other adverse effects associated with the other behavioural tests apart from mild stress. This will be controlled with appropriately handling and habituation. There is stress associated with swimming in the water maze.

The water is moderately adverse in order to motivate escape. Stress will be minimized by ensuring the water is of an appropriate temperature, and initially habituating the mice to the maze with a visible platform so they quickly learn how to escape. Animals will be hand dried and kept in proximity to a heat source to assist with drying.

All animals will experience moderate discomfort and pain at the incision site as a result of the surgical procedure. Analgesics will be provided to assist with post-operative pain relief. However, it is difficult to distinguish shams from hypoperfused animals. Hypoperfused animals generally lose no more than 3% of body weight, which recovers to baseline within 4 days. Condition will be recorded and monitored once per hour until recovery and at least 3 times in the first 24hrs. Animals will be humanely killed if they exhibit signs of poor health that would exceed the moderate severity banding.

All animals will experience moderate discomfort as a result of the anaesthetic procedure required for MRI. However, recovery generally occurs quickly (within an hour) and there are no signs of abnormal behaviour or distress. Nevertheless, scan times will not exceed 4 hours and there will be no more than 2 scans in the animals’ life time.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

All mice will experience moderate severity. The hypoperfusion surgical procedure requires anaesthetic and mice will experience pain surrounding the incision site following recovery. They may also experience mild weight loss (3%) and develop cognitive impairments with time. The mild stress associated with any accompanying behavioural tests will not exceed this moderate severity limit.
Approximately 20% of the mice will undergo food or water restriction to motivate performance in the operant conditioning chambers. The minimum amount of restriction required to produce motivation will be employed. Animals will be supplemented with food/water over weekends. This procedure will also not exceed moderate severity as there is no lasting pain or harm. The additional anaesthetic associated with an MRI scan (approximately 1/3 of animals) is also not anticipated to exceed the moderate severity banding. While there is some stress and anxiety associated with the anaesthetic, there is no pain or lasting harm and the mice generally recover very quickly.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no suitable alternative to animals to model a chronic, progressive, and heterogeneous condition in which the primary symptom is a decline in cognitive function. We wish to assess complex behaviours, and this is not possible without animal models.

Which non-animal alternatives did you consider for use in this project?

We considered using in vitro preparations, for example, induction of inflammation in endothelial cell cultures. We have also considered mathematical modelling as an alternative to animals.

Why were they not suitable?

We use in vitro cell culture preparations routinely to examine cellular changes and molecular pathways. However, it remains impossible to extrapolate these findings into cognitive changes at the level of the whole organism. In vitro cell culture preparations will complement our in vivo approach, they just can not replace them completely. Mathematical models require some input, and there are too many unknown variables to predict. However, we are currently using mathematical modelling with some of our neuroimaging data to obtain a preliminary understanding of the changes in the brains of our animals in response to vascular risk factors. This information could be applied to future experiments as a possible replacement strategy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

There are several strategies that can be used to approximate the number of animals required. One strategy involves comparison to existing literature, and group sizes tend to be in the range of 5-8 for this model. We have found that small group sizes tend to have higher variability and particularly for behavioural measures, group sizes of approximately 12 animals result in predictable variability.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have applied the principles of Good Laboratory Practice to design experiments. We have carefully considered the requirement of control groups, such as sham procedures to control for the effects of anaesthetic, surgical incisions, analgesics and pre or post-operative care on behavioural outcomes, or, on the vascular inflammatory responses we wish to measure. We have also considered the feasibility of using the same group of animals to address multiple objectives (ex vivo tissue samples or imaging to follow a cohort). We have made use of the NC3Rs Experimental Design Assistant (I collaborate with some members of the EDA working Group) and this tool will be used to help design study protocols.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have specifically requested the ability to perform essential pilot studies to help refine new outcome measures. We have also received mouse brain tissue samples from collaborators using this model to help shape some of the objectives of our experiments. For example: we have found evidence of inflammation in the endothelial cells from the brain sections.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Model:

The only available models of sporadic (environmental rather than genetic) vascular dementia are produced via hypoperfusion to the brain. These are considered refined as there are few adverse effects associated with the surgical procedure required to induce

brain hypoperfusion. Aside from some pain due to the incision site, and distress associated with anaesthetic, animals generally recover well following surgery. They are indistinguishable from shams and do not exhibit excessive weight loss.
They maintain the ability to feed, groom, move or climb. In mice, the most refined hypoperfusion procedure is accomplished via stenosis of the carotid arteries with small microcoils, as complete ligation can lead to severe outcomes.

Methods:
Behavioural testing:

The most refined methods for non-aversive handling will be used wherever possible throughout the experiments.

The most refined methods to examine executive function involve operant conditioning. The mice are offered high value food rewards in exchange for correct responses (nose poking into light cued holes). Food OR water restriction is necessary as high value rewards are not sufficient to induce poking responses in all mice. Food restriction represents the most refined method of motivation as hunger causes the least amount of distress. The animals will be without food for a minimum of 4 hours and up to a maximum of 23 hours per day for a maximum of 12 consecutive weeks. We aim to refine this by employing the minimal amount of restriction time required to motivate the animals to perform in the behavioural test. Weight loss will not reduce to less than 85% of free-feeding body weight and animals will be returned to free-feeding status if weight can't be maintained at appropriate levels. Water restriction represents the next most refined method to motivate performance and is preferred in situations in which dominant animals may hoard food. The animals will be without water for 12-16 hours prior to testing for a maximum of 5 consecutive days. We aim to refine this by employing the minimal amount of restriction time required to motivate the animals to perform in the behavioural test.

Weight loss will not reduce to less than 85% of free-feeding body weight and animals will be returned to free water status if weight can't be maintained at appropriate levels. Both restriction regimes have been published extensively, and while there is evidence that water restriction results in better performance in operant conditioning tasks, the discomfort scores are slightly higher than those when mice are food restricted. However, discomfort scores under both regimes were categorised as mild (Goltstein, et al., 2018. PLoS ONE. 13: e0204066).

The Y, radial arm and water maze are the most well characterized, widely published tests to benchmark spatial learning and memory. They are considered the most refined, as deficits are predictable with a minimal amount of distress for the mice.

The water maze is the only test that is associated with distress that can't be alleviated with handling and habituation. The animals will find the water uncomfortable (it is the aversive stimulus required to motivate escape). To minimise distress, the water will be warmed to 24 ± 2°C and mice will not undergo more than 4 trials per day (no more than 90s per trial) and there will be an inter-trial interval of at least 20 minutes. Animals will be hand dried with paper towels and kept in proximity to a heat source to assist with drying.

Cognitive tests that do not require spatial navigation may also be employed to assess short term memory. Novel object recognition allows animals to explore an environment with new objects. This test is considered the most refined test of object memory as distress or discomfort is unlikely.

Mice may also undergo simple sensorimotor tests to ensure cognitive deficits are not due to underlying sensorimotor problems. The rotarod is the most refined as it is well characterized and widely published whilst only being associated with a mild stress for the animals due to the short fall.

Magnetic resonance imaging:

MRI can be considered the most refined method to measure various aspects of brain structure and function, as it is completely non-invasive. The distress that is expected will be due to the anaesthetic, but there will be no pain or lasting harm.

Why can’t you use animals that are less sentient?

We have selected the mouse as the lowest sentient species suitable for replicating cognitive behaviours that occur as a result of the interaction between the vasculature and the brain. Mice can be used for a large number of outcome measures, including behaviour, imaging, and ex vivo tissue analysis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Model:

To minimise harms for the animals following surgery, pain relief (analgesics) will be provided with consultation from the NVS. All animals will be provided with wet diet to assist with feeding and appropriate fluid replacement, until weight stabilises. Animals will be monitored once per hour until

recovery and at least 3 times in the first 24hrs. In the following days, animals will be monitored at least twice a day until weight stabilises.

Behavioural testing:

To minimize the discomfort associated with food restriction, animals will be maintained at 85% of initial free feeding weight (measured daily) and the shortest possible restriction times that still result in motivation will be used. Typical water restriction schedules allow 1hr of unlimited access to water within every 24hr period, but we will use the shortest restriction schedule possible to still motivate poking responses. Weight will be monitored daily.

Stress will be minimized in the water maze by maintaining the water temperature above 20°C (24 ± 2°C
). Stress can also be reduced by initially habituating the mice to a visible platform so they quickly learn how to escape. Limiting trial times will minimize fatigue and mice will be dried and kept in proximity to a heat source before being returned to their cages.

Magnetic resonance imaging:

The distress associated with MRI will be minimized by restricting the number of measurements and measurement time (4hours), for each animal. Animals will not undergo more than 2 imaging sessions over the course of their lifetime, and there will be a

minimum 24hrs between sessions in order to allow adequate recovery time from the anaesthesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Good Laboratory Practice, the ARRIVE guidelines, and relevant NC3Rs guidelines to ensure experiments are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly monitor the 3Rs webpage and Twitter feed, and follow all communications. If advancements that could help refine our models occur during the course of the study, we will be enthusiastic about implementation.

132. Evaluation of cancer therapies in orthotopic cancer models

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunology, Orthotopic, Therapy, Vaccine

Animal types	Life stages
Mice	Adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to evaluate identified cancer therapeutics which can be used to prevent or treat orthotopically implanted cancers.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite significant progress, cancer continues to be a major cause of mortality in humans with the lifetime risk of an individual developing cancer in one form or another being approximately 1 in 2. Approximately 440 people die of cancer every day in the UK (Cancer Research UK statistics).

Although current treatments such as radiotherapy, chemotherapy and hormone treatments can be effective against primary and secondary cancers, they can be associated with significant toxic side- effects, and therapeutic resistance often occurs. The spread of primary disease to other tissues (metastasis), tumour relapse and resistance to therapy remain the principal causes of death for patients with cancer. Metastasis is a particular problem and accounts for ~90% of cancer-related deaths.

What outputs do you think you will see at the end of this project?

The outputs of this project will include;

- Publications in Open Access Journals.
- Dissemination of information at National and International Conferences.
- Identify a treatment approach that could progress to a clinical trial.

Who or what will benefit from these outputs, and how?

The immediate benefit from this project will be for basic science by producing world-leading and internationally recognised work that will be published in high impact journals.

Output from this project may be utilised by others including preclinical academics, industrial partners and clinicians. We will disseminate our results via both National and International conferences and workshops.

While Basic science will benefit in the short-term (1-3 years), clinical impact may take a longer period to be achieved. This may have the potential to be a therapeutic or diagnostic tool.

The time taken to fully evaluate a given therapeutic or diagnostic tool is likely to go beyond the five-year duration of the programme of work due to the complexities involved in the research.

How will you look to maximise the outputs of this work?

The collaborations and services provided will lead to both the furthering of our existing knowledge and build new knowledge surrounding treatments in orthotopically implanted cancer. This may lead to joint applications for funding if the results show promise.

It is anticipated that the findings from these outputs may be disseminated through peer-reviewed journals, conferences and marketing materials.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All of our experimental procedures will be performed in either wild-type or genetically-altered mice models. All the studies in this project will use adult mice from 6 weeks of age.

Mouse models have many similarities to humans in terms of anatomy, physiology and genetics in the way tumours metastasise. The animals used in our research will help us understand the mechanisms that underpin cancer, such as the growth and spread of tumours, and to develop new ways of diagnosing, treating and preventing the disease.

Mouse models are essential in cancer research. They are used to understand the genetic basis of tumour development and cancer progression. The MHC transgenic mouse models we propose to use have the same HLA haplotypes as humans for Class I and Class II which makes the results obtained more translatable in humans. They can also be used to test the efficacies of different anti-cancer agents. Moreover, in translational cancer research, they represent a powerful tool in assessing the potential validity of targeted therapy because the targets can be precisely studied in the setting of a developing or developed tumour.

Typically, what will be done to an animal used in your project?

Typically actions in this project include:

Implantation of tumour cells orthotopically

Administration of substances

In vivo imaging Blood sampling

Animals will be humanely killed at the end of the experiment

The animals will be implanted with tumour cell lines orthotopically to establish the appropriate tumour growth rate. Blood samples may be taken from a superficial vessel under terminal anaesthesia. Imaging may be performed up to three times a week in which case the animals may be injected with substrate prior to induction of anaesthesia and placement into the in- vivo imager.

The animals in this project may be injected on more than once occasion with test items (by one or more of the following routes -subcutaneous, intravenous, intraperitoneal, intradermal, intramuscular, intranasal, gene gun, gavage, topical, drinking water, diet or infusion via a pump or pre-implanted cannula(e) attached to a subcutaneously implanted mini-pump.

The typical duration of these types of studies will vary from between 4 weeks to 12 weeks and beyond dependent on the design of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that animals may experience moderate discomfort as a result of tumour cell implantation and the pump or pre-implanted cannula(e) if fitted. Some animals will experience mild transient discomfort during this project as a result of administration of substances, blood withdrawal and in vivo imaging.

A bodyweight loss of up to 18% may be observed up to 5 days post-surgery, however, recovery would be expected after this time.

Following 5 days post-surgery if the onset of clinical signs such as lethargy, ataxia is observed, the animals will be monitored on a more frequent basis, (at least 3 times a day). If weight loss of up to 15% in combination with other clinical signs is observed, which would indicate a deterioration in the physical condition of the animal, and it is at this point the animal will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is inevitable that a small proportion of animals will show adverse effects, due to the nature of the intervention.

The severity level of this project is moderate and it is anticipated that approximately 94% of the animals used will fall under this severity level.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although this research employs an extensive portfolio of in vitro laboratory techniques, these cannot adequately model the complete array of biological and immunological events that are involved in tumour growth and microenvironment or the generation of protective anti-tumour immunity, all of which are important to our understanding of tumour

immunology and the development of new therapeutic strategies in orthotopically implanted tumours. In -vivo studies in mouse models are therefore essential as they have the integrated physiological systems which are required.

Which non-animal alternatives did you consider for use in this project?

2D and 3D cell cultures can be used to some extent to assess the effect of a given treatment on a tumour cell line in vitro, however, they cannot completely replace the information gained from animal experiments as the entire tumour microenvironment is difficult to replicate in the laboratory.

Why were they not suitable?

In -vitro studies can produce valuable information, however, they cannot mimic the exact in -vivo environment to exhibit the effects that a whole biological system has on disease progression and therapeutic intervention.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals have been estimated based on previous usage and expected usage (up to 30 animals per study) based on conversations with researchers and service users.

In-house discussions with a biostatistician were held to review our experimental designs and the numbers are also based on our previous usage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will ensure that we use the minimum number of animals required to answer the scientific question by performing power calculation studies. We will also apply the NC3Rs experimental design assistant tool for appropriate experimental planning. We will regularly consult qualified statisticians about experimental design and perform imaging and histology for tumour evaluation where possible. We will regularly consult with the qualified statisticians about experimental design and statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Both sexes of animals may be used in the experiments.

Double transgenic (2 genetic modifications) will be used whenever possible, thereby reducing the number of animals being used.

Pilot orthotopic tumour growth studies will be performed where appropriate to establish tumour growth rates prior to use in the prophylactic and / or therapeutic studies.

All experiments using live animals will adhere to the ARRIVE guidelines on design and reporting. Good principles of experimental design will be applied to ensure sufficient group sizes will be used to adequately test the hypothesis. Sample sizes are estimated from pilot studies and previous data using power analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically-altered mice bred and maintained are of a non-harmful phenotype. Prior to implantation all cells are prepared in a sterile environment and are administered using sterile technique.

Cells will be administered orthotopically in a sterile manner under general anaesthesia. Animals will receive analgesia pre and post-surgery in order to mitigate pain and discomfort.

Substances are prepared and administered using sterile techniques. The route of administration is via the least invasive method appropriate to the model. The volume of substances to be used will be in accordance with the Laboratory Animal Science Association (LASA) good practice guidelines.

Pilot studies will inform on tumour development and end-points prior to moving into a therapeutic setting and these will be used to determine the most appropriate method of assessment of tumour development. It is anticipated that some animals will be monitored using body weight measurements and some animals will be monitored via imaging which will require transient anaesthesia to immobilise them while an image is acquired. Once completed, the animals are expected to make a full recovery within 30 minutes. Each method will allow us to identify tumour growth rates and end-points.

Blood sampling will be performed using sterile techniques and volumes collected will be in accordance with the LASA / NC3Rs guidelines. We will aim to take the smallest volume which will allow for adequate analysis.

All animals will be humanely killed a Schedule 1 method.

Why can't you use animals that are less sentient?

The studies proposed in this project could not be undertaken in animals with a lower form of immune system (e.g. drosophila, C.elegans) because those models do not show comparable responses that are seen in humans. Furthermore, to achieve the maximum relevance and utility from this project, it is essential that we use genetically altered transgenic mouse models e.g., for particular human HLA types as these have been used previously and identified areas of interest which will be investigated further under this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Over the last 5 years, a number of refinements have been made and considerations to refinements is an ongoing process. The procedures that are in place to administer substances and monitor the animals will be reviewed regularly and techniques will be refined where possible and additional monitoring is performed where necessary and is carried out by the PIL holders. Any relevant refinements made are discussed and disseminated to the other users by the animal care scientists.

The Veterinary surgeon also observes the work undertaken under this project and will offer suggestions for refinements where necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines published by the Workman Group on welfare and use of animals in cancer research published in 2010. The ARRIVE guidelines Animal Research: Reporting of In Vivo Experiments) and LASA Good Practice Guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will maintain close interactions with the relevant welfare, training and information officers as they oversee and perform in vivo studies. The PPL holder will stay informed of advances in the 3Rs by regularly checking the NC3Rs webpages (https://nc3rs.org.uk/the-3rs) and newsletters which are circulated monthly.

Moreover, the PPL holder will attend appropriate seminars, symposiums and conferences deemed suitable.

133. Production of antibodies, antisera and blood products iii

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Blood products, Tissue samples, In-vitro diagnostic reagents, Controlled environment, Antibodies

Animal types	Life stages
Rabbits	adult, juvenile
Llamas and Alpacas	juvenile, adult
Pigs	juvenile, adult
Animal types	Life stages
Goats	juvenile, adult
Sheep	juvenile, adult
Cattle	juvenile, adult
Guinea pigs	juvenile, adult
Mice	juvenile, adult
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This service provided under this project licence will supply in-vitro diagnostic reagents and animal tissues to research groups and biomedical companies, nationally or internationally to further their fundamental and applied research for the development and application of research projects and new treatments in support of human and animal healthcare.

This includes:

- Provision of blood products Provision of tissue samples
- Production of antibodies to microorganisms e.g. bacterial / viral antigens for use in diagnostic tests
    - Production of antibodies to purified peptides / proteins

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This service provided under this project licence will supply in-vitro diagnostic reagents and tissues for ex-vivo studies to laboratories, nationally or internationally and underpins research ranging from fundamental or specific disease focused basic research to the commercial development of new treatments in support of human and animal healthcare. Antibodies play a part in many aspects of today's drug discovery and development. The antibodies can be then used in a multitude of applications, including but not limited to western blot (WB), immunoprecipitation (IP), immunofluorescence (IF), immunohistochemistry (IHC), chromatin immunoprecipitation (ChIP), and flow cytometry (FC). As a cornerstone of the body's immune response, antibodies can provide significant data to support scientists' research.

Drug discovery starts with identification and validation of targets, and antibodies are the gold standard when it comes to the specific detection of an interesting biomolecule or pathway. Most life science laboratories use antibodies in some way. Due to their outstanding specificity they make exquisite tools that allow researchers to identify molecules that cannot otherwise be identified. Thus enabling conclusions to be drawn about the target molecule and pathway of interest. In addition, the management of infections, in humans and animals, due to microorganisms is aided by the use of appropriate antibody diagnostic tests. Polyclonal antibodies are invaluable tools for research and diagnostics. The main reason for this is their ability to provide signal amplification. These antibodies can bind to several epitopes of the same antigen. Thus, several antibodies can bind to the same target antigen, leading to a strong signal or more effective capture of the target antigen. The use of antibodies in research has been the cornerstone of numerous discoveries and they will continue for the foreseeable future. The use of whole blood and its products is a key step in large numbers of research projects. Be this as a source of immune cells, all major immune cells can be found in the most natural condition in freshly drawn peripheral blood. In addition, peripheral blood is increasingly used to obtain stems cells. Or as a reagent within a particular in-vitro test. For example for:

- Addition to microbiological media to grow fastidious microorganisms Production of standard reagents for laboratory procedures or diagnosis

- Developing techniques for determination of immunological response (e.g. ELISA or RIA) Normal negative controls for diagnostic assays
- Dilution of antisera for diagnostic assay kits

This licence will provide whole blood and its products to aid research and development projects. Where possible, this will be obtained from other sources (e.g. abattoir, butcher). On occasions the use of abattoir blood isn't appropriate. For example, if it is not possible to guarantee the sterility of blood obtained from an abattoir. As it is not possible to sterilise whole blood products, blood must be collected aseptically from a live animal.

Isolated tissue and organ preparations allow researchers to investigate the physiology and pharmacology of various tissue samples in a controlled environment without the complications of an intact animal model. These in vitro/ex vivo experiments can be performed using a variety of tissues and organs including smooth muscle, skeletal muscle, cardiac muscle, gastrointestinal and urogenital tissue samples. Because of the high metabolic activity of certain tissues, especially hearts it is not possible to obtain these tissues from other sources or after the animal has been killed using a schedule 1 method, due to the prolonged times and crude extraction procedures of non-research facility removal protocols.

For hearts it is necessary for the explantation process to be carried out under controlled conditions by trained personnel with immediate cardioplegic arrest (minutes), in order for the samples to remain alive and viable for the ex vivo studies. These tissue samples must be removed under terminal anaesthesia.

What outputs do you think you will see at the end of this project?

Research undertaken using tissue samples or antibodies supplied via this project licence will be used to advance the science of the respective projects.

This will either be by the progression of the strongest candidates into clinical development with the intention of developing marketable products or the development of new processes or equipment to aid recovery or quality of life of patients.

They will lead to an increase in the understanding of the underlining biology behind the diseases investigated.

The data generated from these studies will be used to help the researcher understand the biology behind the diseases of interests. Data will also be used for filing new patents and thus disseminated through the patent publication pathways.

In addition, to patent applications, scientific publications and conference presentations will be used to disseminate key scientific findings and promote the general advancement of the research studied.

Who or what will benefit from these outputs, and how?

In the first instance the tissue samples and antibodies generated from studies will aid the researchers in their continued research. Allowing for the continued research for new treatments for diseases which will lead to their further development (e.g. in clinical trials) and could potentially lead to new therapies being introduced to the market.
Long term, the research projects have the potential to significantly enhance the quality of life for people and animals suffering from diseases or potentially cure them. This will

benefit the whole society via reduction in absenteeism from work or school and reduction in demand on health services.

How will you look to maximise the outputs of this work?
Our commercial client will, where not confidential, look to publish the information via scientific publications and conference presentations in addition to patent applications. One of the key goals of our academic clients will be to p**ublish the results via scientific publications and conference presentations, in order to promote the general advancement of the fields studied.**

Species and numbers of animals expected to be used

- Cattle: 300
- Sheep: 375
- Goats: 135
- Pigs: 450
- Camelids: 60
- Mice: 350
- Rats: 350
- Rabbits: 110
- Guinea pigs: 275
- Turkeys: 150
- Chickens: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All animals will be juvenile or adult. These two categories are included as the immune system changes during development and specific ages of animals maybe required. This species included in this licence are: Camelid, Cattle, Pig, Sheep, Goat, Poultry, Guinea pig, Rabbit, Rat and Mouse.

In the first instance the species selected are the most relevant to the scientific aims of the particular project. Each individual requestor will be required to justify their species of choice as part of the formal request. These requests are often very specific in the nature of the samples or antibodies required and they are not available commercially. We are able to meet these very specific needs.

While we may use multiple species in a number of the protocols, we predict that pigs will be the species used the most to supply tissue samples. For example, pig hearts are very similar to humans and therefore the pig would be the species of choice for this research area. Because of the high metabolic activity of certain tissues, especially hearts, it is not possible to obtain these tissues from other sources. This is due to the prolonged times it takes to collect these samples and the complicated process required to successfully remove the organs.

For antibody production, camelids, sheep and goats will be the species used most often. Camelids produce specific antibodies called VHH fragments. The unique size and structure of these antibodies mean they are able to bind to hidden antigens that are not accessible to whole antibodies, for example the active sites of enzymes. Sheep and goats' antibodies have a high affinity and sensitivity, and are particularly adapted to small antigens or small epitopes. In addition sheep and goats allow the production of larger volumes compared to smaller species and the animal does not necessarily need to be culled as part of the process.

Typically, what will be done to an animal used in your project?

After arrival all animals **will be allowed at least 7 days to become acclimatised to the unit. Then depending on the protocol:**

Blood sampling: One or more blood samples will be taken. The animal will be assessed between each sampling and only sampled if considered to be fit and hea**lthy. At the end of the blood sampling period the animal will either be re-used for tissue sample collection, returned to stock or re-homed.**

Tissue collection: The animal will be terminally anesthetised and the tissue sample collected. After which the anim**al, still under terminal anaesthesia, is euthanised.**
Antibody production: The animal will be immunised with the antigen, given a booster injection if required and blood samples taken for antibody extraction. The animal may be used in one or more rounds of **antibody production. The animal will be assessed between each round and only used if considered to be fit and healthy. At the end, the animal will either be re-used for tissue sample collection, returned to stock or re-homed.**

What are the expected impacts and/or adverse effects for the animals during your project?

The provision of tissue samples should have no adverse effects on the animals. The collection will either be a simple blood sample or collection under terminal anaesthesia.

Antibody production should also have little or no impact on the animals.
This will involve simple injections and blood sample collection.
There is the potential for an animal to have an allergic reaction to the antigen which may induce some adverse effects.
This is expected to be transient and have no lasting effect on the animal.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of animals, the severity level will be mild. However, as stated above, in some studies the animals may experience some adverse effects. These would only cause the animal a moderate level of distress which will in most cases be transient.

What will happen to animals at the end of this project?

- Killed

- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

At a certain point in research projects there is a point where in vitro studies cannot completely answer the question being asked. This is due to the **complexities of the microenvironment of tissues and the involvement of the immune system. This cannot be fully replicated in a laboratory setting.**

Because of the high metabolic activity of certain tissues, especially hearts, it is not possible to obtain these tissues from other sources or after the animal has been killed using a schedule 1 method, due to the prolonged times and crude extraction procedures of non-research facility removal protocols. For hearts It is necessary for the explantation process to be carried out under controlled conditions by trained personnel with immediate cardioplegic arrest (minutes), in order for the samples to remain alive and viable for the ex vivo studies. These tissue samples have to be removed under terminal anaesthesia. Blood is required as a source of primary cells for in-vitro/ex-vivo studies. Wherever possible, blood products will be obtained from abattoirs or after animals have been put down for other reasons. In many cases, abattoir samples may not be suitable due to contamination or lack of information and/or traceability on the specific animal being used. Also, it is not possible to sterilise whole blood products, blood must be collected aseptically from a live animal.

It is also now possible to generate antibodies using non-animal derived methods, thanks to developments of new technologies. There are however still cases where there are simply no non- animal derived antibodies available as a suitable alternative. Particularly in the generation of polyclonal antibodies. This is the area of antibody production that we focus on.

Which non-animal alternatives did you consider for use in this project?

The very nature of the blood and tissue sample supply included in this project licence means that at the point we are approached, the use of non-animal alternatives has been completed or cannot answer the questions being asked.

Phage display library monoclonal antibody production is a valid alternative to using animals to produce monoclonal antibodies.

Why were they not suitable?

Currently the production of polyclonal using phage display libraries is not as effective as using this system to produce monoclonal antibodies. There is a need still to produce polyclonal antibodies, particularly in applications where their heterogenous nature is beneficial for recognition of multiple epitopes.

When monoclonal antibodies are required, phage display libraries are the leading technology to use for the production. However, there are limitations. they can produce

large amounts of specific antibodies but may be too specific to detect across a range of species. They are vulnerable to the change of epitope. Even a slight change in conformation may lead to dramatically reduced binding capacity.

Developing a monoclonal takes time and requires high technical skills.

There is still a role for polyclonal antibodies in research. Polyclonal antibodies are ideal reagents in diagnostic assays and hemagglutination reactions due to their ability to recognize different epitopes of a target molecule. This makes them more sensitive and able to detect antigens in very low concentrations. The best use of polyclonal antibodies is to detect unknown antigens. Polyclonal antibodies are used as a secondary antibody in immunoassays (e.g. ELISA, western blotting, microarray assays, immunohistochemistry, flow cytometry). Their role is to bind to different epitopes and amplify the signal, leading to better detection.

In addition, with immunohistochemistry the effects of the tissue fixation and processing on the epitope is unknown and highly variable, Polyclonal antibodies can be a better option because their multi-epitope binding allows for antigen recognition even if some of these epitopes are affected by changes in an antigen's structure or accessibility due to the processing of the tissue samples.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies.

Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been calculated on the numbers used under the previous 2 project licences. The number of possible projects we are aware of, either from our external clients or from academic grants that are being submitted by researchers over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure we use minimal number of animals required to obtain meaningful and relevant data, we have extensively consulted available literature, attended experimental design and statistical courses, discussed with statisticians and NC3Rs staff and reviewed information provided by the NC3Rs. All requestors will be required to justify the number of animals required and if appropriate show how they came to this number.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In many cases, the numbers of animals required will be reduced by re-using animals for the mild procedures e.g. blood sampling. There is evidence that the immunisation of animals with multiple antigens at the same time give a good antibody response and the

separation/purification of the different antibodies is possible. The animal experience is no different when give one or a multiple antigen immunisation. This can significantly reduce the number of animals required.

When providing tissue samples, we try to coordinate it so that multiple tissues can be taken from the same animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In the first instance the species selected for antibody production and blood products supply are the most relevant to scientific and logistical (e.g. sample volume) requirements of the project and within the constraints of the licence.

Study protocols will be designed to ensure that any harmful effects resulting from any procedure will be detected early. For example, by including specific periods of observation when we know adverse effects are most likely to occur, e.g. the first 15 minutes post-dose. Having a dosing regime that allows time between each animal dosed, if an adverse effect occurs, we can intervene to stop other animals being affected.

Terminal tissue/organ sampling will be conducted under anaesthesia, so the animal feels no pain or suffering during the procedure.

Why can't you use animals that are less sentient?

The studies, tissue and blood sampling undertaken will be very species specific. The most appropriate ones for reach request will be used. All requests will have to justify why that particular species is required.

The process of whole body anaesthesia, for simple procedures like blood sampling, would be more stressful to the animal than the actual sampling.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The least invasive route of substance administration will be used. Along with the minimum number of injections to produce the required response and smallest needle gauge appropriate will be used if the blood sampling can be fulfilled, (e.g. minimum blood volume for the species fits with the scientific aims) with one or more species e.g. sheep or cattle,

then the species which is easier to handle (therefore the procedure will be less stressful for the animal) and in ready supply will be chosen.

All animals will receive appropriate operative care in terms of anaesthesia and pain management both during and after the procedure.

When appropriate, blood sampling maybe conducted on farms, thereby reducing the stress to the animal by transporting them and introducing them to a new environment prior to sampling.

In house expertise further enhances animal welfare, by providing close collaboration with dedicated animal care staff and veterinary consultants, and ready access to highly skilled advice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult all the relevant references listed therein, e.g. NC3Rs Blood sampling resource. (Reference: NC3Rs/BBSRC/Defra/MRC/NERC/Royal Society/Wellcome Trust (2019) Responsibility in the use of animals in bioscience research: expectations of the major research councils and charitable funding bodies. London: NC3Rs).

For substance administration the LASA substance administration guidelines will be consulted (Reference: Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider. J Am Assoc Lab Anim Sci. 2011 Sep; 50(5): 600–613).

Animals will continually be monitored for signs of pain and distress, especially post-challenge, by use of the grimace scale;
https://www.nc3rs.org.uk/sites/default/files/documents/Guidelines/MGS%20

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continuously monitor publications and the NC3Rs website for new and alternative models that could be implemented as part of this project. In addition, articles on advances in the 3Rs are regularly p**ublished on our internal Users News Forum and other relevant information is circulated by AWERB. Whenever possible we will implement these refinements into our studies.**

134. Investigating the immunology of cancer and the development of cancer therapeutics

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunology`, Therapy, Tumour, Vaccine

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify cancer therapeutics which can be used to prevent or treat cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite significant progress, cancer continues to be a major cause of mortality in humans with the lifetime risk of an individual developing cancer in one form or another being approximately 1 in 2. Approximately 440 people die of cancer every day in the UK (Cancer Research UK statistics).

Although current treatments such as radiotherapy, chemotherapy and hormone treatments can be effective against primary and secondary cancers, they can be associated with significant toxic side- effects, and therapeutic resistance often occurs. The spread of primary disease to other tissues (metastasis), tumour relapse and resistance to therapy remain the principal causes of death for patients with cancer. Metastasis is a particular problem and accounts for ~90% of cancer-related deaths.

What outputs do you think you will see at the end of this project?

The outputs of this project will include;

Publications in Open Access Journals.

Dissemination of information at National and International Conferences.

Identify a treatment approach that could progress to a clinical trial.

Who or what will benefit from these outputs, and how?

The immediate benefit from this project will be for basic science by producing world-leading and internationally recognised work that will be published in high impact journals.

Output from this project may be utilised by others including preclinical academics, industrial partners and clinicians. We will disseminate our results via both National and International conferences and workshops.

While Basic science will benefit in the short-term (1-3 years), clinical impact may take a longer period to be achieved. This may have the potential to be a therapeutic or diagnostic tool.

The time taken to fully evaluate a given therapeutic or diagnostic tool is likely to go beyond the five-year duration of the programme of work due to the complexities involved in the research.

How will you look to maximise the outputs of this work?

The collaborations and services provided will lead to both the furthering of our existing knowledge and build new knowledge surrounding treatments in cancer. This may lead to joint applications for funding if the results show promise.

It is anticipated that the findings from these outputs may be disseminated through peer-reviewed journals, conferences and marketing materials.

Species and numbers of animals expected to be used

- Mice: 7,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All our experimental procedures will be performed in either wild-type or genetically altered mice. All the studies in this project will use adult mice from 6 weeks of age.

Mouse models have many similarities to humans in terms of anatomy, physiology and genetics, in the way tumours metastasise. The animals used in our research will help us understand the mechanisms that underpin cancer, such as the growth and spread of tumours, and to develop new ways of diagnosing, treating and preventing the disease.

Mouse models are essential in cancer research. They are used to understand the genetic basis of tumour development and cancer progression. The MHC transgenic mouse models we propose to use have the same HLA haplotypes as humans for Class I and Class II which makes the results obtained more translatable in humans. They can also be used to test the efficacies of different anti-cancer agents. Moreover, in translational cancer research, they represent a powerful tool in assessing the potential validity of targeted therapy because the targets can be precisely studied in the setting of a developing or developed tumour.

Typically, what will be done to an animal used in your project?

In this project, mice will be bred to have specific genetic modifications which are not expected to be harmful and will be bred using natural mating and maintained for use in this or other protocols.

Typically actions in this project include:

Implantation of tumour cells

Administration of therapies

In vivo imaging Blood sampling

Animals will be humanely killed at the end of the experiment

The animals in this project may be injected multiple times with the candidate items that will be tested (by one or more of the following routes -subcutaneous, intraveneous, intraperitoneal, intradermal, intramuscular, intranasal, gene gun, gavage, topical, drinking water, or diet to assess whether the the therapeutics are immunogenic. The subcutaneous tumour models will be set up and the candidate therapies tested using pre-determined vaccine strategies. In some studies, blood samples will be taken from a superficial vessel followed by a sample taken under terminal anaesthesia. A second injection of tumour cells may be given to assess memory responses.

The typical duration of a study will vary from between 4-12 weeks and beyond dependent on the study design.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that some animals will experience minor transient discomfort during this project as a result of administration of substances, implantation of tumour cells, blood withdrawal and in vivo imaging. During the tumour growth phase some animals may show signs of tumour ulceration for up to 7 days with recovery. This will cause the animal moderate discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on our experience in the previous licence, we estimate that in this project 47% will be subthreshold, 43% will be mild and 9% will be moderate.

What will happen to animals at the end of this project?

Used in other projects
Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although this research employs an extensive portfolio of in vitro laboratory techniques, these cannot adequately model the complete array of biological and immunological events that are involved in tumour growth or the generation of protective anti-tumour immunity, all of which are important to our understanding of tumour immunology and the development of new therapeutic strategies. In vivo studies in rodent models are therefore essential as they have the integrated physiological systems which are required.

Which non-animal alternatives did you consider for use in this project?

2D and 3D cell cultures can be used to some extent to assess the effect of a given treatment on a tumour cell line in vitro, however, they cannot completely replace the information gained from animal experiments as the entire tumour microenvironment is difficult to replicate in the laboratory.

Why were they not suitable?

In vitro studies can produce valuable information, however, they cannot mimic the exact in vivo environment to exhibit the effects that a whole biological system has on disease progression and therapeutic intervention.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals has been estimated based on previous usage and expected usage based on conversations with researchers and service users.

In-house discussions with a biostatistician were held to review our experimental designs and the numbers are also based on our previous usage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In-house discussions with a biostatistician were held to review our experimental designs.

We will ensure that we use the minimum number of animals required to answer the scientific question by performing power calculation studies. We will also apply the NC3Rs experimental design assistant tool for appropriate experimental planning. We will regularly consult qualified statisticians about experimental design and statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding will be performed in a way to maximise efficiency, reduce surplus mice and ultilise both sexes in the experiments.

Both sexes of animals maybe used in experiments.

Candidate vaccines will be designed and assessed for their suitability with the use of in silico and in vitro techniques prior to moving them into the animal setting.

Double transgenic (2 genetic modifications) will be used whenever possible thereby reducing the number of animals being used.

Pilot tumour growth studies will be performed where appropriate to establish tumour growth rates prior to use in the prophylactic and / or therapeutic studies.

All experiments using live animals will adhere to the ARRIVE guidelines on design and reporting. Good principles of experimental design will be applied to ensure sufficient group sizes will be used to adequately test the hypothesis. Sample sizes are estimated from pilot studies and previous data using power analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered mice bred and maintained are of a non-harmful phenotype.

Prior to implantation, all cells are prepared in a sterile environment and are administered using sterile techniques and the lowest volume of cells.

Substances are prepared and administered using sterile technique. The route of administration is via the least invasive method appropriate to the model. The volume of substances to be used will be in accordance with the Laboratory Animal Science Association (LASA) good practice guidelines.

The assessment of tumour development will be assessed on their known characteristics. Some animals will be monitored using callipers to assess tumour growth rates and some animals will be monitored using the in vivo imager which will require transient anaesthesia to immobilise them while an image is acquired. Once completed, the animals are expected to make a full recovery within 30 minutes.

Blood sampling will be performed using sterile techniques and the volumes collected will be in accordance with the LASA / NC3Rs guidelines. We will aim to take the smallest volume which will allow for adequate analysis.

All animals will be humanely killed by a Schedule 1 method.

Why can't you use animals that are less sentient?

The studies proposed in this project could not be undertaken in animals with a lower form of immune system (e.g., drosophila, C.elegans) because those models do not show comparable responses that are seen in humans. Furthermore to achieve the maximum relevance and utility from this project, it is essential that we use genetically altered transgenic mouse models (e.g., for particular human HLA types) as these have been used

previously and identified areas of interest which will be investigated further under this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Over the last 5 years a number of refinements e.g., reduction in the number of injections for a given therapy, changing to a less invasive route of administration, increased frequency of clinical observations has been made and considerations to refinements is an ongoing process. The procedures that are in place to administer substances and monitor the animals are 'fluid' whereby any opportunity to refine a technique or ensure additional monitoring is performed where necessary, which is carried out by the licensed scientists. Any relevant refinements made are discussed and disseminated to the other users by the animal care scientists.

The veterinary surgeon also observes the work undertaken under this project and will offer suggestions for refinements where necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines published by the Workman Group on welfare and use of animals in cancer research published in 2010, The ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments) and LASA Good Practice Guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will maintain close interactions with the relevant welfare, training and information officers as they oversee and perform in vivo studies. The PPL holder will stay informed of advances in the 3Rs by regularly checking the NC3Rs webpages (https://nc3rs.org.uk/the-3rs) and the newsletters which are circulated monthly.

Moreover, the PPL holder will attend appropriate seminars, symposiums and conferences deemed suitable.

135. Isolation and propagation of virus in eggs

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Influenza, Vaccine, Pandemic, Epidemic

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To isolate and propagate influenza viruses in embryonated hens' eggs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Influenza viruses continue to threaten human and animal health. They are best controlled by vaccines and antiviral medicines.

The vast majority of influenza vaccines for humans are produced in hens' eggs and require the initial virus from which the vaccine is produced to have been isolated in embryonated hens' eggs and to have been exclusively propagated in hens' eggs. Hens' eggs are also

the most appropriate for examining the properties of certain influenza viruses of animals (e.g. poultry) that infect humans, and so pose a threat to public health and pose a pandemic threat. This project primarily covers the isolation and propagation of human and animal influenza viruses in embryonated hens' eggs and the analysis of the properties of these viruses.

What outputs do you think you will see at the end of this project?

The work entails the isolation of influenza viruses in hens' eggs and their detailed characterisation. These isolates can be further developed for the generation of egg-propagated candidate vaccine viruses that can be used by vaccine manufacturers for the production of influenza vaccines. This will be done as an ongoing process throughout the period of the project.

Assessing the properties of new influenza viruses of animals that infect humans allows for an assessment of the impact such viruses can have on human health, this includes the susceptibility of such viruses to antiviral medicines. The results of these analyses will be shared with the World Health Organisation (WHO). This will also be done as an ongoing process throughout the period of the project. Work will be published in peer-reviewed journals where appropriate.

Who or what will benefit from these outputs, and how?

Public health will benefit from the work.

The properties of viruses of animals that infect humans, zoonotic influenza viruses, will be shared with WHO for their risk assessments of the pandemic potential of such viruses, and these assessments lead to the subsequent prioritization of viruses for the generation of vaccines for pandemic preparedness purposes.

The isolation and propagation of egg isolates of human influenza viruses are the first steps on the path to the provision of the large majority of influenza vaccines. Selected viruses will be further developed as candidate vaccine viruses and, ultimately vaccine viruses for the production of human influenza vaccines.

Examining antiviral treatments and assessing the sensitivity of newly emerging viruses to antiviral treatment also benefits public health.

How will you look to maximise the outputs of this work?

This work will continue throughout the project. It is critical to select viruses for isolation and characterisation in hens' eggs on a timely ongoing basis as the influenza viruses evolve. This ensures that the most appropriate viruses are available for seasonal influenza vaccines and for vaccines developed for pandemic preparedness purposes.

Virus isolates deemed suitable for further development will be shared with other laboratories that carry this out. Updates on progress will be shared with WHO and vaccine manufacturers.

Assessment of the susceptibility of newly emerging influenza viruses to antiviral medicines is one of the key factors in the assessment of the risk posed by zoonotic influenza viruses to human health and is part of a process conducted by WHO -The Influenza Pandemic Risk assessment (see https://apps.who.int/iris/handle/10665/250130).

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 28,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

At present the vast majority of influenza vaccines are produced in hens' eggs and are based on viruses exclusively propagated in hens' eggs. Alternative platforms, cell culture-based vaccines and recombinant vaccines, have been developed but these are not yet extensively used and the work here is to produce viruses for use in the egg-based vaccine platforms. Under these circumstances, it is not possible to develop an alternative to the isolation of viruses in hens' eggs and have an adequate vaccine supply to meet public health needs.

Isolation of viruses following amniotic inoculation is needed for most human influenza viruses. The efficiency of this process is much higher following inoculation of 14-day old embryos rather than, for example 10-day old embryos. The use of the older aged embryos is not possible to avoid without compromising the number of isolates recovered.

The examination of antiviral treatment in ovo provides a mid-point between examining the effects in tissue culture and in small animal models. This would be done on 9-day old to 11-day old embyronated eggs, but is included in this application to cover an experiment that might be required to proceed into the 14th day of embryonic development.

Typically, what will be done to an animal used in your project?

Embryonated hens' eggs of typically 14 to 16 days of embryonic development are to be inoculated in the amniotic cavity with virus with clinical samples or virus having been propagated in eggs or in tissue culture. The eggs will be incubated at 34o to 37o for typically 48 to 72 hours and then chilled to 4o prior to harvesting the propagated virus.

Embryonated hens' eggs of typically 10 to 11 days of embryonic development are to be inoculated in the allantoic cavity with virus with clinical samples or virus having been

propagated in eggs or in tissue culture. The eggs will be incubated at 34o to 37o for typically 48 to 72 hours and then chilled to 4o prior to harvesting the propagated virus.

In antiviral experiments 9-day old to 11-day old embryos will be used and the effects of possible antiviral medicines on virus replication will be examined for up to four days and then chilled to 4o.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the influenza viruses used cause no obvious adverse effects on the embryo. For those that do, like highly pathogenic avian influenza viruses that can cause zoonotic infections and may have pandemic potential, pilot studies will be carried out on small numbers of eggs of younger age (typically 9- to 11-days of embryonic development) to determine the mean death time, usually between 24 and 48 hours following inoculation, and in subsequent work eggs will be chilled at least 2 hours prior to the mean death time to reduce severity.

Amniotic inoculation is a difficult procedure and a proportion of eggs can die as a result of damage to the embryonic membranes. Allantoic inoculation causes very little damage to the embryo.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As indicated above, most of the viruses used cause no obvious adverse effects on the embryo. Most highly pathogenic avian influenza viruses are likely to be inoculated into earlier aged embryos and so will fall outside of the scope of the act. Work on such viruses has represented less than 5% of the viruses with which we have worked in recent years. Inoculation with such viruses can kill the embryo however, this is prior to sentience (2-days prior to hatching) and so severity is deemed mild. Chilling at least two hours prior to death is used to reduce impact on the embryo.

Amniotic inoculation can result in the loss of up to 20% of the inoculated embryos. Allantoic inoculation results in the loss of approximately 5% of embryos.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As indicated above, at present the vast majority of influenza vaccines are produced in hens' eggs and are based on viruses exclusively propagated in hens' eggs. Alternative platforms, cell culture-based vaccines and recombinant vaccines, have been developed but these are not yet extensively used.

Under these circumstances it is not possible to develop an alternative to the isolation of viruses in hens' eggs and have an adequate vaccine supply to meet public health needs.

For studying antiviral intervention, embryonated hens' eggs can serve as an intermediate between studying antiviral activity in tissue and organ culture, and in small animals. Use of eggs of 9-days or 10- days of embryonic development for this would be usual but some experiments might need to be extended up to and including 14-day old embryos.

Which non-animal alternatives did you consider for use in this project?

Egg-based influenza vaccines remain the mainstay for public health intervention against influenza. Under this current situation, there is no non-animal alternative for this type of activity for the production of such viruses to be developed for use in vaccines and we are committed to making such virus isolates for development into vaccines.

Tissue culture and organ culture are the first steps in analysing antiviral activities but eggs can serve as an intermediate between tissue and organ culture and small animal models. Thereby, eggs serve to reduce the use of animals, and will not usually be done at late stages of development (after 14-days of embryonic development).

Why were they not suitable?

There was no alternative available for producing viruses in hens' eggs for egg-based vaccines, and these remain the main type of influenza vaccine used globally.

In ovo assessment of antiviral treatments serves to reduce animal usage and will typically use eggs at earlier stages of development, and this work will build on work done in tissue and organ culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We need to have produced a number of influenza viruses of each influenza A sub-type (H1N1, H3N2) and influenza B lineage (B/Victoria lineage and B/Yamagata lineage) for initiating the development into new vaccine candidates as the human influenza viruses continually evolve, causing yearly epidemics and occasional pandemics, and warranting new influenza vaccines on a very frequent basis. Also needed are isolates of zoonotic and potentially pandemic influenza viruses.

It is important that sufficient viruses are isolated in hens' eggs are available to screen for ones expected to be able to be developed into a suitable influenza vaccine. The isolation rate of viruses from suitable clinical samples is currently in the order of 50% to 60%. Typically up to around 100 human clinical samples are taken each year for attempted virus isolation in eggs.

Most antiviral experiments done in ovo will be initiated on early-stage embryos and very few eggs will progress to 14-days of embryonic development.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In most cases once a virus has been clearly established as an isolate we can use eggs of lower embryonic age for further propagation, and so not subject to the legislation of the Animal (Scientific Procedures) Act 1986. This reduces the number of animals used under the project licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We estimate the numbers from our experience over the last decade that can be developed further. Not all selected viruses will prove to have the properties to take them forward for further development and some of those developed further might not be deemed to be suitable for use as a candidate vaccine virus.

In studying antiviral treatments, eggs of the youngest age (e.g. 9-day old to 11-day old) will be used to initiate the experiments. As above, it is not envisaged that many treatments would extend to 14-days of age.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Embryonated hens' eggs are to be used and these will be inoculated with samples containing influenza viruses into the amniotic and allantoic cavities.

Why can’t you use animals that are less sentient?

Success in the initial isolation and the early passage of virus, notably for influenza A(H3N2) viruses, one of the main causes of epidemic influenza, is best performed using older-aged embryos. This is based on our observations, along with those of others, that as the human influenza virus has evolved the ability to isolate viruses in hens’ eggs has become markedly reduced. This decrease in virus isolation in eggs reduced the number of viruses that could be developed into viruses suitable for influenza vaccines, thus potentially compromising influenza vaccine availability. It was discovered that inoculation of embryos of 14 or 15 days of development, followed by incubation for 3 or 4 days, increased the probability of virus recovery and thus provided us with a reasonable number of candidate viruses that have the potential to be developed into vaccine viruses. Very few embryos, if any, would reach a stage of development when the embryo is deemed to be sentient (1 to 2 days prior to hatching).

Following an isolate being successfully propagated in 14-day old embryos it will be subsequently passaged in 10-day old embryos and incubated for 48 to 72 hours, an age not covered by the law.

Antiviral work will be initiated in 9-day old to 11-day old embryos, but the treatment might extend to or beyond 14-days of development.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Minimisation of any suffering will be done by using embryos less well developed whenever possible. For viruses that might cause the death of the embryo, pilot studies will be carried out to determine the mean time to death in younger aged embryos (typically 9 - to 11-days of embryonic development) and in subsequent work the embryos will be chilled to 4o prior to this time.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The production of viruses in hens' eggs for the development of viruses for development into egg-based human influenza vaccines is an activity done by very few laboratories globally. We will discuss with the other laboratories that carry out similar work whether they discover that younger aged embryos can be used for virus isolation without a

significant reduction in the successful isolation of viruses and whether they have improved procedures.

Work on antiviral treatments will be done according to protocols developed to be robust.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The host institution provides regular updates on advances in the 3Rs. We discuss our work with the small number of other laboratories doing similar work globally.

136. Developing non-viral gene therapies

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

delivery technologies, therapy, non-viral gene medicine, precision medicines

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop and test novel non-viral gene medicines for rare genetic diseases and other diseases for which our technology could lead to significant clinical benefits., for example muscular dystrophies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Non-viral gene medicines have great promise as treatment for multiple diseases for which there is currently no (effective) treatment. However, most such medicines suffer from an inability to be effectively delivered, via the blood stream, to target organs in order for them to generate a clinical benefit. We are aiming to develop delivery systems for non-viral gene

medicines, which enable efficient delivery to target organs such that a clinical benefit can be obtained. The nature of our technology is such that there is a potential for its application in many disease areas. We aim to develop new non-viral gene medicines for diseases of muscle, heart and brain for which there are no current treatment options.

What outputs do you think you will see at the end of this project?

Primarily, we expect this project to generate lead candidate compounds for translation to the clinic for the treatment of Duchenne muscular dystrophy, a severe genetic neuromuscular disease. We expect to develop new intellectual property on compounds identified as part of this project. In addition, we intend to publish our findings at scientific meetings and in written peer-reviewed scientific journals.

We aim to advance our first programme for Duchenne muscular dystrophy (DMD) to an application for 'first in-man' studies. In addition, we expect the data generated for this programme will guide the development of our technology for several other gene medicines.

We envisage that the longer-term benefits of this application will be to establish a new technology for gene medicines that allows the rapid development of therapies for both genetic and non-genetic diseases

Who or what will benefit from these outputs, and how?

Developing novel treatments for genetic diseases could have a huge impact on the quality of life of patients and their families. Furthermore, the impact on society in general is potentially significant. For instance, the 'burden of illness' for rare diseases (e.g., Huntington's Disease) are typically high, due to life-long needs of the patient (approx.£70k/pa). However, these costs are typically 45% of the true burden of disease (families providing healthcare and/or requiring adaptations to their homes). NHS England annual spend on rare disease is £3.7b, suggesting the additional costs bore by society in general are £1.7b.

We intend to publish our work in the form of patents and publications in scientific journals which will inform researchers of our new technology.

Long-term, we hope to develop methods to make new non-viral gene medicines, that decrease the time and cost required to get a new drug approved for use in humans. These new approaches could establish new working practices to produce cost-effect therapies for conditions with profound unmet clinical needs.

How will you look to maximise the outputs of this work?

This project will inform the development of gene medicines based on the same technology for additional indications. We have strong links to pharmaceutical companies, all developing similar types of drugs to improve the quality of life. These interactions allow a

freedom of academic exchange that benefits all parties and the success of this project will hopefully lead to inward investment from these companies to develop additional drugs for different diseases. Thus, we expect to positively impact on drug development, both nationally and internationally with a program that reduces the time to market and reduces the extent of animal-based experiments.

To emphasise our commitment to public health understanding, we engage with relevant charities in disease areas of interest to ensure that all drug development programs are made in consideration of a ‘patient-first’ approach. The success of this program could have a positive impact on more global aspects to human health. Our data may be valuable to policy makers in channelling funds to support specific types of research, and regulators developing guidance and legislation for new therapeutic modalities.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse has been chosen as the most appropriate species for our studies as it is the lowest form of mammal that allows the study of human diseases. This project is concerned with creating new gene medicines to treat diseases with unmet clinical needs, including muscular dystrophies. In this project we will use mouse strains that have similar genetic mutations to humans suffering from specific conditions and therefore also develop similar symptoms..

New medicines will be investigated to treat the primary cause of the disease (e.g., restore missing proteins), in addition gene medicines will be investigated to treat complications that develop because of the disease (e.g., inflammation and fibrosis).

Diseases can develop in both young and older people depending on the particular disease. Therefore, we plan to use mice over a range of ages (both young and older/adult) to mimic the human disease as closely as possible. This will give the most valid information on the suitability of the gene medicine for treating the disease in question.

Typically, what will be done to an animal used in your project?

Genetically altered mice and mice with naturally occurring diseases (such as muscular dystrophy) will be bred. Before any treatment, non-invasive baseline assessments may be performed (e.g., to assess heart function or general mobility) to enable assessment of the impact any treatment. Muscle regeneration might be induced by intramuscular injection and substances may be administered by intravenous injection to aid drug delivery. Non-

viral gene therapy agents to treat the primary condition or associated pathologies will then be administered either by an intravenous or subcutaneous injection. Non-viral gene therapy agents may also be administered by a small pump inserted under the skin or by oral administration. Depending upon the assessment being conducted, the non-viral gene therapy agent may be given to the mouse once or on multiple occasions. Following the final dose of the non-viral gene therapy agent, the mouse may then be assessed again for any physiological improvements (e.g., heart function, mobility, ability to exercise). Depending on the assessment being conducted, the mice will be sacrificed 1 – 4 weeks following the final dose of the non-viral gene therapy agent and appropriate tissues collected for further analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

All experiments are designed to minimise the number of mice used, with the minimum impact on the mice. Mice might experience minor adverse effects from the administration of the test compounds. They are expected to recover quickly and will be monitored for changes in body weight, condition, assessment of the injection site and food and water consumption. Appropriate modifications to housing, access to wet chow and treatment of injection site will be made if necessary. When surgery is carried out, painkillers and post-operative care will be given in addition to the monitoring described above. No serious adverse effects are expected for the non-invasive physiological assessments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: Mild: 85%

Mice: Moderate: 15%

What will happen to animals at the end of this project?

Killed

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of the program is to develop a series of novel gene medicines to treat neuromuscular, neurodegenerative, cardiac and metabolic diseases. In order to support the development of medicines intended for human use, from therapeutic concept to human clinical testing, animal testing is a necessary requirement to assess whole-body responses to novel medicines which cannot be assessed in non-human or non-animal models.

Which non-animal alternatives did you consider for use in this project?

First, our programs will be informed by the current practices and what has already been published. In most aspects of our programmes, initial testing and assessment of novel compounds will be carried out using computer programs or cells cultured in an incubator. This allows predictions to be made as to the suitability of each synthetic gene medicine before it enters experiments in animals. We have developed a number of tests, using cells grown in an incubator that provide key data about potential toxicity and efficacy of our candidate synthetic gene medicines; all these tests lead to higher quality data being produced and a reduction of the number of animal required. These hard stop:go outputs derived from a computer program and/or cells in culture support our ‘fail fast’ philosophy and the increased likelihood of clinical translation of the respective programs.

Why were they not suitable?

The target organs for the respective gene medicine/indication combinations are complex tissues that responds to environmental influences in a number of ways and, as such, cells in culture and whole organ studies are not suited to the full assessments of the potential therapeutic benefits; nor, due to the complex interaction that each tissue has with its environment, would it be possible to fully assess the benefits of our gene medicines

In addition, cells of skeletal muscle, heart and brain typically do no undergo cell division in adults. In particular contractile cells of the heart (cardiomyocytes) do not divide and there are no cell lines that are representative of these cells. It is therefore necessary to use animals for such studies evaluating cardiomyocyte function within the intact heart, as there are no non-animal alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal experiments will require pilot studies to determine whether our experimental approach is worthy of further study. Such studies also can inform on the numbers of animals required based on the early observations of the effect of our new gene medicine.

In addition, animal number requirements will be informed by published data from studies by others using the same animal models, where possible. Based on our previous work, for each new pipeline program in which pilot studies, safety studies and efficacy studies are conducted, based on the types of disease under investigation 200 - 400 mice are typically used; this number enables the collection of robust data sets that supports the continuance of the pipeline towards first-in human studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals used in the project, we have developed a mathematical process that includes the experimental design and methods of analysis of the results. This process will be ongoing in collaboration with trained statisticians and reviewed within our team. Such training programs are reviewed annually with new staff undertaking an induction statistical program to cover how to produce high quality data with best outcomes commensurate with the 3R's. With appropriate statistical analysis being performed, both the qualitative and quantitative measures collected will be maximised. In addition to our review process, our participation in numerous 'networks of excellence', together with the literature will inform on optimal experimental design that will positively impact on the numbers of animals required, yet ensuring the delivery of clinically meaningful benefits.

We build out and internally disseminate a stepwise visual representation of our planned animal experimentation. This promotes greater critical assessments of our workflows and provides feedback and advice from colleagues with considerable animal experience. This iterative approach establishes best practice to define the relevant preclinical (and therefore, clinical) outcome measures and accompanying appropriate analyses.

Our practices, thus comply with the NC3Rs PREPARE guidelines, that further disseminate best practice to the wider community as a whole. With memberships of numerous 'Networks of Excellence' (groupings of experts that share best practice) this sharing of information leads to standardised operating procedures permitting greater comparisons between studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At the outset of establishing novel gene medicines for a new disease indication, prior to establishing a new pre-clinical mouse model, we will seek opportunities to obtain tissues from others that have archival tissue material. This helps establish a set of parameters to best identify the types of pathological changes that would be of interest when in vivo studies are conducted. Our experience is that this approach reduces the numbers of animals required per program.

We will aim to limit the numbers of mice produced for our program by collaboration with external service providers; Where possible, animals will be obtained from centralised breeding facilities following advance planning taking into account preparation time for

planned experimentation. In addition, where possible both male and female animals will be used for our studies which will separately contribute to the reduction of surplus animals.

For experiments where breeding of animals needs to be done in-house because the animal model cannot be obtained from centralized breeding facilities, clear estimates of animal numbers required for experiments will be produced ahead of time to determine the appropriate number of breeders to use to minimise surplus animals.

The incorporation of computer-based and cell culture-based screens prior to any animal study will minimise the number of compounds tested in animals and therefore, the number of animals used.

We have developed appropriate non-invasive outcome parameters that allow repeated measurements on an animal which promotes a greater level of data being generated per individual study AND individual animal. For post-mortem tissue analyses, we have established protocols to assess functional, histological, and molecular parameters from the same tissue samples; this multiple sampling data generation from the same tissue leads to the reduction of animals required to obtain the data to progress the program into clinical trials.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Pre-clinical mouse models available for our studies are based on the same genetic defects that result in the specific human condition under evaluation, for example muscular dystrophy. Together, there has been considerable data, often collect over tens of years, that has convinced medicine regulators globally of the relevance that such models have, with particular reference to the type of gene medicines we are analysing. For example, models of dystrophic mice are accepted as ideal systems in which to conduct early evaluations of novel therapeutic agents. Delivery of non-viral gene therapy agents by injection or through food will allow us to study the effect of these new medicines on the primary disease and pathologies that are caused as a complication of the condition.

All our experiments are designed to cause the minimum amount of pain, distress, or lasting harm; this is done by adopting standard operating procedures and training by trained and competent staff.

Why can’t you use animals that are less sentient?

The mouse is the lowest sentient mammal used in this type of study to inform on the human condition. There is significant overlap between mice and men in molecular and cellular programmes during development and/or regeneration. Other experimental models, e.g., fruit flies, nematode worms and fish, do not share these characteristics and hence extensive studies have been performed in rodents as they are appropriate models to assess the suitability of specific therapeutic regimens. In addition, we have developed protocols that allow us to interfere with gene function in rodents which aid the study of tissue functions or metabolism in our relevant models, including muscular dystrophy and metabolic disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Suffering will be minimized by the use score sheet to assess the severity of experimental interventions and the use of appropriate humane endpoints. Animal husbandry will be modified where appropriate (e.g., floor feeding). Adopting non-invasive imaging and functional assessments will permit longitudinal studies and lead to a refinement in humane pre-clinical endpoints and improve the quality of the data. Animals will be continuously assessed and scored against recognised welfare parameters to ensure pain, suffering, distress, or lasting harm to the animals does not occur.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Throughout our workstreams we will adopt a 4 step approach to Animal Research

9. Appraisal of best practice as described by the Laboratory Animal Science Association https://www.lasa.co.uk/current_publications/

10. Use PREPARE guidelines in concert with the animal facilities to plan any animal research programs to minimise use and/or levels of harm. https://norecopa.no/PREPARE

11. Highlight and promote improvements that have impacted on the 3R’s; not being restricted to prepared manuscripts.

12. Comply with the ARRIVE guidelines to ensure best practice and report outcomes are communicated effectively to engender and comply with best practice. https://arriveguidelines.org/arrive- guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Best practice dictates that one is guided by the literature and from our own experiences. Keeping abreast of the developments in science (via appraisal of the literature, scientific Networks of Excellence, scientific meetings or press releases and/or news letters from key

opinion leader (e.g., NC3Rs) will ensure constant reflection and, where necessary, adoption of modified practices that will conform with any ‘new’ best practice.

137. Molecular mechanisms of t cell mediated immune responses

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Immune response, Egr, Tbet, autoimmunity, Tumor microenvironment

Animal types	Life stages
Mice	adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Based on our recent findings of the function of early growth response gene 2 (Egr2) in T cells and the establishment of therapeutic vaccines, this project has two aims:

1) Define Egr2 controlled molecules in self-reactive T cells for the development of diagnostic biomarkers used for autoimmune diseases,

2) Develop a therapeutic vaccine for treating solid tumours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Both autoimmune diseases and cancer result at least partly from the dysfunction of T cells. The regulatory mechanisms in T cells hold the key to not only effective immune responses against pathogens and cancer but also the ability to tolerate self-tissues. The disorders of such mechanisms will lead to autoimmune diseases as well as impaired anti-cancer responses. We have discovered two molecules in T cells, early growth response gene (Egr) 2 and 3, which have a reciprocal function in promoting the anti-pathogen function of T cells while controlling their inflammation. This function is essential for both optimal immune responses against pathogens and cancers, and also preventing the development of autoimmune diseases. Recently, we discovered that the anti-inflammation function of Egr2 in T cells is due to the inhibition of another molecule, transcription factor T-box expressed in T cells (Tbet). Tbet in T cells causes inflammation, leading to a potentially dangerous autoimmune reaction. Therefore, this mechanism for controlling Tbet will be applied for the diagnosis and novel therapy of autoimmune diseases. With the understanding of factors regulating the function of T cells, we have also developed a therapeutic vaccine that can up-regulate the anti-cancer responses of T cells.

Based on our findings and newly established Egr2-Tbet transgenic mouse models, this project aims to uncover the molecular mechanisms in preventing autoimmune diseases and promoting anti-cancer responses. The discoveries will be applied for the development of diagnosis and novel therapeutics for autoimmune diseases and cancer.

What outputs do you think you will see at the end of this project?

It has been established that dysfunction of T cells can lead to both autoimmune diseases and cancer. The poor understanding of the reasons leading to this dysfunction limits the development of new diagnostic methods and treatment. One of the major outcomes of this study is to apply Egr2-regulated molecules in activated T cells as early markers for inflammation of autoimmune diseases, so it is possible to allow effective management of these patient’s illnesses. At the end of the project, we will not only publish our findings in leading journals, but crucially, provide scientific base for applying these markers in lupus and arthritis clinics.

The other major outcome is to develop a novel immune therapy for individual treatment of cancer. Microsome vaccine developed in this project was made by isolated membranes from surgical removed tumour tissues. We will use our models to refine the productive methods involved and try to combine this with other immune treatments to maximize efficacy. At the endpoint, we will have enough results to apply grants for translating our findings in mouse models to develop therapeutic vaccines for the treatment of solid cancers such as lung and pancreas cancer.

Who or what will benefit from these outputs, and how?

In short term, our findings (with in the PPL period) will benefit researchers in both basic and clinical groups to understand the mechanisms of auto-reactive T cells in disease

models and the new form of vaccine delivery systems for cancer vaccines. These benefits will be realised soon after we have results from phenotypes and clear assays of the T cells from our models and from efficacy analysis of vaccine treated tumour bearing mice. As this study is closely collaborated with our clinical investigation in T cells from the patients of autoimmune diseases and cancer, the findings after completing this project will be ready to translate into clinical applications.

The knowledge transfer will be realised after second year of the project, some of our findings will start to be translated as clinical tools for autoimmune clinics and at the end of the project hopefully we will apply our findings into translational research to develop diagnostic methods and novel vaccine for diagnosis and treatment for relevant human diseases.

How will you look to maximise the outputs of this work?

We are an established research group in T cell biology and have collaborators across the world. This project is the major piece of active research within our group. The discoveries will be published in high impact journals and international conferences. We will communicate and report all of our research approaches within our field and offer newly developed tools and models to other groups. Importantly, we have established close collaborations with three major clinical research institutes in the UK, Germany and China in cancer immunology and arthritis studies. The support of this global network will ensure the highest possible impact of our findings.

Species and numbers of animals expected to be used

- Mice: 3800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Systemic analysis of immune function can only be done under living conditions and it is impossible to use humans as experimental models. We have chosen to use mice since the parallels between the mouse and the human immune systems are well understood and mouse models of the diseases are well established. This means that reagents are readily available and obviates the need to establish novel models which greatly reduces animal use.

Adult mice will be used to assess the immune function when immune systems are fully developed.

Typically, what will be done to an animal used in your project?

The following procedures will be carried out some examples what will be done as following:

- collect lymphoid organs from culled mice (at the end of most experiment and procedures).

- Breeding transgenic mice (for breeding and maintenance of genetically altered protocols, duration of less one year);

- Injection of immune modulators such OVA/SEA or microsome ip.(in the protocol of In vivo immune responses, with repeated 2 times per animal, duration of less 10 weeks);

-Adoptive transfer of isolated T cells from one type of mice to other, iv,(in the protocol of adoptive transfer of immune responses, once per animal, duration of less 12 weeks);

- Irradiation of live mice for bone marrow transfer (in the protocol of tumour prevention and treatment, once per animal, less 12 weeks);

-Injection of tumour cells subcutaneously (in the protocol of tumour prevention and treatment, once per animal, less then 8 weeks, but tumour growth will be limited less than diameter of 10 mm);

- infection with recombinant vaccinia virus i.p.(in the protocol of viral prevention, less 2 times per animal, less than 12 weeks).

What are the expected impacts and/or adverse effects for the animals during your project?

The impacts could be as following:

- Local pain from injection for a few minutes, but less 48 hr (in most procedures involved).

- Weight loss after viral infection for 3 to 7 days (eg, in protocol of viral prevention), but the weight loss will be limited no more than 20%)

- Tumour grow for 7-14 days (in the protocol of tumor prevention and treatment), but tumor will be limited

< 10mm diameter.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities are no more than moderate which only occur in less than 20% of experimental mice in all protocols based on previous my PPL experiences with similar procedures as below:

- for protocol of "Breeding and maintenance of genetically altered with moderate protocol": 1500 mice; Moderate.

- for the protocol of "In vivo immune responses": 700 adult mice; Moderate.

- for the protocol of "Adoptive transfer of immune responses": 600 adult mice; Moderate.

- for the protocol of "Tumour prevention and treatment": 1000 adult mice; Moderate.

- for the protocol of "Viral prevention": 1000 adult mice; Moderate.

-for the protocol of "Breeding and maintenance of genetically altered with mild protocol", 1800 mice; Mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To understand the mechanism of key molecules in T cells, a systemic analysis of the immune system under living conditions is not possible with humans in vitro. Therefore, animal models are the only solution.

We have chosen to use mice since the parallels between the mouse and the human immune systems are well understood and mouse models of the diseases are well established. This means that reagents are readily available and obviates the need to establish novel models which greatly reduces animal use.

We will carry out, if possible, pre-experiments on cell lines to optimize the procedures and ensure the success of the animal experiments.

Which non-animal alternatives did you consider for use in this project?

We will assess mechanisms of molecular interaction using cells in vitro (after adding or removing Egr2) in a laboratory without using alive animals. Thus, the number of animals used in this project is limited only for the specific analysis of systemic functions of T cells in disease conditions.

Why were they not suitable?

Immune function is systemic and only established in living animals. Therefore, it is impossible to use a cellular system to complete the project. The function of Egr2 and 3, and Tbet in T cells can only be revealed during immune reaction in disease models in living animals. The gain (with gene high level) and loss (genes defected) approaches are more effective methods to understand the function of molecules such as Egr2 and Tbet. Therefore, we have genetically modified the Egr2, Egr3 and Tbet in T cells to control their presence or absence during immune responses.

We cannot carry out any of these experiments in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Due to the factors that the experimental models used are very well established and used worldwide, we have used all the models in our previous three PPL projects and the minimum requirement for measuring T cell function in systemic immune responses are well defined in our animal models.

Therefore, in this project we can accurately estimate the number of animals needed. For all phenotype analysis, differences between groups of mice will be assessed by effective statistical analysis, such as power calculations will be performed to determine the minimal number of animals needed to obtain statistically significant data dependent upon the level of effect for the parameters being assessed. Thus, if the size of the effect is equal to a standardised difference of the mean of between 1-2, each experimental group will contain between 4 and 16 mice with age- and sex-matched, which will allow a significance level of 0.05 with 80% power to be achieved. Scientifically, each experiment has to be repeated at least three times. However, one of the aims of this project is to define the molecular signatures in T cells after immune reactive to experimental diseases. In this part, we have established refined molecular approach to detect molecular differences in a minimum of 50000 cells. Therefore, we will use three to five mice in one experiment and isolate cells (mainly lymphocytes) from each mouse, then compare the difference between mice in same group to reach scientific conclusion. In tumour vaccine experiments, a minimum of 5 mice has to be used and at least repeating three time to reach scientific conclusion. With refined technology in cell lines and well experienced protocols for tumour vaccine, we can estimate the number of animals used.

A total of around 3800 mice will be needed for the PPL applied. As average homozygous production rate in transgenic lines is about 75%, about 2800 transgenic mice needed to reach enough 2200 homozygous mice, so total 3300 (with 500 breeding mice) for GA breeding protocols (including the moderate breeding and mild breeding), which will be used for the experiment: 700 for protocol of in vivo immune responses; 600 for protocol of adoptive transfer of immune responses; 1000 for protocol of tumour prevention and treatment; and 1000 for protocol of viral prevention.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will plan the experiments that can allow us to monitor as many biological parameters as possible in T cells, such as identifying DNA bindings of Egr2 in T cells from virus infected mice. Thus, we could use one designed experiment to answer multiple questions.

We will plan experiments, including breeding strategies, in advance so that breeding will be limited as necessary. Where possible, randomised block and factorial designs will be introduced into experimental strategy in order to minimise the number of animals used.

We will focus on three elements in our design to reduce number: 1) do pre-experiments in cell lines for in vitro methods such as phenotyping, RNA sequence and chromatin remodelling to optimise protocols before starting in vivo experiments; 2) combine different experiments in one animal experiment such as identification of prototypes and analyse chromatin remodelling of effector T cells are combined in same viral infection experiment; and 3) extensive literature searches, inform and communicate with related labs/groups to avoid necessary replication of the experiments that have been reported. We will also maximise use of tissue, and genetically altered animal lines to maximum the efficiency to get the results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have good experiences in animal experiments and the models used in this project which allow us to design breeding program together with experiments. We are closely collaborating with groups sharing similar interests in T cell biology and extensively analyse reported database to avoid repeated experiments. We have published modelling of T cell function regulated by Egr2 that allows us to focus on key questions investigated by well-designed experiments. These will reduce significantly the number of animals used in this project.

All the experiments will be designed with not only the concurrent and relevant to make the outputs addressing the proposed question directly, but also with accurate repetition and controls based on randomisation, power calculation and biological relevant. At same time, we will avoid bias, repetitive to other reported experiments and maximising data acquisition in each experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are going use mouse model. Mice are considered to be a mammalian organism similar enough to humans to provide invaluable information from pre-clinical testing of potential therapeutic approaches before progressing to human clinical trial.

As the aim of project is to study the role of molecules Egr2 and Tbet for the function of immune system, we are going to use Egr2 and Tbet related transgenic mouse models for this project, so that the experiment system is sensitive and clear for the purpose, and to maximum the efficiency of experiment result output.

The methods used in this project, eg, we will infect mice with modified experimental virus which can activate immune system but not cause severe symptoms; injection of well-established tumour cells under skin which will result in local tumour and tumour induced immunity, but will not cause organ damage; transfer of T cells from one type mice to other to define specific function of genetic modified T cells in normal mice, and bone marrow transfer to assess the function of newly developed effector T cells from donor mice in recipient mice.

Why can’t you use animals that are less sentient?

Mice are the lowest vertebrate animals in which immunological studies are possible to conduct.

Immune system is essential for keeping wellbeing of normal life of human being. Closely related and less sentient animal is mouse. Therefore, majority of immune science are now investigated in mouse models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In this project, we only use well-established disease models that have well defined clinical symptoms and will control the level of clinical sign to minimum severity.

In addition, we will follow the best practice with all the procedures as much as possible to reduce welfare costs, for examples:

-To optimize breeding program of EGR KO mice in order to avoid welfare problems in offspring (protocol of breeding and maintenance of genetically altered with moderate): Previously, it was found that the failure of some mice to thrive in the first 21 days of life with slow growth rate and less activity than normal is due to “tooth development problem" with Egr3 deficiency. Moreover, the double KO female mice usually had less care for their offspring. To avoid these problems, a special breeding strategy has been considered by using Egr2homo/Egr3homo (male) with Egr2homo/Egr3 heter (female) for the breeding in order to improve the health of offspring and we will regularly check the new-burns to eliminate the problem at the earliest time point (e.g., by giving some mashed food around 20 days; keeping the KO babies with the breeding females for one month instead of 21 days).

- For microsome vaccine test in tumour models (protocol of tumour prevention and treatment): only subcutaneously route for the tumor injection will be used as it is less harmful to the mice and easy monitoring the tumour growing comparing any other injection methods.

- For viral infection study (protocol of viral prevention): when vaccinia viral system is used with intranasal (i/n) route the mice showed clear clinic symptoms but more stressed with a lower food intake, less active and loss more body weight compared with intraperitoneal (i/p) route. However, for the purpose of investigation of T cell responses in this PPL, the study can be achieved using i/p. instead of i/n., which would have less harmful to the mice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The disease models and bone marrow transfer are well established in countless publications from other and us. In which the unified practice guidance is adapted worldwide. We will stick on the the most practice guidance which have been reported in our publications and accessed many times by local ethic committee and Home office.

We will follow best practice based on published data, below as some examples

- For Reconstitution of bone marrow (protocol of adoptive transfer of immune responses): A fractionated dose for whole body irradiation using “2X of 5.5 Gy with 3 hours apart" will be less harmful for the animal. Furthermore, we have recently been able to refine the irradiation process by optimising the orientation of mice to the irradiation source which is less restraint to the mice.

- For viral infection and tumour in vivo study (protocols of tumour prevention and treatment and viral prevention): It is not possible to study the mechanisms of Egr2 and 3 in the development of T cell function without using animal model. We have established best possible experimental models in both viral infection and tumour to achieve the induction of T cell immune responses with minimum discomfort. In virus infection, we have refined protocols that results full immune responses in infected mice within 20% of body weight

loss. In tumour models, the local growth with limitation of 1cm size will induce detectable anti-tumour immune responses with limited stress to the animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are constantly communicating with top level scientists in our field to renew our technologies to avoid unnecessary mouse experiments. We carry out pre-experimental tests in cell lines, and molecular network modelling to refine the mouse experiments at maximum scientific outcome and minimize the use of animals. We have well implemented these in our recent research. With our regular meetings which a 3Rs agenda is regularly discussed and updated, we share 3Rs news including technical updates, relevant publications and meetings or conferences.

Home Office

138. Understanding immune cell development and its functional consequences

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Immune cell development, Immune cell function, T cells

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project seeks to better understand the mechanisms that underpin the development of immune cells; that are critical effectors in all immune responses. Importantly, it will focus on how development of immune cells impacts on their subsequent function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding how the immune system functions to combat infections and malignancy, while at the same time being tolerant to our own tissues and harmless surroundings, has never been more important. Critical insight into these complex functions comes from a thorough understanding of how these cells are generated. Thus, this project focuses on the mechanisms by which immune cells develop and how this influences subsequent immune cell function.

What outputs do you think you will see at the end of this project?

The studies detailed in this proposal will significantly advance the understanding of how immune cells develop, particularly T cells that are generated in the thymus. These new insights will be communicated at National and International conferences (e.g. as poster or oral presentations). We will also publish key findings that advance the field in journals that have wide-ranging reach and impact, with a particular emphasis on open-access publication and data sharing.

Who or what will benefit from these outputs, and how?

A key focus of this work is the development of immune cells (known as "unconventional" lymphocytes) that are increasingly considered to connect the broadly reactive, rapidly acting innate immune system with the delayed responses of the pathogen-specific adaptive immune system. A better understanding of the development of unconventional lymphocytes will provide critical insight into how they function. In turn, this will better inform manipulation of unconventional lymphocyte responses in disease, and will better advise how these cells can be utilised in therapeutic strategies, for example to augment anti-tumour immune responses.

Thus, in the short-term benefits of these outputs would be to other researchers in the field of lymphocyte biology (e.g. developmental immunologists, T cell and B cell biologists). In the mid-term, these outputs may advise modifications to the development and use of unconventional lymphocytes in immuno- therapeutic strategies, particularly in the cancer setting. And finally, long-term benefits may be to patients who benefit from therapies that utilise immune cells to ameliorate chronic and potentially fatal diseases.

How will you look to maximise the outputs of this work?

We have a strong track record of maximising the impact and reach of publication outputs through international collaborations. We have also made regular contributions to the field in the form of review, opinion, and perspective articles, and talks at National and International conferences, in which unpublished work, concepts, ideas and plans are discussed with the scientific community.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Genetically modified animals will be used either because no other suitable tools exist, or because a modification that cannot be achieved by other means is required.

Genetically modified mice are ideal for these investigations as they have been the model of choice for studies on the development and function of the immune system for decades. Thus, data generated form these investigations can be analysed and understood in the context of the wealth of previously obtained information related to the subject.

Animals will be culled by schedule 1 methods to obtain tissues from mice at embryonic stage day-11 (E11) through to adult mice (<15-months). It is important for this project on lymphocyte development to use embryonic and neonatal stages as development of the immune largely occurs between the ages of E11 to 3-weeks of age.

Typically, what will be done to an animal used in your project?

Typically, an animal used in this project will be bred and maintained and then killed by schedule 1 methods (or under terminal anaesthesia by exsanguination then schedule 1 method, or fixation perfusion as described above), at any age from embryonic stages to adult mice (<15-months).

Depending on the genetic modification an animal may have a tissue biopsy taken to determine genetic status by one of the following methods: ear punch, blood sampling, hair sampling (rarely, due to technical problems during analysis, a second sample may be taken using the least invasive method).

For strains with inducible genetic alterations, animals will be injected or treated with appropriate compounds in order to activate the specific genetic alteration. Mostly mild effects are expected from this dosing, but some animals may show some transient moderate effects. In all cases of administration of substances, we will follow LASA and Refining procedures for the administration of substances (Morton et al. 2000) guidelines. Animals will be monitored daily during the dosing days for general health and any animal showing any unexpected distressful response (no activity, unresponsive, hunched, loss body weight to 20%) will be culled by a Schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

The phenotypes of the mouse strains used in this project are anticipated to have no harmful effects.

The substances that we will use in this project to induce genetic alterations in mice with inducible genetic modifications have been used previously in other laboratories. They are widely used substances for which the toxicity and side effects are well known, e.g. doxorubicin and tamoxifen. These genetic alteration-inducing protocols are highly unlikely to cause adverse events of more than mild, short and temporary harm.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity for breeding and maintaining GA animals is mild; >99% sub-threshold. Expected severity for induction of inducible genetic alterations in mice is mild (100%).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

These studies aim to define the molecular basis for the dynamic interactions of different cell types within the distinct spatial anatomy of organs where immune cells develop, such as the thymus, bone marrow, and gut. Such complex, dynamic interactions cannot be adequately represented by sole use of cell lines, models in vitro, or mathematical models. However, as we learn more about the key interactions between cell types, e.g. within the thymus or gut, we shall maximise our efforts to use organ cultures for dissecting key pathways, as we have published. Nonetheless, we require live animal models to accept or to refute hypotheses concerning the molecular basis of lymphocyte development, and the pathophysiologic importance thereof for human beings. As such knowledge emerges, our collaborations with various clinical research teams will promptly investigate the parallels using human cells and clinical material.

Which non-animal alternatives did you consider for use in this project?

We have considered and will continue to consider the use of non-animal alternatives. These include in vitro organ culture, and exploring the use of "organ-on-a-chip technologies. We also utilise various types of thymic organ culture, using thymic tissue ex vivo, for the vast majority of our experimental investigations, to avoid doing these in intact animals in vivo. We are also actively looking at ways to reduce the use of animals in research by developing better in vitro models.

Why were they not suitable?

We use thymic culture techniques in the lab whenever feasible. However, none of these, as yet, fully reproduce the dynamic interplay between different cell types within the distinct

spatial anatomy of organs where immune cells develop. Thus, we still require tissues ex vivo to set-up and seed many of our culture systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

During similar work under the animal licence of our collaborator we calculated that we bred and used 150 animals in an average month. For any one month, this would represent 30 animals (approximately four litters) from five mouse strains. This would supply the necessary tissues (largely thymus) for our program of experiments ex vivo. In addition, we are using the NC3Rs EDA tool to assess individual experimental design. This ensures that the correct number of animals are used per experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our Institute statistician was consulted during the experimental design phase of the project. The NC3R website also contains many useful guides for experimental design, e.g. NC3R's Experimental Design Assistant. Moreover, most of work will be directly linked to appropriate breeding colony management, and our team has sound expertise on GAA breeding, according with international guidelines (Jax Labs US-https://www.research.uci.edu/forms/docs/iacuc/JAX-breeding-strategies.pdf).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are continually looking to refine and improve our methodologies for running organ cultures in vitro. For example, better utilisation of stromal cell lines that support lymphocyte development would reduce the number of mice required to supply primary stromal cells ex vivo. We are also exploring new technologies, for example organ-on-a-chip approaches.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are used in this project to provide tissues (primarily thymus) for experiments and culture systems in vitro. The genetically-modified strains of mice used to provide these tissues are either "knockout" mice, or 'Knock-in" mice with a deficiency or increase in a particular gene product, respectively. These either affect the presence or absence of particular immune cells (e.g. Rag-1 KO mice that lack all lymphocytes), or affect a particular signalling pathway (e.g. constitutively active signalling "knock-in" mice). Generally, these mice do not have phenotypes that impact negatively on the health or well-being of the animals. Mice generated and maintained to supply these tissues with be killed using schedule 1 methods. Thus, pain, suffering, distress, or lasting harm is not expected in our protocols and will be kept to an absolute minimum (e.g. tissue sampling for genotyping).

Why can't you use animals that are less sentient?

We will use mice in this project as the basic physiology of immune cell development is sufficiently compatible with human, and already well-characterised (hence, a better context for new findings). In addition, the mouse model allows for use of genetically altered animals, of which there are now thousands. Note that humans and mice have a comparatively similar immune system that is also observed in most jawed vertebrates (although fish are somewhat different too). More primitive animals (e.g. nematodes, drosophila) do not have comparable immune systems so would not be an appropriate model to study lymphocyte development.

As the primary focus of this project is the development of immune cells, tissues are used primarily from young animals (embryos, neonates, and mice between 1-6-weeks of age), as choosing these ages better captures the developmental process. Occasionally we will use older adult mice (as a comparator) up to 12-months of age.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The protocols for breeding and maintenance of the genetically-modified animals in this project are mild (as are the strain phenotypes), with <1% expected mild or short-term moderate adverse events.

Nonetheless, we will stay up-to-date with the latest recommended protocols, e.g. when performing tissue biopsies to determine genetic status by one of the following methods: ear punch, blood sampling, hair sampling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Regular reference will be made to the Home Office homepage and documents, NC3R homepage and documents, and ARRIVE or PREPARE guidelines. This will ensure full transparency in reporting all the in vivo experimental data. In all cases of administration of substances, we will follow LASA and Refining procedures for the administration of substances (Morton et al. 2000) guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The latest advances in the 3Rs will be obtained through information/newsletters from the Home office and NC3Rs, attendance at relevant academic conferences, and regular literature searches. Identified new methods/protocols will be discussed with our Biological Sciences Unit staff, NVS and Home Office Inspector.

139. Mechanisms of cardiac arrhythmogenesis – insights from murine model

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

heart, arrhythmia, mitochondria, ion channel, electrophysiology

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall purpose of our project is to determine the link between the genetic causes of inherited arrhythmic syndromes and more general phenotypes associated with acquired arrhythmias. In doing so, we aim to advance understanding of arrhythmogenic mechanisms in order to aid future therapeutic and clinical intervention.

Our project is defined by the following key elements:

1. The mechanisms underlying arrhythmias caused by genetic perturbations

2. The possibility for drugs restoring the function of ion channels and metabolic regulators affected by such genetic perturbations to rescue atrial and ventricular arrhythmias.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding mechanisms for arrhythmia particularly in ageing remains a main stay in the diagnosis, treatment and prevention of cardiac arrhythmia. In addressing this global challenge, the use of animal models with targeted disruption of specific physiological pathways provide valuable insights into the elucidation of arrhythmogenic mechanisms. Concerns and lack of fundamental mechanistic understanding with regards to ageing and sodium channel pathologies has led to limitation in how new drugs are develop and an aged arrhythmic patient is managed in clinics.

Our work is fundamental to the understanding of arrhythmia and its propagation, a question of particular importance to electrophysiologists, but also importance to the study of biological pattern generation associated with drug administration and ageing. It will link the underlying pharmacology to cell membrane and intra-cellular currents, bridging research between drug-induced disturbances and physiological effects. It will allow this novel paradigm to be scrutinized as a platform for analysis of electrophysiological abnormalities in a range of pharmacological agents. The work will be of relevance to pharmaceutical researchers and cell biologists, who will gain insight into the role of ageing and selected drugs in cardiac function and correlation with electrical and cellular abnormalities.

What outputs do you think you will see at the end of this project?

Beyond the inevitable short-term output of an enhancement in our foundational scientific understanding of arrhythmogenic mechanisms by the elucidation of candidate molecules and associated signalling pathways, our work will have even more direct clinical implications. Notably, by addressing our objectives outlined previously, our expected long-term outputs are the identification and vetting of: (1) biomarkers for improved diagnoses and prognoses7; and (2) pharmacological targets for the development of efficacious novel drugs8. We aim to publish our data in high-impact academic journals,
national and international conferences, and, by extension, disseminate them to the wider, global community of cardiac electrophysiologists – a feat we believe highly likely given our publication of over 60 papers in the last years and our presentation at more than 80 events.

Who or what will benefit from these outputs, and how?

Given that, every year, there are 50-100 Sudden Cardiac Deaths (SCDs) per 100,000 members of the population in Europe and the USA, the translation of our findings based on the laboratory Genetically- Modified (GM) murine model into diagnostic tests and pharmacological or other therapies at clinicians' disposal will undoubtedly be perceived as worthwhile by the patients who benefit from them.

Additionally the pharmaceutical industry or biotech companies may also benefit from this work given that we may potentially identify new 'drug-able' targets. A corollary of patient benefit is, of course, the diminished economic and health burden of arrhythmias on the NHS.

How will you look to maximise the outputs of this work?

Our experience from previous projects, as well as through our collaborators, who have held Project Licences in the past, ensures we will minimise pursuit of unproductive lines of enquiry, such as a drug soon identified as producing unacceptable side-effects. Likewise, this will maximise pursuit of novel avenues on signalling molecules and drug targets that exhibit early promise. Importantly, we aim to greatly facilitate the clinical limb of our translational research program through fostering a link with NHS hospitals, using the results of laboratory experiments involving our transgenic mouse model to focus on the electrophysiological assessment potentially in patients.

Likelihood of achieving benefits with these models and methods

All protocols and techniques necessary for the generation of monogenic perturbations in mouse lines such as those described above have been well established by scientific consensus in the electrophysiology community and refined through our own experience in using similar Genetically- Modified (GM) murine models for 15 years under the previous Project Licences. Given the critical role that ion channels permitting currents play in the waveform of the cardiac action potential, it is highly likely that any metabolic regulator directly or indirectly modulating channel gating properties will precipitate arrhythmogenesis when either absent or overexpressed in our GM mice lines. Furthermore, owing to the function of metabolic regulators such as PGC1 as transcriptional coactivators of genes upregulated by nuclear receptors, coupled with the observed and highly substantiated contribution of an aberrant cardiac transcriptional profile to arrhythmias, our analysis of age-related homeostatic disturbances is also very likely to identify mediators of the link between metabolic dysregulation (as in obesity and diabetes mellitus) and arrhythmias.

Of the completed series of experiments working with previous collaborators, many have provided a basis on which to conduct predictive testing. Importantly, the identification of high-risk patients permits rapid instigation of protective measures, such as the installation of an implantable cardiac defibrillator (ICD), to reduce the incidence of sudden cardiac deaths (SCDs) that would otherwise arise from arrhythmic events. In fact, such diagnostic utility is evident in the implantation of more than 15,000 ICDs globally. Moreover, the use of our GM mice to understand the basis of arrhythmogenic risk in monogenic disorders has

already facilitated, and will continue to permit, characterisation of molecular targets for therapeutic, and especially pharmacological, intervention. Our GM mouse model conveniently provides a means for testing not only the efficacy, but also the safety, of any pharmacological agent. We thus consider it highly likely that, with such links, our generation of knowledge on the biochemical structure, biophysics and molecular interactions of putative targets will drive future development of antiarrhythmic drugs specific to patients with metabolic disease, with the long-term aim of reaching phase I clinical trials.

Species and numbers of animals expected to be used

- Mice: 240

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These animals have been validated to provide the most translational results that will closely resemble conditions affecting humans. It is not possible to undertake such experimental interrogations in humans.

We are aiming to study the effects of certain gene mutations in the ageing process. We will use mice up to the age of 24 months old since mice ranging from 18-24 months of age correlate with humans ranging from 56-69 years of age. This age range meets the definition of “old,” which is the presence of senescent changes in almost all biomarkers in all animals. We will not use mice older than 24 months as mice are then considered “very old” and survivorship drops off markedly.

Typically, what will be done to an animal used in your project?

Breeding, ear clipping for identification (ear notching), maintenance up to 24 months of age, drugs administration, ECG recording under anaesthesia and surgery for telemetry under anaesthesia.

Humane killing with a Schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

Pain during injections can occur. Otherwise, any other adverse effects may be related to the normal ageing process. For this reason, animals will be monitored regularly. Moderate to long term administration of substances/drugs can cause repeated incidences of mild pain and therefore stress to the animal. Additionally, this is coupled with the stress of repeated handling during the injection or oral gavage procedure. Insertion of needle ECG,

whilst done under anaesthesia, may have some minimal lasting mild soreness at needle entry site. Animals that undergo surgery will have incision wounds that will take time to heal and this can cause low grade inflammation and pain over the healing process.

There may be some initial discomfort due to post-surgical anaesthesia or due to the device implanted within the body cavity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate – We predict that approximately 50% of animals to be used in this license will be subjected to Protocol 3 and thus would be subjected to moderate severity. This is estimated at approximately 240 mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The heart is a complex organ with several processes occurring simultaneously under physiological and pathophysiological conditions (e.g. organelle and cellular interactions , dynamic metabolic changes, hormonal alterations and more). The ageing body, especially when coupled with other conditions such as obesity and diabetes add to the complexity of the studied processes. Hence, compared to cellular or tissue models, an animal model is better suited in studying physiological processes in the heart.

Cultured cell lines, although useful for initial non-translational discovery testing, cannot reproduce the complete array of molecular, cellular, neuronal, physiological, and pathological aspects of the mouse model necessary to fully understand the mechanisms investigated in this project, especially regarding ageing and additional co-morbidities. While it is evidently possible to corroborate our data with in vivo studies on human arrhythmia patients, it is not possible to attempt experimental drug rescue on them, creating the need for an animal model. Furthermore, while it is also clearly possible to conduct ex vivo experiments on atrial samples isolated from humans, such experiments would not be translatable to ventricular samples, which are: (1) considerably more difficult to obtain; and (2) unable to maintain an intact arrangement of cardiomyocytes.

This study will be performed using mice because all relevant methods and techniques are successfully established in this species, and because of the availability of genetic alterations in these species. With this approach we will be able to study specific biochemical pathways with a view to understand disease progression. Understanding the effects of interfering with the disease process at specific points in underlying pathways can lead to the development of new treatments for heart disease. All procedures will be conducted by highly skilled, licenced personnel, and non-invasive techniques will be used where possible. Components of procedures will be the minimum required to be consistent with reaching the scientific objectives. Animals will be closely and regularly monitored during the study.

Surgical animals will receive pain relief as standard. Any clinical problems will be dealt with in consultation with the veterinary surgeon. There are strict pre-determined 'humane endpoints' in place, based on clinical signs, at which animals are promptly and humanely killed to ensure that any animal does not suffer unnecessarily.

Which non-animal alternatives did you consider for use in this project?

in silico mathematical models of myocardial conduction human iPSC-derived ventricular and atrial cardiomyocytes

Why were they not suitable?

It should be noted we have considered using our in silico mathematical models of myocardial conduction as an alternative. The basis of such models in the first place is the experimental data collected from our murine model. We then use the computer model to refine our experiments on the GM mice.

Furthermore, since 2018, we have also been developing human models in the form of in vitro experiments on human iPSC-derived ventricular and atrial cardiomyocytes and gradually using them as an alternative to the murine model. However, despite replacing some aspects of the work on GM mice, this in vitro model is largely complementary and thus unable to completely replace our in vivo GM mice model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The design of individual experiments generally involves factorial design to maximise the information obtained. The majority of measures are quantitative and suitable for statistical

analysis. Comparison between groups will be made by 1-way analysis of variance (ANOVA) or a 2-way repeated measures ANOVA followed by an appropriate post hoc test. We have reviewed a range of published studies that use similar techniques being proposed here and observed great variability in the number of animals used per experimental group. Following our discussions with a statistician, we have calculated our sample sizes for our quantitative experiments by power analysis using a significance level of 5% and a power of at least 80% (Ref: http://dx.doi.org/10.1136/emj.20.5.453).

We will need 8 groups of mice due to:

- 2 mouse genotypes (WT or respective mutant)
- 2 age groups (young or old)
- 2 treatments (control vs treatment with relevant drug – please see details above)

The standard deviation within a group is unknown, hence our power calculations are conducted based on effect size. Aiming for power of 80% and significance level of 5%, an effect size of 1.51 (i.e. the difference between the means of the groups is 1.51 multiplied by the standard deviation) is consistent with 8 mice per group. Based on our previous studies, attrition rates in this kind of experiments is higher in aged mice compared to younger mice. For this reason, we need to add 2 more mice to our calculated n=8/group, thus requiring n=10/group. It should be noted that the exact numbers of animals required will vary with specific experiments as well as the estimates of the coefficient of variation for specific outcome measures; nevertheless, the general principle outlined in the example will be followed. In summary, we need 8 groups of mice at 10 mice/group for a total of 80 mice per readout.

The readouts for each experimental condition include surface ECG recordings, telemetry recordings, patch clamp recordings, and Langendorff recordings. Surface ECG and Langendorff recordings will be performed with the same group of mice, whereas separate groups are required for telemetry and patch clamp recordings. The final number of mice is estimated at 80 mice per readout for surface ECG/Langendorff, telemetry, and patch clamp recordings (total of 240 mice).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have performed pilot experiments in cells to determine a range of appropriate dosage for the drugs we are aiming to use in vivo. Moreover, we have longstanding experience on maintenance and breeding of the appropriate number of animals to maintain the line. Typically, we will always have 2-3 breeding pairs for each line to minimise risks of ‘losing’ the line due to disrupted breeding. From previous experiments, we know when we might need to separate pairs if no experiments are planned. We have also consulted a statistician in our efforts to calculate the appropriate number of animals required in this study. Moreover, as part of our experimental design and good laboratory practice, we will

continuously monitor our experimental needs and re-evaluate the number of mice necessary in our project and data analyses. We will measure production and breeding performance for each line and ensure only the minimum numbers of animals required are bred in any case. Finally, based on previous pilot studies we have optimised serial assessment of electrophysiological measurements and, for example, confocal microscopy experiments to generate data from the same animal, thereby reducing the number of mice necessary in our studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have recently refined our techniques to include, rather than merely determination of monophasic action potentials and restitution metrics, a multi-electrode array that enables detailed analysis of conduction properties. Importantly, this method is ideal for providing an experimental platform to define not only the role of individual genes in arrhythmogenesis, but also to systematically examine the effects of pro- and anti-arrhythmic interventions on arrhythmogenic substrates.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal models: C57BL/6 and S129 mice with mutations such as Scn5a+/- sodium channel haploinsufficiency; deltaKPQ sodium channel gain of function; RyRP2328 ryanodine receptor mutation, Atf5 deletion. The GAA we will use in our experiments have been validated in prior experiments and they are useful models for the project.

Methods include breeding and maintenance, ECG recordings, telemetry, patch clamp, Langendorff, drug administration.

Why can't you use animals that are less sentient?

In principal, mice, despite having a smaller heart that works at much higher heart rates compared to humans, share considerable genetic homology and their hearts have similar cardiac conduction systems to humans. This justifies using mouse models in studies of arrhythmogenic phenomena.

Furthermore, genetically modified murine cardiac models potentially fully replicate the genetic changes underlying congenital clinical conditions associated with arrhythmogenesis, without requiring prior pharmacological intervention – we have previously developed a range of monogenic mouse models in our previous Project licences (Scn5a+/- sodium channel haploinsufficiency; deltaKPQ sodium channel gain of function; RyRP2328 ryanodine receptor mutation) and will now use these models, as well as other commercially available GM models in this study. These mice make powerful drug testing models to explore the cardiac electrophysiological events associated with drug administration, as well as the response mechanisms particularly in arrhythmic conditions.

Using a transgenic mouse model will allow us to continue delving into the mechanisms by which genetic alterations coincide with complex disease fostering a proarrhythmic environment. No other species less sentient is available at the moment that will allow obtaining these results.

Large animals models are not suitable for this study when it comes to ageing as they require longer durations to age and thus lead to more welfare implications. Whilst pigs maybe an option (ignoring ageing component) the preclinical perspective is not entirely captured by the pig model. An equally valid and suitable GM model is not available in pigs and the mouse model purposed offers also the advantage of being already a validated model for these conditions and drug testing.

Given the well-established contributions of sedentarism, obesity, diabetes mellitus and metabolic syndrome to the presently increasing prevalence of arrhythmic phenotypes in the UK population, such an opportunity is of great relevance to the future clinical treatment of NHS patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals used in the experiments described herein are not expected to exhibit any harmful phenotype. For older animals, special consideration will be given to their environmental enrichment. Enrichment for aged mice will follow best-practice guidelines as recommended by the Experimental Biology Unit. We will be monitoring our mice on a daily basis. After initial recovery from surgery, adverse effects may include wound infection, which is extremely rare. We will prevent that using good aseptic technique in our procedures, perioperative analgesia and implementing a monitoring regime. In the event of any animals showing any signs of mild discomfort (e.g. swelling, redness or discharge at the operation site), but are otherwise well will treated by minimally invasive methods following advice from the NVS. The animal will be culled by a Schedule 1 method if no improvement is observed within 24 hours of treatment. In all cases, we will work closely with the NVS and seek advice on animals whose welfare is giving reasons for concern. We will use gas anaesthesia which is safer than injectable anaesthesia and we will monitor our animals during anaesthesia and keep them on heating pad. Whenever possible we will try to carry out more techniques during the same anaesthesia event to reduce them (ex.

Imaging, drug administration, sampling during the same anaesthesia). We have implemented a specific welfare monitoring method for ageing signs and a details scoresheet with actions to better assess old ageing animals welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The most effective means of elucidating the function of genes whose perturbations are implicated in cardiac arrhythmogenesis is the integration of a GM mouse model with other laboratory experiments. Mice lines with defined and well characterised genetic background such as Scn5a+/- sodium channel haploinsufficiency; deltaKPQ sodium channel gain of function; RyRP2328 ryanodine receptor mutation; PGC receptor mutation, Atf5 deletion are readily available and suit the work of this project. The mouse lines chosen have extensively been validated and have previously been successfully used to recapitulate the human condition thus proving to be a superior translational model. All lines used in our work will thus conform to such rigorous selection ensuring that only the most reliable and translationally relevant modules are utilised.

All the mice will be protected against any potential infection as they will all be maintained in a full- barrier clean environment in our recently opened state-of-art new Biomedical Research Facility.

Environmental enrichment will provide good living conditions to the mice and reduce the stress and mice will be checked at least once daily. Enrichment for aged mice will follow best-practice guidelines as recommended by the Experimental Biology Unit. All procedures will be performed by trained and competent persons and following NVS advice. We will perform ECG which are well characterised procedures carried out routinely and very well tolerated in rodents. To minimise stress ECG will be carried out under anaesthesia following NVS advice and animals will be checked after the procedures. We have extensive experience (15 years) in ECG recording and experienced problems in less than 2%.

Animals undergoing surgery may experience transient post-operative pain or discomfort. Anesthesia and pain management regimes will be administered upon advice from our NVS. Adequate analgesia will be provided at the beginning and after the surgery to minimize animal suffering. We will provide particular care for recovery after surgery and will include an animal welfare scoring sheet for each animal for health check. If the levels of pain, suffering or distress exceed severity limits indicated by the protocol, we will take advice from our NVS and, if necessary, sacrifice the animal with a Schedule 1 method.

Our animal technicians and NACWO are experienced in management of animal population health and welfare. We also have extensive experience (6 years) in surgery to implant telemetry and have rarely experienced any adverse effects (less than 5%). Surgery for implantation of telemetry device is performed under aseptic conditions and has a moderate severity limit. In addition, this surgical procedure is a well-characterized technique done

routinely by our group and the implant is well tolerated by rodents. Mice will be euthanized by schedule 1 methods or under terminal anaesthesia under protocol 1,2,3,4 and, whenever reaching humane endpoints detailed in the protocols, with a Schedule 1 method.

Animals receiving drugs treatment will be monitored appropriately and whenever possible oral route of administration will be favoured to parenteral routes. Drugs tested, including their dosage and length of administration, will be selected mainly among well characterised drugs and their use will be preceded by literature review and eventual previous in vitro tests. We will use single use needles for all our injections and avoid tail handling our mice.

Animals will not be single-housed and the last mouse in a cage will be used within 1-2 days after its last cage mate is taken. The study design has included comparison between knockout and wildtype littermate controls which will reduce the biological variation and increase the sensitivity, reducing the number of animals needed.

In carrying out our work, we aim to use older mice with florid phenotypes in order to minimise their suffering and the total number of GM and WT mice in use.

No severe protocols will be used.

Finally, we will adhere to the ARRIVE guidelines in regards to the reporting of research involving animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will be checking the literature for 3Rs advancements regularly and implement these accordingly. In addition, we will be working closely with the NACWO, NIO and NVS, as well as engage with the University’s User Forum and latest guidance from the NC3Rs on recent and general advances in the 3Rs.

140. Modelling gene therapy for congenital bladder dysfunction

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

therapy, congenital, urinary, genetic, neuro-muscular

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to take the first experimental steps to cure congenital diseases that affect the nerves and muscle of the bladder and prevent normal urination. We will gain biological insights into these diseases by studying genetic mouse models. We will use these models and the biological insights as a platform to test whether gene therapy can safely cure these diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Nearly 30 in 10,000 live births have congenital anomalies of the urinary tract, the 3rd most prevalent anomaly in the UK, and one of the commonest disorders detected when prenatal ultrasound screening is performed. Some severely affected foetuses undergo termination while others are born. Of those born, many suffer from kidney failure as children or adults, and require dialysis or transplantation, without any cure for the underlying pathology. One particular subset of anomaly affects nerve – muscle communication and as such causes functional, rather than anatomical, obstruction of the urinary tract.

In the last 25 years, genetic causes of many congenital diseases have been defined, opening the possibility of developing cures that target the underlying molecular pathology. Effective cures for diseases with a genetic basis are being sought in other disease systems, utilising understanding of the genetic and biological disease pathology, for example in Spinal Muscular Atrophy. Here, modified viruses are used to deliver therapeutic genes to the affected tissues. This has not been attempted for diseases that affect the urinary tract, despite the associated health burden and an increasing understanding of the genetic bases for these diseases. Neuro-muscular diseases that affect bladder voiding are a promising target for gene therapy as there is no anatomical anomaly per se, opening the possibility that by resolving the underlying defect at a gene level we will be able cure the disease. To establish whether gene therapy could be efficacious it is essential to fully understand the disease processes, and how these change with age (the disease natural history). We will use this knowledge to design and test therapeutic strategies in animals that have the disease. This will pave the way for evaluating the safety and efficacy of therapies in people with congenital voiding dysfunction.

What outputs do you think you will see at the end of this project?

This work will demonstrate the feasibility of using gene therapy to treat mouse models of bladder voiding dysfunction. Such studies have not been performed previously in the urinary tract and the results will form the basis of multiple high impact publications. Totally novel information will be obtained on the feasibility of using viral vectors to deliver therapeutic molecules, and treatment parameters will be defined. Crucially, the efficacy of using viral vector-delivered gene therapy to prevent congenital bladder dysfunction will be determined. If the pre-clinical trials described in this licence are successful, they will pave the way for use in human clinical trials.

Who or what will benefit from these outputs, and how?

There is no cure for congenital bladder dysfunction, and affected individuals are at a high risk of renal failure and death, with costly continual treatment. Therefore, there is an urgent need to develop new treatments. In the short term, these studies will set a precedent for

how advanced therapies, such as using viruses to deliver gene therapy, can be used to treat animal models of voiding dysfunction. This will be of great interest to various parties, including urologists, researchers that study the urinary tract, and researchers who are involved in the application of advanced molecular therapeutics.

From a patient perspective, these studies are designed to lead to clinical trials and as such will be of potential direct benefit to affected individuals. Here, we can look to the precedent set in the treatment of spinal muscular atrophy, where successful preclinical trials of viral vector mediated gene therapy were run in genetic mouse models of the disease. This subsequently led to human trials and regulatory approval in USA and EU in under eight years, with treated children effectively cured.

From the perspective of policy makers and funding bodies, this work will demonstrate another disease system in which gene therapy can be efficacious. We are working closely with large program bids to attract funding for Rare Disease research, and this work will contribute to the relevance of ‘personalised medicine’ in treating rare and costly diseases.

How will you look to maximise the outputs of this work?

Our results will be published in original research papers in high impact journals. We will report ineffective therapeutic strategies as well as the effective strategies, an essential step in the development of novel therapeutics. We will also discuss our work at international conferences, such as the International Continence Society, and we have collaborations with both gene therapy and urology experts.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Urinary voiding is a complex, multi system behaviour. Mice model many of the physiological aspects of human voiding, and there are genetic mouse models for diseases that affect bladder voiding, including a number with a neuro-muscular basis. It not possible to model the full range of physiological defects and therapeutic effects in non-mammalian systems. We will study embryonic and postnatal to adult mice, to identify the developmental origin and natural history of the diseases being studied. This will inform our therapeutic strategy by indicating a therapeutic window. In addition, we also require adult mice to maintain our genetic mouse colonies.

Typically, what will be done to an animal used in your project?

Mice will be bred from parents that each have one copy of a mutant gene, resulting in ¼ offspring with both copies of the mutant gene. These mice will have bladder voiding dysfunction. Within 48 hours of birth, the mouse will receive an injection of the virus containing the therapeutic gene, into the superficial temporal vein. The therapeutic administration causes no lasting harm to the mouse, but can involve anaesthesia. The mouse will be observed and analysed by non-invasive techniques, such as ultrasound or voiding behaviour evaluation for up to eight weeks. The mouse will be humanely killed or will undergo a physiological technique to measure bladder function, while under terminal anaesthesia, and then be humanely killed. Some mice that are not used to model a therapy will be studied for up to one year to understand the underlying disease mechanisms. While alive, they will be studied with the same non-invasive techniques and then humanely killed or analysed for bladder function while under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will be bred from parents that each have one copy of a mutant gene, resulting in ¼ offspring with both copies of the mutant gene. These pups will have bladder dysfunction and may develop mild urinary tract malformations, which is compatible with normal health. There is a small possibility of significant dysfunction developing, which would put mice at risk of developing kidney failure. While this condition is not painful it does cause ill health. Accordingly, mice will be monitored from birth and those showing persistent signs of ill health will be humanely killed, to ensure the project does not exceed moderate severity. Homozygous mutants in our established Hpse2 and Lrig2 mutant lines show slower weight gain compared to their littermate controls. We will monitor litters for signs of distress and weight gain, and cull any mice that show signs of distress or abnormal behaviour, or if weight gain is sufficiently slow that they approach 50 % weight of littermate controls.

Pups up to two days old will be treated by injection of therapeutic molecules into the superficial temporal vein in the head. This route of delivery does not cause any lasting harm to the mouse, but there is a risk of maternal rejection when the pup is returned to its mother, and there is risk associated with anaesthesia, if used. To minimise this risk we will allow the mouse to ‘pinken’ on a warmed pad before return.

The viral vectors we use have been extensively studied in animal models and have been approved by the EU and the US FDA for clinical use. They are non-pathogenic, are engineered to be replication and integration deficient, and the risk of an auto-immune response is exceedingly small in laboratory animals. The therapeutic molecules that will be delivered by the viral vectors are widely expressed in wildtype mice and each transgene will be individually assessed for risk in the relevant GMO form.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The heterozygous with wildtype breeding animals are all expected to have mild severity; offspring of heterozygous with heterozygous parents may experience moderate severity depending on their genotype. Treated mice will also experience a moderate severity. Overall, 2/3 of animals will experience a mild and 1/3 a moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Voiding is a complex, multi system behaviour. Although there is considerable data on gene expression patterns in the organs of the urinary tract these are not sufficient to allow an understanding of the anatomical and physiological perturbations that are caused by mutations in these genes and it is not possible to model the full range of physiological defects and therapeutic effects in non-mammalian systems. Given the need for realistic preclinical models, there is currently no alternative to using live animals. Rodent urinary voiding models many of the physiological aspects of human voiding, and there are faithful genetic mouse models for many diseases.

Which non-animal alternatives did you consider for use in this project?

We have used cell lines, including nerve cells and muscle cells, to model specific aspects of the genetic diseases and test the therapies described in this project. For example, we test the ability of each viral vector to get into the cell and drive expression of the therapeutic gene before we use the vector in the animal model. Viruses are applied to cells in culture and the amount of gene being produced will be assessed quantitatively, and visualised to see if it is in the expected part of the cell.

Why were they not suitable?

Cell lines and other in vitro techniques do not model the complex interplay between multiple tissue types that is necessary to understand these genetic diseases. Delivery of therapeutics to cell lines gives some indication of the potential efficacy of the strategy but do not offer further insights into how these technologies will behave in the complex environment of a living animal. For example, it is also not possible to model an immune response in vitro or how other organs will be affected. It is essential to gain knowledge on all of these aspects of the disease and the therapeutics as the fundamental aim of the project is to bring these technologies into the clinic to treat patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Extensive experience with animal models in previous similar projects indicates that 2000 animals will be required for five years to maintain the multiple colonies used in this project, while a similar number will be required for the specific experimental protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use non-invasive techniques to obtain a large amount of data for each mouse. We will use scans to monitor the structure of the renal tract, which require anaesthesia but are minimally invasive and can be used recurrently on a single mouse to monitor disease. We will analyse voiding behaviour with the voiding stain on paper technique, which simply involves placing a mouse on blotting paper for some hours then imaging the urine stains, but gives a lot of information on the ability of the mouse to void.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Each experiment has been assessed by to determine the optimal number of mice. We have considerable previous experience and data from animal models to do this accurately. Our group also has great experience in efficiently running mouse colonies to ensure the minimal required numbers of mice are bred.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models we will use are faithful genetic models of human voiding disease, and as such will themselves have urinary voiding dysfunction. The primary defects do not cause

significant distress to the animals and we will humanely kill any animal that displays signs of secondary disease, such as kidney disease. We use non-invasive techniques multiple times on individual animals to maximise the data gathered from a single animal, without causing harm. We have refined our techniques in line with changing good practice and our own expertise, for example in regards to the superficial temporal vein injection into neonates. Originally, we used both anaesthesia and ice-induced hypothermia. Along with our colleagues, we have determined that the ice is not necessary to immobilise the mice and we have removed this step from the protocol. We will receive training to develop our pup restraint technique to not require anaesthesia, as this bears some risk to the pup. In addition, as our understanding of the therapeutic vector efficacy develops, we will further refine this protocol by selecting only the mutant mice and appropriate controls for treatment - this will require tattooing pup foot pads, taking tail clips from the neonatal mice and rapidly genotyping the whole litter.

Why can’t you use animals that are less sentient?

To accurately model the efficacy of therapies it is essential to use animals with mature voiding function that is similar to adult human voiding. We have intensively studied Hpse2 and Lrig2 mutant mice and confirmed they have bladder voiding dysfunction similar to that seen in human patients with urofacial syndrome (other groups have studied mice with mutations in Chrm3 and ChrnA3 and also identified bladder dysfunction). In addition, there are no non-mammalian species that provide a sufficiently faithful model of normal human voiding, or of human congenital bladder disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will stay informed of updated and variant protocols being used in the scientific community, such as best practice for temporal vein injections, by reading the literature and discussing at meetings.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow LASA guidelines and NC3R guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly check the NC3R website for changes in best practice advice, and engage with the animal facility for guidance on other advances.

141. Metabolism as a novel target for cancer therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Metabolism, Therapy

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand what factors determine how tumours metabolize different nutrients and how to manipulate these factors in order to develop more efficient anti-cancer therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The abnormal metabolism is one of the well-known hallmarks of cancer. Tumours have been demonstrated to consume more of various nutrients, including glucose and glutamine, and catabolise them differently from normal tissues. Different types of cancers can be stratified based on the expression of metabolic enzymes and genes encoding them, which can predict the aggressiveness of the disease and the therapeutic outcome. The catabolism of major nutrients through specific metabolic pathway in tumours fuels the synthesis of molecules vital for proliferation and survival of cancer cells as well as their ability to metastasize. Metabolic enzymes regulating these pathways in tumour cells have been proposed as plausible therapeutic targets. However, metabolism of tumours and their metabolic requirements and dependencies are determined by multiple factors including genes driving cancer, the tissue a tumour originates from and the interaction between tumour and non-tumour cells. We will evaluate how this interaction between genetic and non-genetic factors determines how tumours metabolise different nutrients and what nutrients and metabolic pathways tumours depend on. With this we hope to be able to dissect the complexity of tumour metabolism in order to understand how to target it for therapeutic benefit.

What outputs do you think you will see at the end of this project?

In this project, we expect to advance our knowledge of how cancer and normal cells metabolise different nutrients and how these processes are being regulated. We will share our results with other researchers in the form of peer-reviewed original research articles and reviews in specialised scientific journals as well as, potentially, in cancer biology book chapters. We also aim to develop novel cancer models, other technical resources such as protocols and analytical tools for cancer and metabolism analysis and, importantly, novel anti-cancer therapies.

Who or what will benefit from these outputs, and how?

Clinical and academic research scientists and students of cancer biology would benefit from the knowledge/resources generated in this project. The project will also facilitate the identification of key metabolic specializations between different organs in health and disease. Novel therapeutic targets may be discovered for developing new drugs. Therefore, ultimately patients with various types of cancer may benefit from these novel treatments.

How will you look to maximise the outputs of this work?

We aim to disseminate our findings to scientists in our own and other fields, as well as more widely in the public domain, by presentations at national and international meetings and publications in high- impact journals.

Species and numbers of animals expected to be used

- Mice: 26,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project is focused on contribution of major oncogenes disregulated in human cancers and tissue environment to metabolic changes observed during tumorigenesis in vivo to identify novel therapeutics for cancer patients. Therefore, we will need to use adult mice as a model for our project, because they have shorter latency of tumour development compared to higher vertebrates, yet their physiology, anatomy, metabolism and pathological manifestations better resemble those in humans compared to the features of other commonly used animal models, such as nematode (C. elegans), fruit fly (Drosophila melanogaster), or zebrafish (Danio rerio).

Typically, what will be done to an animal used in your project?

Most of the animals used in this project will develop primary tumours of the internal organs, such as the lung, liver, mammary gland and intestine. These primary tumours may metastasise to other parts of the body, such as the brain, liver or lung, causing formation of secondary tumours, as it happens in human cancer. The tumours will either appear spontaneously due to inherent genetic alterations or be induced by the administration of either viruses or plasmids that will carry either enzymes or genes enabling such genetic alterations or by a transplantation of cancerous cells or tissue pieces.

After tumour induction, animals will undergo different experimental procedures. Animals may be sampled for small portions of blood to monitor changes in various biochemical parameters related to cancer development. We may treat animals with chemical substances that switch on or off the function of some genes or proteins, that could be relevant to tumour growth, or with labelling agents that would facilitate visualisation of certain types of cancer cells or cells interacting with the tumour. Animals may be placed on modified diets lacking certain nutrients. The control animals in this case will be placed on artificial diets with controlled complete composition. Animals may undergo imaging to monitor tumour growth by using both modalities that are used in humans, e.g., ultrasound, MRI or PET, and by state-of-the-art specific animal imaging approaches based on luminescence and fluorescence measurements. Most of the animals as well as control counterparts, which will not have tumours or will not undergo the abovementioned procedures, will be culled by approved humane methods and their tissues will be dissected and used in experiments in vitro to examine the molecular and cellular mechanisms of the processes driving cancer growth and metabolism.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the experimental animals in our project will develop some forms of tumours. In general, tumours in mice either emerge spontaneously or are triggered by injection of viruses or plasmids that will carry either enzymes or genes enabling genetic alterations and or by transplantation of malignant cells. In mice genetically predisposed to develop cancer spontaneously, tumours typically develop in the period between 3 to 6 months; in some cases, up to 12 months. Depending on the site of the tumour development and its stage, animals will experience different adverse effects. Animals with liver tumours may develop anaemia, jaundice and ascites (abnormal build-up of fluid in the abdomen). Animals with lung cancer may be asymptomatic initially, but after several months may develop breathing difficulties and anaemia. In addition, a proportion of the lung tumours may be highly metastatic and in the end stage, lung cancer may be accompanied by disturbances in other organs affecting animal well-being. In animals with spontaneously emerging (autochthonous) tumours, these side effects typically occur at the end stage of tumour development, gradually developing over 1–2 months.

For transplantation models, the time frame between tumour transplantation to the humane endpoint is shorter, typically between 1 and 2 months. Some of the adverse signs mentioned above for spontaneous cancer models will therefore develop over a shorter period of 1–2 weeks. In addition, mice undergoing transplantations may be impacted by the effects of injections, which could cause local haemorrhage and damage to the organs being injected.

In all cases, tumour burden will be limited to the minimum required for a valid scientific outcome. Animals may display tumour ulceration, labored respiration, or persistent diarrhea, but they will be immediately culled after any of these symptoms is observed. The animals will be also monitored for weight loss and body condition score, and mice dropping below the set criteria (e.g., 15% weight drop) will be immediately culled to prevent excessive suffering.

Animals that will undergo surgical procedures may experience mild to moderate pain immediately after the surgery and they will be given analgesics to minimise post-surgical pain.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of mice that will be developing tumours in the course of the project and/or will undergo surgeries (80% in total) the severity will be moderate. Approximatly 20% of these animals will be used for tumour and other tissue collection after being killed by a Schedule 1 method or after a non-recovery procedure under general anaesthesia (approximately 20%). The rest will be either administered different gene/protein modifying or therapeutic agents, and/or placed on modified diets or subjected to food restrictions. In all of the cases the overall severity will not exceed moderate level. For the rest of

the animals, which can be either genetically modified but without any obvious clinical signs or wild type and/or receiving infrequent injections, the severity will be mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To identify mechanisms of tumour growth and metabolism in physiological condition, which are meaningful for human clinical studies, we need to use animal models because they develop tumours similar to human ones. In addition, the metabolic interactions between tumour and a host as well as effect of local and systemic effect of dietary manipulations can only be meaningfully studied in vivo.

Which non-animal alternatives did you consider for use in this project?

Evidence will be collected from initial studies using in vitro cell culture /organoids/tumourspheres model systems, where appropriate, as well as by surveying the mammalian and other literature. In addition, we will use non-regulated procedures to collect expression data from fixed non-GM mammalian tissues and functional/expression data from genetically and/or environmentally manipulated in vitro system.

Those generated data sets will be analysed by bioinformatics, and thus to identify the most promising candidates to be validated in experiments in vivo.

Why were they not suitable?

Organ- and cancer-specific metabolic pathways are highly influenced by nutrients, oxygen, circulating hormones and other aspects of the complex physiological environment inside the body. It is not yet possible to recapitulate all of these parameters in vitro, nor to mimic the metabolic crosstalk between different organs and tumours –a key aspect of this research project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers were estimated based on our previous experiences, statistical modelling, and predictions for exploratory experiments. For spontaneously occurring tumours (autochthonous models), due to the high variability in tumour progression, for each cohort we normally would need around 20 animals per group for study, whereas transplantation models would normally need between 10–20 animals per group.

We will take as an example an experiment where the requirement of a metabolite both produced by a biosynthetic pathway and available through a diet is being evaluated for the progression of tumours. In this case animals are either administered an inhibitor of the biosynthetic pathway producing the metabolite or place of a diet lacking this metabolite or a combination of both treatments is being used. Considering these potential treatment combinations, each experiment would normally need at least four groups: control/vehicle treated/control diet; metabolic inhibitor/control diet; vehicle treated/experimental diet; metabolic inhibitor in combination with an experimental diet. Furthermore, for all novel therapies, the dosing frequencies and drug dosage needs to be optimised first. There are also at least two different regimes: prevention and intervention. In the liver model we will test these combinations in the inducible liver models and in the model induced by hydrodynamic transfection (3 oncotypes per each model): (20GEM + 10 hydrodynamics) x 3 oncotypes x 4 experimental groups x 2 designs = 720 animals. For 3 treatment combinations we will need 2160 animals (Metabolism of Liver Tumours).

Additionally, to evaluate how our findings would translate in human cancers we will use xenograft models. For 5 xenogfrats we will perform treatment combination experiments: 5 x 10 mice per group x 4 experimental groups x 2 designs = 400 mice. For 3 treatment combinations we will need 1200 mice.1200 = 1200 mice with xenografts.

For these experiments we mostly plan to use mouse models of the two major cancers: mammary gland and liver, comparing at least 3 oncotypes per each type.

As mammary gland tumour models, we will also propagate 15 breast cancer PDXs and will perform initial multiomics analysis (10 animals for propagation + 10 for analysis): 20 x15 = 300. For 5 PDXs we will perform treatment combination experiment: 5 x 10 mice per group x 4 experimental groups x 2 designs = 400 mice. For 3 treatment combinations we will need 1200 mice. 1200+300 = 1500 PDX mice. Some of these PDXs will be propagated and used in the experiments with fat pad clearance.

Altogether, we will use 2160 GEMM animals and 1200 animals with xenografts for the metabolism of liver and mammary gland tumours each, In addition, 1500 animals with breast cancer PDXs. 8220 animals altogether.

In addition, we will run pilot exploratory experiments with smaller groups of animals in lung and intestinal tumours, probing different approaches to study the relationship between metabolism and tumours. We will need approximately twice fewer GEMM animals in this initial phase (2,200 in total). Therefore, we will need 8220 +2200 = 10420 mice in experimental protocols, out of which 6520 are GA animals.

Considering that some animals may not develop tumours or may be excluded from the subsequent experiments due to various reasons before overt tumour development, as well as taking into account that some animals will have to be initially generated from breeding of GA mice, where not all progeny will be suitable for experiments (some genotypes can be 30-25%), we would need to produce on average 3×6,520 = 19,560 GA animals for the programme of experiments. For those we will need 1222 breeders (8 mice per litter, 4 litters per breeding pair). Altogether – 20,782. Some of the breeders will be on doxycycline inducible diet (200). Finally, we envisage that we may need to generate new genetically altered lines of mice or import some novel genetically altered animals from other laboratories. For this purpose, we will need 1500 animals. Therefore, we plan to use 3,900 (PDXs/xenografts) +19,560 (GA) + 1,222 (breeders) + 1,500 (new strains) = 26,182 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The efficiency of animal usage is maximised in consultation with animal technicians by careful control of breeding to match research needs with respect to numbers, phenotypic uniformity and health. In addition, we will also take advantage of the online tools, including the NC3Rs Experimental Design Assistant to help us with experimental designs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

This programme of work will make optimal use of several tissues, fluids and cell types per individual mouse. We will aim to collect organ samples from multiple body sites and to provide other affected tissues to appropriate scientists, so that they do not have to breed mice specifically for their experiments. This highly integrative approach will maximise the information obtained from the minimum resources. Cryopreservation of gametes, embryos, tissues and cells is a routine procedure and will ensure that the minimum number of mice is bred.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice have been selected for the majority of this work as it is an appropriate model for providing insights into human diseases and it is the species in which reliable transgenic and knockout technologies are most advanced. Wherever appropriate, we will minimise the adverse effects associated with genetic alterations by using inducible or conditional alleles to delete gene activity from specific tissues rather than from the entire mouse.

Genetic alterations or transplantation methods will be used to induce tumour formation. These models possess relevant pathological features similar to those in human patients, allowing us to investigate basic tumour biology and to perform preclinical trials. This will obviate the need to use higher vertebrates. Furthermore, whenever possible, we will perform experiments in transplant models, which usually exhibit a faster disease course, thus minimising the duration of distress and lasting harm to the animals. We will only perform key experiments in the autochthonous settings, particularly when we will need to elucidate how tumours develop, evolve, and interact with their native microenvironment.

In all surgery, analgesia will be provided according to contemporary best practice and advice from the NVS/NACWO. Good aseptic surgical techniques, heat & fluid therapy will be provided as necessary. In the case of cancer models for example, we will follow the guidelines in Workman et al, British Journal of Cancer (2010) 102, 1555 – 1577.

Whenever possible, we will use terminal anaesthesia to perform surgical experiments in animals to decrease their pain and suffering.

Why can't you use animals that are less sentient?

This project is focused on understanding the role of metabolism in tumourigenesis in vivo to identify novel therapeutics for cancer patients. Therefore, we will need to use a model system that is able to establish tumours and has metabolism closely resembling that of human. Therefore, mice would be the most appropriate animal model for our project. Less sentient animal models, such as nematodes or flies, will not be suitable for our purpose. Whenever appropriate, we will carry out experiments in terminally anaesthetised animals, but for some of the proposed experiments, we will investigate various methods to intervene with the tumour progression. In such cases, we will need to observe the animals over a prolonged period of time until the assigned endpoints are reached.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all manipulations we will adhere to local or national guidelines that aim to minimize suffering. Many of the genetic and dietary manipulations as well as the administrations of gene inducers/repressors or other agents are standard and previous refinements from the literature will be used. If, however, there is insufficient information available, new manipulations will be pre-screened in small-scale pilot studies to obtain indications of the minimum dose and exposure time that is likely to be effective, thereby minimising any potential suffering.

We will also consult our NVS to improve the surgical methods and procedures we are using.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experiments will be planned in accordance with the recently formulated PREPARE guidelines.1 For surgical procedures, we will follow the guidelines set out in LASA Guiding Principles on Preparing for and Undertaking Aseptic Surgery. With regards to the experiments in cancer models, we will adhere to the Guidelines for the Welfare and Use of Animals in Cancer Research2 and will monitor body condition according to system developed by Ullman-Culleré and Foltz3. In addition, I will also follow the latest advancements in relevant fields, by attending conferences, reading journal articles, and collaborating with experts in these areas, to ensure that the experiments will be conducted in the most refined way.

1. Smith, A. J. et al. PREPARE: guidelines for planning animal research and testing. Lab Animals 52, 134–141 (2018).

2. Workman, P. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010).

3. Ullman-Culleré M.H. and Foltz C.J., Lab Anim Sci. 1999;49(3):319-23

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will keep following up the latest publications in the fields as well attend courses and seminars and follow NC3Rs and NORECOPA websites to learn any advances in the 3Rs.

142. The role of morphological and genetic abnormalities in tumour progression

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, tumour microenvironment, centrosome amplification, tumour evolution, chromosome instability

Animal types	Life stages
Mice	neonate, juvenile, adult, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims at investigating how well-established alterations that occur in cancer cells, and not in normal cells, impact the architecture of tumours, what surrounds them and how they progress.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many cancer-associated abnormalities cause irreparable stress and are thus poorly tolerated by normal non-cancer cells. However, cancer cells inevitably find ways to cope with these aberrations. Understanding how these specific cancer-associated traits impact tumours will allow us to establish and explore survival mechanisms employed by cancer

cells to cope certain abnormalities. This is key to develop better therapies that aim at targeting these coping mechanisms to selectively kill cancer cells.

What outputs do you think you will see at the end of this project?

At the end of this project, we will have generated new information regarding how cancer-associated abnormalities impact how tumours progress, how it modulates the tumour architecture and surrounding environment and how these changes affect tumour progression. The new information generated will be made available to the scientific community via publication in peer reviewed journals.

Who or what will benefit from these outputs, and how?

In the short-term duration of this project (up to 5 years) the main benefactors of this work will be scientific community that will have access to our research through publications and presentations. This project will provide valuable information about how cancer cells respond to specific cancer-associated abnormalities and how this affects how cancer cells progress, metastasize and change their surrounding environment.

In the long-term, after the completion of this work, the information obtained has the potential benefit cancer patients as follow:

• Development of biomarkers for disease progression and response to therapy by whole exome sequencing of tumours collected in this study. Some cancer-associated abnormalities can be associated with poor prognosis and disease progression. Furthermore, these abnormalities frequently require cancer cells to adapt in order to effectively grow and divide. These adaptations can indeed be targeted, making these abnormalities attractive for the development of specific therapeutic strategies. Thus, defining signatures to identify these abnormalities could lead to the development novel prognostic biomarkers and to define appropriate treatment options.

• Development of novel therapies that target changes in the tumour surrounding environment induced by cancer cells carrying specific abnormalities. Despite recent progress, it is clear that novel and selective therapies that kill cancer cells are needed. We hypothesise that how cancer cells adapt to and grow in the presence of specific abnormalities is an important part of their survival requirements that could be targeted. We will explore if changes induced by these abnormalities are important for their survival and adaptation and could be used to develop novel therapeutic strategies.

How will you look to maximise the outputs of this work?

It is important to maximise the outputs of our studies, more so if the studies involve animals. To do so, we have in place the following strategies that will be implemented:

- Make data available through Open Access peer-reviewed publications will ensure that our work reaches the wider scientific community.

- All proteomics and sequencing data obtained from this work will be made available in appropriate public repositories: PRIDE (proteomics; http://www.ebi.ac.uk/pride/archive/), Arrayexpress (RNA-seq data; https://www.ebi.ac.uk/arrayexpress/).

- Dissemination via talks and posters at scientific conferences will allow our work to reach scientific community before its publication.

- Dissemination in the context of 3Rs, for example NC3R meetings and workshops, which will allow us to share our findings and keep up with best practices to improve our animal work.

- Establishment of collaborations, for example with scientist clinicians that could help translation of our work to the clinic.

- For most of our animal tumour experiments, we maximise outputs by removing other tissues of interest that could be shared with colleagues to develop new projects. For example, we propose to remove lungs, mammary gland, ear, tail and lymph nodes.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our goal is to develop a better understanding of cancer progression, dissemination and evolution in order to develop therapeutic strategies that can be translate to the clinic. The mouse has many

characteristics that makes it is an ideal model for our studies:

- Mice have been used successfully for decades by scientists to understand tumour biology and develop effective drugs in the clinic.

- Mice have a breeding-cycle that is relatively quick.

- Many genetically altered (GA) mice are available to make scientific research efficient, relatively quick, and require fewer animals (no need to generate some of the models that already exists). The technologies to generate further GA mice that possess more relevant gene modifications is now routine and provided through commercial sources which limits the errors by less experienced staff in making these animals.

Because we are interested in cancers that occur mostly in adult humans (breast, pancreatic and ovarian cancer), we will use adults and aged animals. For genotyping, which may need to be done early, we can also use neonates and juveniles.

Typically, what will be done to an animal used in your project?

- All experiments require a pre-planned series of procedures that are designed to maximise the data from the use of the mice, while using the minimum number of mice and imposing the minimum amount of discomfort and harm.
- Some experiments may require mice to undergo repeated anaesthesia, often firstly for a minor surgery to allow implantation of cells. Most therapies that require repeated administrations are given via IP or SC as this seems to be give minimal discomfort and results in rapid accumulation of the compound in the circulation. For most injections mice are not anaesthetised, as experienced staff do each injection in a few seconds removing the harm of additional anaesthesia. Repeated tail vein injections are avoided as much as possible as tails can be become inflamed and scabbed with the repeated wounding with a needle.
- We use many types of imaging to monitor the progress and response of tumours and ensure they will not exceed the limits allowed for tumour size/volume. These require mice to be anaesthetised and injected with either a substrate (luciferin) or a radiotracer (for SPECT or PET studies). MRI does not require an additional injection but does require more skill in interpreting the resulting images, so this will be factored in when decided what is the best approach.
- A common experiment design for mammary tumours might be: tumour cells are implanted in the mammary fat pad (week 1), this requires surgery and anaesthesia. Tumour presence/growth can be evaluated by palpation. Tumour growth and dissemination is monitored by imaging (e.g. BLI) once weekly (weeks 3-8). Mice are terminated as tumour volume (established using either mm3 determined MRI volumes, calibrated BLI signals from the same MRI analysed mice or using callipers) reaches 1250mm3 total tumour burden or mouse welfare suggest earlier termination.
- A common experiment design for mammary tumours undergoing therapy might be: tumour cells are implanted in the mammary fat pad (week 1), this requires surgery and anaesthesia. Tumour presence/growth can be evaluated by palpation and therapy commences (week 2-3), therapy is repeated 2-3 times (if IP) per week or once daily for a maximum of 7 days if by oral gavage (weeks 3-5). Tumour growth and dissemination is monitored by imaging (e.g. BLI) once weekly (weeks 3-8). Mice are terminated as tumour volume (established using either mm3 determined MRI volumes, calibrated BLI signals from the same MRI analysed mice or using callipers) reaches 1250mm3 total tumour burden or mouse welfare suggest earlier termination.

What are the expected impacts and/or adverse effects for the animals during your project?

- Injections give transient pain as they do in humans and mice recover rapidly.

- Mice recovering from surgery will receive analgesia and usually show little change in their general behaviour, mobility, feeding or drinking suggesting the discomfort is manageable.

- Early tumour growth does not usually cause pain or discomfort. As tumour grows, it is possible that its location may cause physical problems (in eating, mobility) or it may become ulcerated. In most cases these mice will be immediately killed by Schedule 1 unless advice from the NVS suggests the discomfort can be managed with appropriate drugs.

- Implanted tumours tend to develop and grow at a more predictable time frame that GA mouse tumours. Thus, GA mice experiments often require several months before tumours arise and experiments can be conducted whereas implanted tumours are often completed in 3 months.

- If the weight loss reaches 15% the mice will be killed.

- Any procedures applied to mice that result in abnormal behaviours (e.g. lethargy, piloerection, hunched posture, reduced mobility, abnormal respiration, sunken eyes) that equate to significant harm will result in those mice being humanly killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild severity is expected for non-tumour bearing animal models that will be bred under the protocol 1. These animals may include GA Cre lines, Tracer animals (e.g. expressing GFP to label particular cell populations), wild type and immune compromised mice. We expect that animals this severity to affect

>99% of the non-disease animals in protocol 1 (total of 1000 mice).

- Moderate severity is expected for cancer animal models. We expect that under the breeding protocol 2 only <50% (<750 mice) of animals will experience this severity under this protocol since most animals may be transferred before tumour onset and thus will be considered of mild severity. Under experimental protocol 3, we expect that 80% of animals will experience moderate severity associated with spontaneous tumour development and progression (800 mice). Because most animals will be transferred to the protocol before tumour onset, we expect that ~20% (200 mice) will either not

develop tumours or culled before tumour onset and thus will be considered of mild severity. Under experimental protocol 4, we expect that 80% of animals will develop tumours after implantation and will experience moderate severity (4000 mice), we estimate that with the remaining animals (1000 mice) may not develop tumours and will experience only mild severity.

In summary, for this license we expect that 2950 animals will experience mild severity while 5550 animals will experience moderate severity associated with tumour growth.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our main goal is to understand how tumours progress, disseminate and evolve to aid the development of much needed therapeutic strategies to treat cancer patients. Most of our work focused on basic understanding of cancer cells and for that we have used and will continue to use suitable in vitro systems to address these questions. However, cancer is a very complex disease, and in particular the complexity of the interactions between cancer cells and their microenvironment is very difficult to reproduce in vitro, as well as the process of cancer dissemination and evolution. To do so, we will need to use systems that closely match the complexity of human cancer, and in particular that have the following criteria:

- Tumour microenvironment, preferentially matching the tissue of origin of the cancer, composed of other cells that surround the tumours, such as fibroblasts, blood vessels, immune cells;

- Blood supply to enable cancer cells to migrate to distant sites and form metastasis in other organs and that can be used to drug delivery;

- There are no systems in the laboratory that can achieve these 2 criteria except a live animal. Therefore, animals are essential to our programme.

Which non-animal alternatives did you consider for use in this project?

In our laboratory we have successfully used 3-D organotypic tumour models, organoids and 3-D spheroids to study for example the mechanisms of cancer cell invasion, the first step of the metastatic cascade. These models allow cancer cells to grow in 3-D environments that partially recapitulate how they grow inside the body. More recently, we have also established 3-D heterotypic cultures of cancer cells and associated fibroblasts to

look at the interaction between cancer and one component of the tumour microenvironment. These type of model systems are very useful, can be easily established and provided significant understanding that allowed us to refine our animal experiments.

In addition, to develop non-animal alternatives for this project, we have established collaborations with collaborators to establish a 3-D based flow chamber system to study angiogenesis to identify factors important for this process prior to animal studies. These simplified systems are advantageous as they

allowed us to screen different molecules in a very fast and effective manner to refine our animal experiments and therefore allow us to use less animals.

Why were they not suitable?

The laboratory systems we have established are very valuable and can address discrete defined questions and generate valuable knowledge. However, they will never fully recapitulate the complexity of a live tissue that contains blood vessels, lymphatics and cells of the innate and adaptive immune system. All of which work in an integrated manner to facilitate tumour growth and spread. For example:

- In our 3-D systems we may be able to enquire how specific factors impact angiogenesis but we will not be able to address how changes in angiogenesis impact the surrounding environment, e.g. immune infiltrates, fibroblasts. This integrated knowledge is key for us to understand how the different cellular compartments that constitute a tumour interact and impact tumourigenesis.
- Additionally, the metastatic cascade is very difficult to model in vitro as it involves several key steps: local invasion, intravasation/extravasation to and from the blood vessels, surviving in the circulation, ability to attach to other organs and grow to form metastatic lesions. While some steps can be modelled using 3-D in vitro systems, the complexity of the entire process cannot, in particular the colonisation of distant organs and metastasis formation is very difficult to reproduce in vitro.

Thus, although in isolation these in vitro systems are advantageous, they lack complexity and cross talk between the different components that co-exist in an in vivo tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers present the maximum estimation mouse usage based on our current and proposed programme of work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- 20 years of experience in designing, running and publishing research articles means I am well prepared for training and supervising my staff in effective ways of designing and executing a project. I believe this experience is highly valuable when designing in vivo experiments. In addition, we recently started using orthotropic mouse models for breast cancer for which we acquired invaluable knowledge to help designing our project and refining our experiments.

- In preparation for this license, I have become familiar with the excellent NC3Rs EDA tools. I will be introducing these tools to all of my team with the instruction they should become familiar and where valuable, to use them in their experimental designs. The NC3R EDA tools can improve experimental design and increase my staff's knowledge and understanding of in vivo studies. I have also acquired the necessary training prior to writing this license, which helped also with the design of effective in vivo experiments while always considered ways to implement the 3Rs.

- In the last years we become familiarised and have used successfully the on-line power calculation tool (http://biomath.info/power/). This has been instrumental to design animal experiments that have been peer reviewed in our recent grant applications. Our resulting experiments have also produced data that provide statistical significance and thus more scientific value.

- In our laboratory, we always start in vivo work with a clear hypothesis. This is key so that we can design an experiment with defined goals, sufficient numbers of mice, a clear monitoring strategy, a pre- planned means of analysis, a randomisation plan and a data blinding plan. These should be clear and agreed before the experiment commence.

- We will take advantage of current literature, our in vitro work, for example using 3-D organotypic systems, refine our questions to minimise the use of animals. For example, if a therapeutic change is desired, we would first conduct multiple in vitro studies including, if possible, 3-D multicellular pathology-mimicking models to prove that indeed, there is a potentially useful biological effect. Only then would in vivo experiments be considered. Sometimes the justification may come from studies from other laboratories that we will then incorporate in our study. The level of effect helps to determine the expected % biological change that will inform the power calculations.

- We use multiple imaging tools to monitor tumour progression, metastasis and response to treatment. This allows us to follow temporally the change in tumour growth and

activity during an experiment without the need to kill the animal. These tools include bioluminescence, MRI and radio-imaging (SPECT/CT and PET/CT).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Where the scientific question requires modification of gene expression in a target tissue, whenever possible we will always utilise GA mice designed such that there is a minimum number of crosses with other mice to achieve the desired genotype. The wastage in animal life to achieve effective genotypes will always be considered.

- Pilot studies are key to minimise the use of mice in our studies as this will allow us to know with a high degree of confidence the correct number cells to form tumours, the time frame for tumours to grow, whether the tumours spread, the correct dose of drug to achieve the maximum biological effect, the correct dosing to achieve optimal pharmacokinetics. When these facts are in place we can accurately design good experiments to address our questions.

- We are keen to make available spare tissues from our studies to others to use as a means of performing either pilot or even experiments, without the need to use additional mice. For example, we have recently provided control mouse mammary tumour sections to colleagues to test whether this could be a good model to investigate the formation of tertiary lymphoid structures without the need to using additional animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically Modified Mice (GEMM). Some of these mice will naturally develop cancers of interest (including pancreas and breast) so that we can investigate the biology of the developing disease and test our treatments in a model that most closely matches human diseases. For most models, the mice will not develop more than mild pain or discomfort during early stages of tumour development.

However, cancer is a progressive disease and thus, all animal models will be monitored closely to ensure their well fare. Tumour size will be monitored to ensure that the total

tumour burden of SC/mammary tumours do not exceed 1250mm3 and internal tumours (pancreatic) will not exceed 800mm3. MRI monitoring of deep tissue tumours (e.g. pancreatic tumours) provides confidence we can deliver this intention. Some of the GEMM we will use are not tumour models but will be used to label specific tissue compartments and components of the microenvironment (e.g. blood vessels).

Mice bearing transplanted tumour cells/tissues. Cells or tissues derived from mouse or human tumours or circulating tumour cells will be injected or implanted into mice subcutaneously (SC), orthotopically or intravenously (IV), as required by the scientific question. Experienced handlers will inject the SC and IV cells/tissues minimising pain and discomfort to mice. Mice will require anaesthesia and surgery for orthotopic injections and implantations of organotypic gels and will receive peri-op analgesia to minimise discomfort. Surgeries will be conducted by highly trained staff. When possible, orthotopic injections to the pancreas will be conducted using an echo-guided approach that is less invasive than a surgery, to minimise pain and discomfort. In some cases, genetically manipulated cells that contain bioluminescence or fluorescence will be used to accurately monitor tumour development and response to therapy using non-invasive methods, thus minimising pain and harm to animals.

All experimental mice are routinely examined for their health status and any behaviours or appearances that suggest pain or discomfort will be monitored closely with the local BSU staff and as required, the NVS.

Why can’t you use animals that are less sentient?

Most of our experiments require that tumours will develop over a time period. This is because the pathologies are a result of complex interactions between cancer cells and the surrounding tissue. Moreover, it is not possible to use animals that are terminally anaesthetised. In addition, it is important to use a simple mammal in order to closely reflect the biological processes in humans that we are trying to investigate. While non-mammalian models (drosophila, xenopus) are proven very useful, they do not recapitulate the biology that occurs in humans. We have used in the past 48hrs post-fertilisation Zebrafish embryos as a model to investigate cancer cell invasion. However, while this model can recapitulate several steps of the metastatic cascade, it does not provide the time frame to understand this process. Mice are the simplest mammals that through decades of research provides us with confidence that our experimental designs are likely to be as close to our discovery and therapeutic goals as possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- We will use MRI and other minimally-invasive imaging methods available at out institution to improve the analysis and monitoring of metastasis and internal tumours (e.g. pancreas) that develop either through orthotopic implant or growth in transgenic mice. This will be useful for example to use mice that have similar volume tumours at

Day 1 of a protocol, instead of starting therapy on a cohort at a predetermined time interval after injection. This also allows longitudinal studies that formally required cohorts of mice to be killed at intervals, thus saving many mice. The MRI protocol has the immediate benefit that there is limited chance that an animal develops an internal tumour that exceeds home office limits. We will work closely with colleagues in our institute implementing such methods to guide our experiments.

- We will strive to use transgenic mice in which mutations are induced specifically and conditionally in the cell population of interest, using for example Cre-LoxP conditional alleles and Tet-On and Tet-Off systems to temporarily control the expression of oncogenes. These mice should not display a phenotype until the mutation in the candidate gene is induced.

- In all our experiments we will set humane endpoints and write an experimental protocol, which will include details of possible adverse effects. For example, when administering substances or cells to animals, the route used for delivery will be such as to achieve “best practice”, that is to minimise or avoid adverse effects, while minimising the number of animals used, and maximising the quality and applicability of results. For that reason, we propose in this project licence a variety of routes of administration of substances and cells to achieve the scientific objectives, while minimising the waste of animal’s lives.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have been following the ARRIVE guidelines and also use the NC3R EDA tools on line.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute hosts regular updates in experimental animal usage, including new developments in 3Rs that I try to attend or send representatives to from my team. We also have colleagues at our institute that attend/spoke at NC3R events with whom we can discuss the best practices on how other researchers conduct their research.

143. The use of immunological tools for monitoring farm cattle health and prevalence of bovine tuberculosis (btb)

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cattle, tuberculosis, mycobacteria, immunology

Animal types	Life stages
Cattle	juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine immunological base line parameters of farms that have suffered bTB outbreaks compared to animals on farms with no recent outbreaks.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A wealth of knowledge has been generated on the immunological response of cattle to Mycobacterium bovis, the mycobacteria that cause bovine tuberculosis (bTB). This knowledge has been largely acquired from animals held in tightly controlled experimental

conditions. There is now a need to determine the extent to which this knowledge can be applied for enhanced disease diagnosis and infection control in animals managed under commercial farm conditions. There is also a need to determine the extent to which different tests/protocols will be accepted by farmers and regulatory authorities and/or are practical under commercial farm conditions.

What outputs do you think you will see at the end of this project?

The aim of the experiments to be carried out under this licence is to gain a greater understanding of the bovine immune response to mycobacteria under commercial farm conditions by evaluating immune processes, tools and reagents previously generated with cattle housed under experimental conditions. The expectation is that these markers could be used to design and develop novel diagnostic and prognostic tests to maximise detection of infected animals and thus eliminate the risk of infection transmission to non-infected animals (cattle to cattle transfer). We also expect to generate novel markers of infection. Our laboratory has acquired state of the art equipment that will permit us to carry out the analysis of the immune response at different levels and we expect this to allow us to generate novel findings on the host:pathogen interaction during bTB infection.

Any new findings will be published in international, peer-reviewed journals and presented at national and international meetings and conference. Due to the fact that we will be approaching farmers to bleed animals on their farms we also expect to communicate to farmers, community-based farming groups and field veterinarians on the progress of our studies.

Where appropriate, we will seek to protect intellectual property through the submission of patents.

Who or what will benefit from these outputs, and how?

The control of bTB in cattle poses a significant financial burden due to test and compensation costs on the GB taxpayer. In 2017, over 40,000 cattle were slaughtered, which cost the GB public purse over £100M (references). Further, there are direct costs to the farmer such as, loss of product, additional husbandry, etc. due to a herd being under movement restrictions until it regains its bTB-free status. bTB is a progressive chronic inflammatory infectious disease with the potential to directly impact on animal health and welfare. It is also a zoonotic disease and poses a risk to human health. Control of bTB could have benefits in reducing the prevalence, incidence and spread of bTB in the cattle population and could also reduce the severity of a herd breakdown regardless of whether infection is introduced by wildlife or cattle. Ultimately, the control of bTB would result in increased animal health with a concomitant increased in productivity and a reduction in the costs of the control of the disease to the taxpayer and farmers. Control of bTB will also result in a reduction on the risk of zoonotic TB in humans, which was one of the major drivers for the introduction of bTB control measures in the 1900s. It is also relevant to state

that any lessons learnt of the control bTB will inform developments in the field of human TB.

The risk of a herd suffering bovine tuberculosis outbreaks is positively correlated with its size. Herds with over 300 cattle and which have suffered prior bovine tuberculosis outbreaks have been identified as most likely to suffer new outbreaks (chrome-extension://efaidnbmnnnibpcajpcglclefindmkaj/viewer.html?pdfurl=https%3A%2F%2Fassets.publishing.service.gov.uk%2Fgovernment%2Fuploads%2Fsystem%2 Fuploads%2Fattachment_data%2Ffile%2F923195%2Ftb-epidemiology-england- 2019.pdf&clen=2856273&chunk=true). Thus, it is likely that the farms we will work with will house a large number of cattle. In order to maintain a balance between the number of animals per farm to remain representative of that farm and comparison between potentially different management systems, we propose that the minimum number of farms to be sampled will be four and that the maximum number of animals per farm to be sampled will be 150. This allows the sampling of a representative number of animals on farms that use different management systems.

The development of improved tests for the detection of animals infected with M. bovis requires an improved understanding of the immune response against mycobacteria. Infection with M. bovis is a chronic infection that is known to evolve with time; it has also been shown that the immune response to mycobacteria is affected by the application of the skin test (https://www.sciencedirect.com/science/article/pii/S0165242704001989?via%3Dihub). Evaluation of responses after application of the skin test may yield results that would allow the development of diagnostic targets different to those detected by current tests. Therefore, we seek to bleed animal for up to six times per year to allow for monitoring of the immune response over time before and after application of the statutory skin test. Thus, each animal will be bled for a maximum of up to 30 times during the period of the licence.

On a broader aspect, it would be expected that results from the experiments carried out under this licence will benefit stakeholders in other countries also suffering from bTB in their herds.

We also expect that one major output of these experiment will be scientific knowledge on the nature of the immune response of cattle on commercial farms. It is worth mentioning that the knowledge that we expect to generate is likely to have a wider application in our understanding of the bovine immune response to a range of diseases other than just bTB, and to micro-organisms other than mycobacteria. This knowledge in turn is likely to generate patentable intellectual property.

How will you look to maximise the outputs of this work?

We intend to collaborate with colleagues at national and international level. As mentioned above, we will seek to publish our data in international, peer-reviewed journals and

presentations at national and international meetings and conferences. There is currently the possibility of publishing different approaches, whether successful or unsuccessful in pre-print portals, such as bioRχiv, which makes the information available to the international community whilst allowing the community to comment on the publication.

Where appropriate, we will seek to protect intellectual property through the filing of patents, which in turn will allow the publication of data in peer-reviewed journals.

Where appropriate, we will seek to engage with companies to exploit new findings with the aim of reducing the burden of bTB in the UK and other parts of the world.

Species and numbers of animals expected to be used

- Cattle: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Bovine Tuberculosis (bTB) is a disease of cattle and there are currently no in vitro or in silico models that would permit the study of the host pathogen interaction in this disease. The best model for the study of bTB are cattle, which are the target species affected by this disease.

In this project we will be studying animals directly in commercial farm settings, which will allow an interpretation of data that reflects the reality of how this infection affects animals on farm through the course of time.

Typically, what will be done to an animal used in your project?

Animals will only experience the procedure of drawing blood either via the tail vein or jugular vein dependent on volume collected. For small volumes blood will be sampled from the tail and for large volumes bleeding from the jugular vein; the latter will occur only when there are appropriate resources to contain the animal for safe bleeding. In the case of young animals (< 4 months) a halter and two operators may be sufficient. For animals older than 4 months, there will be a need for animals to be contained in a crush

What are the expected impacts and/or adverse effects for the animals during your project?

Theoretically, there may be some haematoma development after bleeding . We will seek to prevent/control haematoma formation by applying pressure on the site immediately on removal of the needle. From prior experience, no haematoma/thrombosis formation has been observed/recorded after this procedure has been performed.

When bleeding from the tail vessels, it is possible that the site may be infected; to avoid this, the area of the bleeding will be cleaned prior to sampling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild

What will happen to animals at the end of this project?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently there are not ex vivo nor in silico models for the study of the bovine immune response to mycobacteria. The most relevant model for the study of the BTB is the target species, which in this case is cattle.

Which non-animal alternatives did you consider for use in this project?

The validation of laboratory findings in farms animals requires by necessity live animals and there are not any non-animal alternatives.

Why were they not suitable?

The purpose of this project is to validate laboratory findings in field settings with a view to develop novel diagnostic tests. This needs to be done in live animals of the target species in which these tests will be used; therefore, no in vitro surrogates can be used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We expect to be able to sample between 5 and 10 dairy and beef farms per year. The average number of animals per dairy herd is of approximately 95 animals, whilst the average number of animals per beef herd is 23 animals. Sampling an equal number of beef and dairy farms would provide an average of 75 animals per farm. We estimate that we will be able to recruit between 5 and 10 farms. It is our expectation to be able to sample these farms between two and three times per year. Thus, we have calculated an average number of 75 animals per farm. Although the aim of the project is to recruit between 5 and 10 farms, for the purposes of this calculation we have used the average of the number of animals in 8 farms, which gives a rounded up value of 600. The increase in the number of animals is requested to ensure that we will be able to sample a minimum number of establishments, which will allow for the potential comparison of different management systems. It is important to bear in mind that the numbers indicated above are averages and that dairy farms in which bovine tuberculosis can occur are generally farms with large numbers of animals. We propose that we will sample a maximum of 150 animals on up to four establishments. This allows the sampling of a representative number of animals on farms that use different management systems.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To our knowledge, an experiment of this nature, i.e. to evaluate the immune response to mycobacteria in cattle on farm has not been carried out and therefore there is currently no data on which we could base our calculations.

Nevertheless, we have sought to sample as representative a cattle population of working farms as possible, hence the idea of sampling from both beef and dairy farms. BTB is a chronic disease which evolves through time, accordingly, there is a need to bleed the same animals (if available) for several times per year. We anticipate that the average number of samples taken from each animal will be three per year, although there may be a need to sample individual animals up to six times per year. The increased number of samples may occur after statutory testing of animals for bovine TB to allow us to assess the effect of the application of the skin test on the immune response to mycobacteria over time. Effects of the skin test on the immune response to mycobacteria could be used to determine prior exposure to M. bovis and therefore be used as potential diagnostic markers.

We believe that bleeds, as currently proposed in the license will be sufficient to address the scientific need of the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As mentioned above, there is currently no experimental data upon which we can base our calculation to optimise the number of animals we will use and this will be dependent on the

results we obtain in our experiments as well as the permissions we are granted by the farmer in terms of access to animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Cattle are the target species of bTB and therefore the appropriate species to be used to achieve the objectives outlined in this license. Bleeding will be performed using standard venepuncture methods for the amount of blood we are seeking to obtain from each animal to allow us to carry out the research we have described in this proposal using state of the art technology. We will work with farmers and veterinarians to minimise pain, suffering and distress or lasting harm to the animal.

Why can't you use animals that are less sentient?

Cattle are the target species of bTB and are therefore the only appropriate model in which to study this disease. It is a chronic disease for which animals are required to live over periods of months and preferably years, which is the reason why this experiment is being proposed over a period of five years.

Cattle on commercial farms are the target for the evaluation of novel diagnostics tests previously developed in animals kept in tightly controlled experimental environments. There is not any other animal that can be used for this purpose.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will be in frequent communication with the farmer and the veterinarians advising the farm to try to minimise any harm to the animals every time they are bled. We also intend to coordinate our sampling with other routine sampling times to minimise the number of times the animals require handling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office Guidance on the Operation of the Animals (Scientific Procedures) Act 1986. We will continue to follow the scientific literature to refine our

experimental approaches with a view to maximising the information we obtain from the blood we withdraw from animals; in time, this will allow a reduction in the amount of blood necessary to obtain similar observations and/or reduce the necessity of extra bleeds. By attending AWERB meetings and Home Office refresher courses on animal handling we expect to keep up to date with the literature that will allow us to perform our experiments in the most refined way possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will be attending the AWERB as and when required and I shall also attend refresher courses as and when required. I will follow advice from our HO liaison officer and the NIO on the documentation and courses to attend.

144. Production, breeding & cryopreservation of genetically altered mice

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words
Genetically altered mice, Genes, Breeding, Biomedical research

Animal types	Life stages
Mice	embryo, neonate, juvenile, pregnant, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to generate, breed and maintain genetically altered mice and supply them for research into the study of normal and abnormal physiology, development, biology or behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The functions of many genes and their products, either individually or in ways they interact to produce their intended effects, or how they are dysfunctional in disease is currently unknown or not fully understood. To understand better the impact of genes on normal physiological and abnormal disease processes requires, when necessary and justified, the use of genetically altered animals.

What outputs do you think you will see at the end of this project?

The investigations carried out on animals bred under this licence hope to obtain new knowledge with respect to basic mechanisms of physiology, behaviour, development and cell biology. Any animals bred under this licence which will be used on other Projects will also have publications generated from the research. GA animals may be culled for invitro work or tissue analysis to provide information that is used to contribute to current or future in vivo projects.

Who or what will benefit from these outputs, and how?

Short term benefits

The short-term benefits from this work include the development of basic understandings of how genetic modifications affect biomedical processes.

Long term benefits

We hope that any new information and understandings found in the work carried out under this licence will lead to new therapies and treatments.

How will you look to maximise the outputs of this work?

New information and data from these investigations will be shared to the scientific community in peer- reviewed scientific journals, meetings and seminars. Some end-users take part in sharing knowledge to the wider community through public engagement with relevant charities.

Species and numbers of animals expected to be used

- Mice: 21500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the most commonly used animals in research due to their similarity to man and are in widespread use in biomedical research to study functions of a mammalian system for translational studies; they are also the species with the lowest sentience that can be used to meet the scientific objectives of this project and projects of the end user.

Adult mice are needed as they are sexually mature and able to provide the offspring needed for study.

The studying of the development of diseases or biological processes may require animals to be used throughout their life span, we do not intend to use animals beyond 1 year old.

Typically, what will be done to an animal used in your project?

The majority of GA mice will undergo the removal of ear tissue (biopsy) for genotyping purposes and then for tissue collection post mortem, some of these may need a secondary biopsy for confirmation of genotype. Some of these mice with be used in other approved project licences under 'continued use'.

Mice used for breeding will not be bred before they reach sexual maturity and the majority will cease breeding at 6 months old.

Some mice will be administered substances to induce genetic alterations such as intraperitoneal injections of tamoxifen.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals (around 90%) are not expected to have negative phenotypes due to their genetic alteration/s but most will experience momentary pain during biopsy. Those which undergo treatment to induce genetic alterations via the administration or application of a substance may experience mild pain and possible weight loss.

Some end-users may require the use of animals that have moderate phenotypes (e.g. tumour growths and hydrocephalus), these may experience moderate level of pain suffering and lasting harm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect most animals to experience a sub-threshold level of severity. Animals which undergo a second ear biopsy will experience a mild severity (around 5% of total animals).

Mice who receive treatment to induce genetic alterations (e.g. tamoxifen, doxycycline) are also expected to only reach a mild severity (no more than 10% of total animals based on current usage).

Mice with adverse phenotypes are not expected to be over 10% of the total number of animals used.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The mouse is the most commonly used animal to study the effects of genetic alterations. Mice often have high fecundity and are reliable breeders. Users of the mice provided often need to study phenomena, diseases and biological processes in a whole animal and tissues taken from mice.

Which non-animal alternatives did you consider for use in this project?

End-users often use well established cell lines for in vitro work. Applications for the use of a new genetically altered strains to the facility (i.e. already established strains but new to the facility) must be approved by the AWERB sub-committee comprising of NVS, NACWO, BSU Manager, a Project Licence holder and a Personal Licence holder to help ensure that alternatives have been considered.

Why were they not suitable?

In vitro and in silico models cannot completely simulate the complexity of a living mammalian system which will be under study using the animals in this licence.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals expected to be used under this licence has been estimated on past usage and planned work in the near future.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A user's requirement of the animals must be confirmed before the animals are introduced and bred in the facility. Cryopreservation, strain sharing and/or repurchasing will be encouraged rather than maintaining lines which are not being actively used.

Unnecessary production or importation of genetically altered animals will be avoided by searching resources such as animal suppliers, biomedical research institutions and industry forums.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible the knowledge of which GA strains are held in the facility is shared to all users, this helps to promote sharing of tissue and collaborative work. The facility has over 20 years experience of breeding GA mice. The staff in charge of breeding and maintenance of all GA lines (in accordance with the 3Rs) and are in regular contact with users to continually assess and adjust breeding to provide the numbers required for their research without over breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using genetically altered mice for this project. The majority of tissue taken for genotyping will be taken from the ear which provides reliable results and also acts as an identifiable marker. Transgene inducing or deleting agents may be administered by injection (e.g. subcutaneous and intraperitoneal), in diet or drinking water (with the exception of tamoxifen) or the implantation of a slow release pellet subcutaneously on one occasion. The mice produced in Protocol 1 are not expected to have any adverse phenotypes.

Why can’t you use animals that are less sentient?

The knowledge sought by our end-users require the studying of processes in a mammalian systems, by using mice we have chosen a model that has the lowest sentience.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The facility has many years' knowledge of breeding and maintaining genetically altered animal. Any mice that are expected to have potentially adverse phenotypes will be monitored using a general health monitoring sheet.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We shall follow Laboratory Animal Science Association good practice guidelines for the administration of substances and the Efficient Breeding of Genetically Altered Animals framework published by the Home Office.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I attend NC3Rs, LASA and IAT webinars and conferences regularly to ensure I am aware of advance in the 3Rs and the facility has an experienced NVS and NACWO who also have up-to-date knowledge of any advances. I am also part of industry forums which provides a place to find out up-to-date information and vital contacts to help improved the 3Rs.

145. Discovery of cancer genes and assessment of their therapeutic potential

Project duration

5 years 0 months

Project purpose

Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer gene, Therapy, Cancer immunology

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our goal is to identify genes which cause or contribute to the cancers and their spread.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK 350,000 new cases of cancer are diagnosed each year and there are around 165,000 cancer- related deaths. If we are to reduce cancer incidence and the associated suffering and deaths, we need to identify tumours earlier and develop new therapies.

Cancer cells have alterations in their DNA, so called genetic changes. These genetic changes allow the body's immune system to detect and kill cancerous cells which can keep most of us cancer free for most of our lives. In many cases however, cancers can make them selves invisible to the immune system and these can then grow unchecked. To better control cancer we need to understand how they hide from our immune system.

What outputs do you think you will see at the end of this project?

New medicines, namely drugs that offer potential new treatments for cancer.

Basic Science benefits:

Information on genes involved in cancer which may be useful for diagnosis

New information that might enable new cancer drugs to be developed

Publications and presentations at meetings

Genetically engineered mice that can be used by others in the scientific community.

Who or what will benefit from these outputs, and how?

Society will benefit from knowledge generated as this provides better understanding of diseases, disease mechanisms and methods to treat and/or prevent them. Scientific knowledge is gained over the shorter-term (2-5 years) while drug discovery and development will take 10-15 years.

Research institutes, pharmaceutical companies and non-governmental organisations will be able to take information produced by our studies and use it to support basic research and the development of drugs that ultimately provide benefit to patients.

How will you look to maximise the outputs of this work?

We will collaborate with other experts, combined efforts will increase output.

We will publish scientific papers in open access journals and deposit papers in appropriate archives thereby disseminating knowledge.

We will share both positive as well as negative results with the scientific community so that others are aware of both successful and unsuccessful approaches.

We will file patents, thereby placing in the public domain detailed knowledge of the discoveries we have made.

We will use the ARRIVE guidlines when publishing our work.

Species and numbers of animals expected to be used

- Mice: 14,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse was selected for this project because of the availability of advanced technologies to genetically alter mice. This is done by adding or removing genetic information at very early embryonic stages, before an embryo has implanted in its mother's womb. The methods to do this are very efficient so fewer animals are needed compared to achieving the same goals in another species.

Adult mice develop many forms of cancer that are similar to cancers in humans, for instance lymphomas, brain, colon, ovarian and prostate cancers. Just like in humans cancers develop in older mice more often than younger ones. Genes have been identified which when damaged cause cancer in humans and mice. One example is a gene known as p53. Mice and humans that have just one copy of the p53 gene instead of the normal two copies, develop cancer much earlier than normal.

Many strains of mice are genetically identical. This enables tumours to be caused by injecting them with cancer cells. This technique has allowed experiments to be performed to discover anti-cancer drugs. Indeed almost all cancer treatments available today have been tested for their ability to cure tumours in mice. Mice, when used in this type of work, give valuable insight into basic disease mechanisms as well as providing a means to test new therapeutics.

Typically, what will be done to an animal used in your project?

To produce transgenic mice fertilised embryos are collected which are manipulated under the microscope. These are transferred to foster mothers who become pregnant, give birth and rear their pups.

The embryo transfer is done under general anaesthesia so the animal will be unconscious and unable to feel pain. A small cut is made in the skin to place the embryos in the reproductive organs (uterus or oviducts). Typically, the mice recover very quickly from surgery, they are actively running around, eating and drinking after 1 hour and are fully recovered within a few days.

A small number of male mice are vasectomised, which are used to mate with foster females. Vasectomy is conducted on anaesthetised males by making a small scrotal incision and cutting the thin tube carrying the sperm. The incision is closed and the mice recover from the anaesthetic within 60 minutes or so. A week or two later the wound will be healed and the mice can be used for mating with females.

Transgenic mice in this project will be bred and weaned. Where the line is not pure bred a tiny piece of tissue from the ear is taken to identify the mice and the bit of tissue that is removed used to identify the genetic alterations they carry.

Transgenic and normal mice are used to study cancer. Cancers may arise spontaneously in some strains but in others we induce cancer by injecting them with cancer cells or with viruses that carry genes which cause cancer. In some cases tumour cells are placed just under the skin of the mice. The growth of these cancers is monitored by feeling the small tumour lump under the skin and the mice are humanely killed before the cancer grows very large (less than 1.2cm2).

In other cases we need to precisely control where the cancer develops, for instance to induce prostate cancer we inject the prostate gland under general anaesthesia. In such a situation the mouse is unconscious and unable to feel pain from the small incision and injection. Typically the mice recover very quickly from these surgeries. Over the following weeks or months they are monitored closely for tumour development. As the prostate can not be seen, we monitor tumour growth by imaging - very much like a scan in a hospital. To do this we inject a dye into the body cavity and while the mouse is anaesthetised we perform a scan to see if a cancer is growing or has spread. We do this monthly to identify tumours before they become too large and impact the health of the mouse. Once a tumour reaches a certain size the mouse will be humanely killed and the tumour recovered for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the animals in this project should not experience any adverse impact as they are used for mild procedures like breeding. Mice are typically breeding for 4-9 months.

Some of the animals will experience transient pain from the minor surgery required for embryo transfer, vasectomy and inducing tumours in specific organs. These procedures will be conducted under anaesthesia so the animal will remain in a state of sleep/unconsciousness during the surgery. Once they have recovered from anaesthesia any pain will be managed with drugs for a few days.

The procedures used for tumour cell inoculation under the skin will involve needle pricks. In procedures which involve anaesthesia, the mice will be expected to be subdued and lethargic for an hour or two but then recover fully as the affects of the injection and/or anaesthesia wear off. Some animals may have an altered immune system that may make them more susceptible to infection. To keep mice with immune deficiencies healthy, they are maintained in a very clean facility where they are not exposed to harmful viruses or bacteria.

The tumours will be allowed to grow to a size where they may cause some discomfort and may cause other clinical signs. We will carefully monitor mice with tumours to make sure

that the tumour is not having a major impact on the health of the mice. We monitor weight, breathing, mobility and general condition of the mice. We also routinely measure tumour size, which may involve feeling it through the skin or using an imaging technique like ultrasound.

Tumour growth will occur over a period of between two months and one and a half years and can be unpredictable, so monitoring will be continuous. Tumour bearing mice will be humanely killed at the point that we judge that the tumour burden is having a significantly health impact or if tumours don't grow within 18 months.

All animals will be killed humanely at the end of the procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse : Mild severity : Greater than 96%

Mouse : Moderate severity: less than 4%

What will happen to animals at the end of this project?

Killed
Kept alive
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancers are usually composed of tumour cells mixed with and normal cells. As they grow new blood vessels form to provide the tumours with oxygen and nutrients. Very often tumours are attacked by cells from the immune system which recognize the cancer cells as "foreign" and in some cases the tumour is controlled or even eliminated. In many other cases the tumour is able to "hide" from the immune system.

When we detect cancers they have usually been growing over a very long period of time, years in humans and many months in mice. During this time the cancers change so they are composed of a mixture of similar but non-identical cells. Cancers that arise in different people have some similarities, but each one is unique.

To control cancer we need to identify the genes which are able to support the growth of cancer and the mechanisms cancers use to hide from the immune system. Studies of

cancers isolated from people and mice over the last 10 to 15 years have given us long lists of "cancer genes". To identify which combinations of genes are contributing to the cancer's initiation and growth requires studies in animals because cancer cells grown in the laboratory are in a very simple environment compared to when they arise naturally in humans. It is not possible to replicate the complexity of how a cancer grows, interacts with normal cells and manages to evade the immune system in a laboratory setting.

Which non-animal alternatives did you consider for use in this project?

Cells isolated from some cancers can be grown in the laboratory. These culture systems have improved in recent years allowing cancer cells to grow into tiny but more complex structures that better resemble some aspects of normal tumour growth. These so called "organoid cultures" are three- dimensional cultures usually composed of a small number of related cell types. While their three- dimensional nature can more closely resemble some aspects of simple tissues they are very simple compared to the highly complex environment one finds in a mouse or human tumour. Organoid cultures are useful for conducting screens for drugs or mutations that can alter a cancer cell's growth but these systems to not have an immune system component, thus drugs which prevent a tumour hiding from the immune system can not be found using such simple systems.

Why were they not suitable?

To study how a cancer evades the immune system and to find rare immune cells which can kill tumour cells it is necessary to study cancers in the presence of a functional immune system. This can't be replicated in the laboratory. Similarly, the process whereby a cancer spreads from its primary site can only be studied in the whole animal system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals estimated to be used for this project are based on many years of experience in generating mice with altered genes. They are also consistent with the usage in the existing project license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Genetic manipulation: More than 90% of the animals used in this project will be used for establishing and breeding combinations genetic alterations together. The numbers of mice

can be estimated from prior experience using genetically modified ES cells to make mice as well as the probability of generating mice with the desired combination of alterations based on patterns of Mendelian segregation.

Where possible we establish mice which breed true.

We test the performance of each genetic alteration before breeding them together.

Cancer studies: Around 5-10% mice in this project will be used to deliver the core scientific objectives, which involve inducing cancers and collecting the resultant tumours and analysing them.

To reduce mouse numbers we will:

Conduct careful quality control on all samples used, such as cell lines and viruses, to make sure that when they are injected into mice there is a very high chance that useful data will be collected.

Use standard operating procedures to ensure that we get the maximum amount of useful biological information from each mouse.

Consult widely to identify and where appropriate introduce improvements in methods to maximise the recovery of data from every mouse

Apply technologies which enables us to gain the maximum amount of information from every sample collected.

Use the NC3Rs Experimental Design Assistant

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

There are many measures we take to reduce mouse numbers:

We use colony management software to keep track of mice in the animal room, set up just the right number of breeding pairs to produce the mice we need.

We conduct pilot experiments using small numbers of mice to assess the performance of a cell line or virus before initiating larger experiments, or not conducting them at all in cases where the pilot does not provide a good basis for continuing.

We stop breeding and preserve mouse lines in cryogenic storage if they are no longer required

We use the most advanced and efficient methods to make genetic mutants which avoids cycles of mouse breeding.

We share post-mortem tissues

We limit "noise" by controlling as many variables as possible including genetics (inbred lines), age, sex, and environment.

In induced tumour models we use randomisation and blinding to control for operator bias.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice with cancer pre-disposition mutations

We use mice with genetic alterations (mutations) in cancer causing genes. If these mice are available from other investigators or public repositories we will import these. If they are not available we'll generate these ourselves. We use refined models so that cancer is limited to the organ we are studying - for instance the prostate.

Some genetically altered mice develop cancers spontaneously. To limit their suffering, we conduct regular screens for signs of cancer and if detected more frequent screens are then implemented.

Mice with immune deficiencies

We use mice with immune-deficiencies to explore the role of aspects of the immune system in controlling cancer. Although, some parts of the immune system are missing in these mice, they are very healthy in the environment in which they are kept.

Transplantable cancers

To conduct controlled experiments, we use cancer cell lines which we implant into mice, either normal mice or ones with immune defects. The tumours are usually injected under the skin which allows us to monitor the size of the tumour to limit any suffering.

Organ specific cancers

These are induced by combining a specific genetic background which may pre-dispose the mouse to develop a specific cancer type with local induction of the tumour by administering a cancer causing agent like a virus. In such cases we will endeavour to design the experiment so that the growth of the cancer can be detected by an imaging technique which will allow us to intervene to prevent suffering.

Why can’t you use animals that are less sentient?

Cancer is a late onset disease in adults. It develops from a single cell that arises in mature organs over many months, thus an immature life stage is not suitable. The immune system is also not mature at an earlier stage (immature life stage).

Some aspects of cancer can be modelled in zebrafish, for example they develop a type of skin cancer known as melanoma, but zebrafish have a very different immune systems to humans and mice, their organ systems are very different to ours and lower organisms can't be genetically engineered to the extent possible with mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I don't anticipate many refinements to transgenic methods as these are already very standardised and efficient, though where these are reported we will test and implement them.

Where possible we will employ highly experienced animal care staff who are familiar with the specific strains, experimental activities and careful handling of the mice. Familiarity with the balance between welfare and experimental needs, observing recording and reporting expected and unexpected outcomes at the cage-side with score sheets is another essential aspect of minimizing welfare costs. An important balance needs to be struck between to much disturbance of the mice while allowing time pre- and post-procedures for acclimatisation and recovery. To improve post-operative recovery heat mats are used to warm mice as well as changes to the environment such as deeper bedding and nests can be provided.

Where possible the mice will not be disturbed unless required for routine husbandry, daily checks or experimental purposes. Environmental enrichments like tubes and nests will be provided. We will however monitor harms via observation and body weight if appropriate and in situations where this does not induce more stress to the mice.

Where possible mice will be acclimatised, for instance when moved between facilities or animal rooms before any experimental procedures are conducted.

We consult existing literature to ensure we use the latest refinements in experiments. Work will be carried out in state-of-the art facilities by highly trained technicians and scientists, all of whom are dedicated to the highest standards of animal welfare. We use imaging and/or calipers to accurately assess the size of a tumour and these are monitored against previous data to enable prediction of the possible disease course.

The scientists and technicians work closely with the trained and highly experienced personnel in the facility and the veterinary surgeon to ensure that animals experience minimal adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I use guidance from the following sources:

The National Centre for the Replacement Refinement and Reduction of animals in Research (NC3Rs) https://www.nc3rs.org.uk

The International Mouse Phenotyping Consortium (IMPC) https://www.mousephenotype.org.

The International Society of Transgenic Technologies (ISTT).

Some of my team members are members of The Laboratory Animal Science Association (LASA) and attend an annual conference where information on best practice is often exchanged.

The PREPARE guidelines have been consulted

The Workman et al., publication, "Guidelines for welfare and use of animals in cancer research" (2010) has been consulted.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I periodically check website for The National Centre for the Replacement Refinement and Reduction of animals in Research (NC3Rs) https://www.nc3rs.org.uk which has many excellent standard operating procedures and videos and consult Norecopa, https://norecopa.no.

I check the website for the International Society of Transgenic Technologies (ISTT) for advances in the field and observations and experience in implementing these.

Implementation of a technical variation will usually be conducted with a pilot experiment to gain confidence in the actual method and its reported advantages, ideally with suitable controls. Once this has been assessed and shown to be an improvement then this will be introduced in the standard operating procedure and then implemented as a routine.

146. Molecular basis of neurodevelopmental disorders

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

autism, neurodevelopmental disorder, protein synthesis, fragile X syndrome, Syngap

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to determine how molecular changes in neurons contribute to autism and intellectual disability, and to identify new treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The worldwide prevalence of autism and intellectual disability is approximately 1%. Affected individuals and family members experience undue burden emotionally and financially, and institutional support is often not sufficient to alleviate these concerns. Treatment options are limited to compounds that target the behavioral symptoms associated with autism and ID, but there are no treatments that target the underlying cause. Identifying new treatments that target the core disruptions is therefore an important unmet need.

What outputs do you think you will see at the end of this project?

The outputs from this project will include new information about the disease mechanisms of autism and intellectual disability. They will also include the outcomes of testing new therapies in mouse models of autism and intellectual disabilities, which will inform further clinical research. This information will be published in major journals, presented at scientific conferences, and disseminated to the lay community through public engagement activities.

Who or what will benefit from these outputs, and how?

The major benefit of this research is the identification of new drug treatments for patients with autism and intellectual disability, which will benefit affected individuals and family members. This research will also benefit researchers in the neuroscience community by identifying mechanistic connections between molecular changes and brain function.

How will you look to maximise the outputs of this work?

Outputs of this work will be published in major journals, presented in international conferences, and shared with collaborators at all stages of development. Information will be shared whether it supports or disproves the original hypothesis, so that the data can be used as a basis for further research.

Species and numbers of animals expected to be used

- Mice: 30000
- Rats: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

A thorough understanding of how neuronal function is altered in autism and intellectual disability requires investigation of an intact mammalian brain. Testing of rodent models of neurodevelopmental disorders at multiple developmental ages is key to uncovering molecular disruptions in the brain that can be targeted with new treatments.

Typically, what will be done to an animal used in your project?

We will breed animals with disruptions in genes that have been linked to autism and intellectual disability, such as the Fmr1-/y mouse model. - In some cases animals may be given drugs to study the effects on brain function

In some cases animals may be given drugs to alter gene expression

Animals may be tested for performance on learning and memory tasks

Animals may be tested for audiogenic seizures

Animals will be killed by humane methods and their brain tissues used after their death to study changes of interest

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals used will carry genetic mutations with no associated harmful phenotype. A small number of animals will carry a genetic mutation associated with a moderate phenotype such as seizures

-Some of the learning tasks will involve food restriction that is not harmful but may result in weight loss

-Some learning tasks will involve inducing a memory by delivering a mild foot shock, which may cause transient moderate pain and discomfort

-For testing audiogenic seizures, animals will be exposed to a loud sound and may experience seizures that will cause transient moderate discomfort

In all testing, attempts will be made to minimize discomfort to the animals (i.e., using the minimum loudness of sound to reveal seizures), and they will be humanely killed at the end of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severities for all procedures will be mild to moderate. The majority of animals will experience an actual severity of mild.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project requires molecular investigation of neuron function and investigation of complex behaviours. To date, experimental systems that allow this are limited and must involve the use of vertebrate animals.

Which non-animal alternatives did you consider for use in this project?

Mammalian cell lines and primary neuronal cultures were considered.

Why were they not suitable?

Neuron cultures provide a limited picture of the molecular function of the brain, and they cannot be used to model behavioral changes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals has been estimated based on the breeding and maintenance required to maintain multiple transgenic lines, and experimental group sizes needed for molecular, biochemical, electrophysiological and behavioral assessment of multiple rodent models of autism. The groups sizes have been determined based on statistical analysis of previously published research, estimates from previous and current studies performed in our group, and collaborators performing similar experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to reduce variability, and thus number of animals required, all experiments will be performed according to the ARRIVE guidelines. As such, genetically altered animals will always be tested alongside unaltered wild type animals that are matched for age and gender, and treated groups will always be compared to vehicle controls. Furthermore, experiments will be performed blind to genotype by using a code (e.g., A or B) to identify each animal. This code will be kept by a person who is not involved in the experiment. Groups will be assigned in a randomised fashion.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For experiments involving brain tissue and brain slices, experimenters can and often do use material from one animal for multiple experiments. In many cases, two researchers prepare hippocampal slices from the same animal to perform their experiments. In

addition, multiple researchers use the same brain lysate samples to perform Western blot experiments for proteins of interest.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will breed animals with disruptions in genes that have been linked to neurodevelopmental disorders. We do not expect these animals to suffer any adverse effects from these genetic alterations. The animals will be killed by humane methods and their tissues used after their death to study biochemical and electrophysiological changes of interest. In some cases animals may be given drugs to study the effects on biochemical/electrophysiological changes but it is not expected that this will cause any adverse effects other than mild clinical signs (such as decreased appetite or lower levels of activity). In some cases, we will test animals for their performance on learning and memory tasks or test them for audiogenic seizures. This will be necessary to reveal potential benefits from our drug treatments. In all testing, attempts will be made to minimize discomfort to the animals (i.e., using the minimum loudness of sound to reveal seizures), and they will be humanely killed at the end of the experiment.

Why can’t you use animals that are less sentient?

A major goal of this research is to identify and correct neurological processes that are disrupted in neurodevelopmental disorders using pharmacological and genetic strategies. The use of the genetically altered mutant rodent models is critical to investigating this question, because they effectively model human mutations that affect brain function. In the majority of our studies, we will use genetically altered mice in order to examine an intact mammalian nervous system. However, we will also need to use genetically altered rat models because they will allow us to assess more complicated cognitive disruptions that are difficult or impossible to observe in mouse models. For example, in behavioural paradigms, rats are more flexible in response to novel situations and have extensive social interactions - two domains specifically affected in autism spectrum disorders.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animals in these studies will be cared for by trained staff within a well-resourced and well- equipped modern animal facility that contains individually ventilated cages (IVCs) and barrier systems to maintain specific pathogen-free (SPF) status/health. Environmental enrichment will be provided.

Mice will be carefully monitored and if there is any evidence of suffering greater than minor and transient or in any way compromises normal behaviour they will be culled using schedule 1 methods.

Animals tested for audiogenic seizures (AGS) will be analyzed using multiple methods in order to identify a signature that is predictive of seizure onset. Identification of this signature may then be used for further studies rather than the behavioral expression of seizures themselves.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will stay up to date on best practice guidelines set forth and regularly updated from the NC3Rs website (Guidance on the Operations of ASPA - https://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the advances in the 3Rs by attending informational events provided locally and provided by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

147. Acute and chronic kidney disease: translational studies using the pig

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

(i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

(ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

kidney, AKI, therapy, porcine, physiology

Animal types	Life stages
Pigs	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Using a pre-clinical, translational animal (porcine) model, this project will develop and test therapies to either prevent, treat or benefit recovery from acute kidney injury (AKI), thereby blunting transition from acute-to-chronic kidney disease

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Acute kidney injury (AKI) is an important cause of in-hospital morbidity and mortality in humans, in both acute medical and surgical specialties. For example, approximately 20% of patients undergoing cardio- thoracic surgery develop AKI, as do between 20-30% of patients in intensive care units and between 5- 15% of all admissions to hospital. AKI is ‘silent’ with no obvious symptoms until severe and currently there are no treatments for AKI. Therefore, at present, treatment can only be supportive, with optimization of fluid balance and blood pressure, avoidance of nephrotoxins and institution of renal replacement therapy where necessary. There has been no significant improvement in the outcome of AKI over the past 3 decades, yet AKI costs the NHS approximately £1.2 billion per year in added costs (increased length of stay, supportive care). Pigs are very similar to humans, especially their kidneys.

Indeed pig kidneys are more similar to human kidneys than the kidneys of non-human primates such as chimpanzees or marmosets. Therefore commercial pigs can be very useful and translational models when assessing kidney health and disease. Here, we have established a porcine model of AKI to undertake work relevant to the three stated objectives in this licence.

What outputs do you think you will see at the end of this project?

Other researchers in the UK: the results and data will be published open-access in peer-reviewed clinical journals. Therefore, the information will be disseminated amongst scientists and clinicians primarily within the nephrology community but will also be of interest to cardiologists and intensivists, since the risk of AKI is high in these settings. Within all these areas there is considerable interest in an early biomarker for AKI as there is no specific treatment for AKI, only supportive therapy. AKI can have a rapid onset and lead to patient deterioration very quickly. For these reasons, AKI is of huge importance to the NHS in the UK but also for health care services worldwide. Potential early detection alone (for example of metal elements in urine) or when such results are input to an iphone and coupled to machine-learned algorithms for early eALERTS of AKI, as has been reported recently, then we may be able to say we have a genuinely ‘early warning system’ for AKI.

International researchers: Globally, 85% of AKI occurs in developed countries. One output from our projects could be an easy-to-use point-of-care-test (POCT) that could be used in resource-limited areas. This would enable early triage of patients to larger hospitals and/or early, easily-administered supportive care, such as fluids and avoidance of nephrotoxic drugs (surprisingly common). A cheap, easy POCT test for AKI therefore has the potential to be distributed globally.

Technology: To date, there are very few hand-held systems for measuring metals in watery environments, with high sensitivity. Most require larger machines. The new technology we aim to develop as part of this licence when used in a novel health-care setting will be of interest to many environmentalists, geochemists working in the field. In

theory, the technology could be applicable in many other settings and be easily transportable.

Who or what will benefit from these outputs, and how?

In this project, using a porcine model of AKI we hope to discover underpinning mechanisms of acute and/or chronic kidney disease that can be exploited first to; 1) guide development of new therapies that may be used to either prevent AKI. This would be important for those individuals with no known underlying renal disease but whom are undergoing procedures that have a known risk of causing AKI e.g. patients admitted for cardiac surgery or into intensive care units (ICU). The timeframe for these advances from underpinning knowledge to clinical translation would be 3-5years; 2) to develop a therapy or technique that could treat those individuals where AKI has already been diagnosed e.g. in the community or within hospital, but at present only supportive care is currently available e.g. by giving fluids. 3) benefit recovery of functional kidney tissue after AKI so as to mitigate the known risk of transition from acute-to-chronic kidney disease. Secondary objectives of the research will be to consider new biomarkers of acute or chronic kidney disease or of successful recovery of kidney function. All research will be conducted alongside clinical colleagues to ensure that the research is grounded in translational science and that any positive outcomes maybe communicated immediately to the relevant (renal consultants and healthcare workers) in the shortest timeframe.

How will you look to maximise the outputs of this work?

There are few groups in the UK doing this type of work. The PPL holder has lines of communication with these other groups and in the past has shared tissues/expertise, as to be expected with such work. Any animal work will be published in peer-reviewed journals and presented at relevant conferences such as The Renal Association, The The Amercian Society of Nephrology etc..

Species and numbers of animals expected to be used

- Pigs: 128

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Upon deciding on the most appropriate animal model in which to satisfy study objectives then we will first consider if in vitro techniques are available and suitable – we are currently developing a number of these (e.g. microfluidics of drug uptake in kidneys). The proposed work will be conducted alongside these approaches. I always consider if less sentient animal models (e.g. flies, worms, fish) are satisfactory for study hypotheses, although for

genuine pre-clinical work in relation to renal physiology these are rarely appropriate. Mice, rodents have only residual renal functional capacity and fail to respond to AKI in a manner similar to human. The pig is the preclinical animal model of choice for testing therapies that may rapidly move to a randomised controlled trial. For example, in terms of general metabolism (but equally applicable to organ function) the pig represents one of the few species of animal that naturally carry a significant amount of cholesterol within the low density lipoprotein (LDL) fraction (similar to humans). For more acute studies in which the similarity between porcine and human physiology is the primary outcome then certain breeds of commercial pig, as supplied by an accredited supplier are suitable. Pigs can naturally develop renal disease, diabetes and heart disease, esp when fed high fat or salty diets. The majority of data generated is readily extrapolated to man, more so than many other animal models.

In order to examine specific mechanisms for the induction of disease then animal studies are advantageous, and whole animal physiology is important to characterise prior to experiment. Pigs can be fed westernised diets, are monogastric omnivores and actually develop all the symptoms and end- stage diseases that are important for this licence aims and objectives. Their size of organs in relation to body weight is near identical to human - this is an important consideration when studying physiology.

AKI is an important cause of in-hospital morbidity and mortality, in both acute medical and surgical specialties. Approximately 20% of patients undergoing cardio-thoracic surgery develop AKI, as do 5- 20% of admissions to general intensive care units. Thus in order to replicate this in an animal model we need to place the animal under general anaesthetic and reversibly occlude both renal arteries for a period of time that parallels clinical practice i.e. patients undergoing cardio-thoracic surgery. Direct occlusion whilst under anaesthetic ensures precise occlusion of the blood flow to the kidneys, as happens clinically with low blood pressure. Furthermore, longitudinal sampling, as enabled by using large animals, ensures less biological variation (within animal variance only) and thus greater statistical power to reduce animal numbers used in experiments.

Typically, what will be done to an animal used in your project?

Typically for any individual animal.

Objective 1-3: The pig will be acclimitised for one week. During this time the animal will remain in a pen, eating standard diet. **A preventive treatment may be given prior to surgery either via diet, water or by injection (Objective 1).** On the day of surgery, the pig will be randomised (sealed envelope) to study group and sedated for intubation and general surgery. Male or Female (usually female) pigs (50-65 kg; Canberra 12 [large white/duroc/landrace]) will be anesthetized for general surgery using an intramuscular dose of buprenorphine (0.05 mg/kg), ketamine (5 mg/kg), and detomidine (0.1 mg/kg) followed by intravenous alfaxalone (0.7–2.4 mg/kg), dosed to effect to aid intubation. Anaesthesia is maintained with isoflurane (1–2% in O_2) and ventilated using a tidal volume of 10–12 ml/kg. A venous catheter is inserted for supportive fluid delivery and vascular

access. Baseline blood samples are taken at this point. A bladder catheter is inserted for baseline urine collection. A midline laparotomy allows visualization of both the right and left kidneys, whereupon one or both common renal arteries are cross-clamped for variable time (commonly 40 mins; but previously from 20 - 60mins) using atraumatic vascular clamps. At time zero, the clamps are removed. At this point, some pigs may remain on the surgical table and physiology followed for a period of upto 4-6hrs, followed by euthanasia (i.e. non-recoverable surgery, **Objective 2**). These experiments will examine physiological events before, during and immediately after AKI. Objectives 1 and 2 will be conducted according to procedures outlined in Protocol 1.

In other pigs which usually have had bi-lateral renal artery occlusion - as with uni-lateral occlusion the remaining healthy kidney in situ accomodates for the reduced function of the previously occluded kidney, the incision site is closed, the bladder catheter (12 Fr) remains in place for upto 72h and pigs are recovered to a pen, thereafter for upto 8 weeks of age (**Objective 3).** Postoperative analgesia is maintained with buprenorphine every 8 h for the first 24 h and thereafter every 12–24 h, including tramadol (4 mg/kg im) as required. This objective will determine how pigs recover from AKI and can be used to test interventions where AKI has occurred in the community for example i.e. no preventive measure could be given. It is often inappropriate to only occlude one kidney as this rarely happens in the real world. Pigs recover fine from such transient occlusion so long as the period of occlusion does not extend beyond 120mins. Objective 3 will be conducted according to procedures outlined in Protocol 2.

All pigs will at a minimum have a baseline paired blood and urine sample, and thereafter be sampled at intervals to 8 weeks of age following prior protocols. At 48-72h, the bladder catheter is often removed to prevent infection and blockage. Thereafter spot samples of urine can be obtained by free catch. In some pigs at a sufficient post-operative recovery time (e.g. at least 5-7days), a percutaneous right kidney biopsy may be obtained with ultrasound guidance and pigs lightly sedated. At study end, all pigs will be humanely euthanised and tissues and biofluids collected as per standard protocols.

Standard measures of AKI are routinely measured in blood samples such as serum creatinine (µmol/l) and urea (mmol/l) will be measured by autoanalyzer (RX-Imola, Randox, Co. Antrim, Northern Ireland, UK) with typical interassay variation of <5%. Osmolality (Osmomat 030, Gonotech) and blood gas analysis will also often be conducted (pH, pO2, pCO2, HCO3, glucose, lactate, blood urea nitrogen, haematocrit (%) & haemoglobin (g/dL), Na+, K+, ionized Ca2+, Cl-; Siemans EPOC blood analysis system) as per individual study protocols. A typical blood sampling regime might be (10ml at each timepoint) 0h (i.e. baseline) and subsequently at 2, 4, 6, 8 24, 48h, 3d, 5, 7, 14 days and every 7 days from three to eight weeks of age.

Standard measures of AKI are routinely measured in urine such as albumin (g/L), creatinine (µmol/l) and their ratio will be determined. Urine samples (2ml at each timepoint) will be withdrawn at 0h (i.e. baseline) and subsequently at 2, 4, 6, 8 24, 48h, 3d, 5, 7, 14 days and every 7 days from three to eight weeks of age. Urine biomarkers of renal injury

will often be measured using commercial, porcine- specific ELISA assays. Nephrocheck© may also be conducted on urine.

What are the expected impacts and/or adverse effects for the animals during your project?

To minimise suffering: All experimental animals will be monitored for good general health, according to an adverse effects monitoring sheet developed by our unit. Each animal with the exception of some sham-controls on occasion, will be placed under anaesthetic for all surgical procedures. This involves sedation, anaesthetic, handling and/or restraint. Any invasive procedure that is likely to cause pain or temporary discomfort, will always be accompanied by appropriate use of analgesia. Animals will be monitored for weight loss over sufficient periods of time although this is not to be expected. Abnormal behaviour is to be expected temporarily post-surgery, and particularly after induction of AKI (moribund, lack of engagement). Such effects last for up to 24h. Analgesia will be used at appropriate intervals to manage any estimated pain, as previously established in association with a european diplomat in anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild to moderate for all procedures. All animals will experience at least a degree of sedation (mild) or general surgery (non-recoverable or recoverable). All animals recovering from surgery are expected to experience moderate severity of procedures, managed using appropriate anaesthesia and monitoring.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to investigate a specific disease affecting a single organ whose dysfunction affects all other organs of the body. Studying physiology is best achieved using live animals, as in vivo physiology better reflects the variable physiological responses observed in humans experiencing similar conditions. Cell-based models or less sentient animals like flies, worms or fish do not adequately reflect the human response to kidney injury. The pig is considered the most appropriate pre-clinical animal model to meet study objectives. For example, pigs are ideal for testing preclinical therapies with respect

to kidney function whereas rodents allow effects of aging or genetic manipulation to be explored. The data obtained will inform computational models of kidney function so that fewer animals are used for similar work in the future.

Which non-animal alternatives did you consider for use in this project?

Non-invasive technologies are available for studying isolated kidney cells and include cell lines from multiple species. In other less sentient animals, then whole kidney responses to lack of blood flow are not able to be recorded and they are not replicable in the clinic.

However, where possible we will develop other in-vitro methods such as cell culture. Indeed, with colleagues we have developed a primary culture-based model of kidney development (HK2 cells) and it is envisaged that we will also try to adapt this method for investigating isolated renal cell responses to certain conditions encountered during IR-injury such as hypoxia. Where appropriate we will also use in silico modelling of kidney function.

Why were they not suitable?

Non-invasive technologies are available for studying isolated kidney cells and cellular response to isolated hypoxia or malnutrition for example. These technologies are considered and used by the PPL holder as appropriate. However, for final pre-clinical discovery science or testing with a view to translation to clinical practice then studying in vivo in the live animal is required. The primary effects to be examined in this licence relate to a whole body physiological response and for this reason it is important to utilise the most appropriate animal model and then establish the causative factors in the circulation that may not be present in a culture dish, such as hormones or anti-sense RNA. With isolation of such putative causative agents then future in-vitro studies are much more realistic. This is not done lightly and all other options are always considered. One strength of the current programme of work is that we will combine these technologies with techniques that are not able to be performed, ethically, on humans e.g. kidney biopsies and for whom it is ethically difficult to acquire control samples e.g. kidney biopsies from individuals with normal kidneys, as a standard biopsy has a 1:3000 risk of fatality. Equally, the size of pigs allows for repeat blood sampling and kidney biopsies to be taken with relative ease and low impact on the animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of pigs allocated per group is ordinarily based on previous studies involving (n = 5-8 pigs/group) and consideration of the variation in primary outcome. Sham-controls are always run alongside treatment groups but numbers are kept to an absolute minimum due to low between-animal variability in kidney function. Where appropriate factorial designs are used to maximise the power of the experiment, plus longitudinal designs to minimise within-animal variation. Groups are determined by randomization (e.g. sealed envelopes) to minimise any subjective study bias. Typical number per group are n = 3/4 for controls and n = 6/8 for treatment groups. These numbers take into account either binomial outcomes (disease noted, yes/no) or quantitative outcomes such as the increment in serum creatinine with AKI.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Aspects of study design and outcome are always taken into account and are pre-determined in discussion with animal bioscientists. Power calculations are performed as necessary, based on aforementioned known variabilities in outcome. The PPL holder helps many other scientists with their statistics and uses the EDA for teaching undergrads study design. The PPL holder holds 'Stats club' sessions on an as needed basis for staff and undergrads. As an example, factorial designs are used to achieve greater statistical power with lower numbers of animals per group. For quantitative data, I always conduct a power calculation to determine optimal sample size and keep animal numbers to a minimum whilst maintaining statistical significance (alpha set at 0.05) and study power (>80%). For example, using a statistical program for performing power calculations then: assuming a 4 group factorial study using one sex, the effects of injury (injury, yes/no) and pre-treatment with a drug (yes/no) are tested for their interaction, then to observe the least significant practical effect size of 20% (e.g. a 20% change in renal creatinine clearance) with a residual mean square (variance) of 15% then we would require n=6 animals per group (total animals=24). Over the course of 3 years, using a similar design it is possible that we will repeat such a design, testing different drugs or different outcomes on at least 4-5 occasions, hence total study number for this PPL could number 128 over three years.

Using the above example, but conducting a split-plot design in which each animal served as its own control (i.e. unilateral renal occlusion) and assuming less (50% less) variance within kidneys than between, then we may be able to reduce animal numbers to n=4 per group or a total number of 16 animals. These figures depend on the experimental design and the variance associated with the outcome of interest. We will however, always make our best effort to accommodate these factors in order to keep animal numbers to a minimum. For example, we have previously justified the use of experimental controls (but not full sham-operated animals) with a small study comparing sham vs. un- anaesthetised controls on our main experimental outcome. Often, however, sham-surgery is required to replicate the minute variations in animal experience, environment, physiology as elicited by the experimental procedures such as surgery.

Experimental variance will be kept to a minimum by: Randomisation of animals to treatments, Explicit inclusion and exclusion criteria, avoidance of anaesthetic agents that may interfere with study outcomes. For each and every experiment, as part of good laboratory practice, we write an experimental protocol which includes: a statement of the objectives, a description of the experiment to be conducted including treatment groups, animal numbers and experimental material, an outline of the analysis and principal experimental outcomes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will only purchase the required number of animals as per the study design. For any testing studies then we will always consider a it a pilot project, not using more than 3 animals for testing. For any new protocol then the design will include step-testing of one animal, then a further animal, then if all outcomes are met a full study design. Any tissue required by others will be biobanked and shared as the PPL holder has done in the past with multiple groupd. Evidence for this can be provided on request.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Upon deciding on the most appropriate animal model in which to satisfy study objectives then we will first consider if in vitro techniques are available and suitable – we are currently developing a number of these (e.g. microfluidics of drug uptake in kidneys). The proposed work will be conducted alongside these approaches. I always consider if less sentient animal models (e.g. flies, worms, fish) are satisfactory for study hypotheses, although for genuine pre-clinical work in relation to renal physiology these are rarely appropriate. Mice, rodents have only residual renal functional capacity and fail to respond to AKI in a manner similar to human. The pig is the preclinical animal model of choice for testing therapies that may rapidly move to a randomised controlled trial.. For example, in terms of general metabolism (but equally applicable to organ function) the pig represents one of the few species of animal that naturally carry a significant amount of cholesterol within the low density lipoprotein (LDL) fraction (similar to humans). For more acute studies in which the similarity between porcine and human physiology is the primary outcome then certain breeds of commercial pig from accredited suppliers will be used. Pigs can naturally develop renal disease, diabetes and heart disease, esp when fed high fat or salty diets.

The majority of data generated is readily extrapolated to man, more so than many other animal models. All pigs will be sourced from an accredited, commercial source with high health status and from a strain likely to be free of malignant hypothermia.

Why can’t you use animals that are less sentient?

In order to examine specific mechanisms for the induction of disease then animal studies are advantageous, and whole animal physiology is important to characterise prior to experiment. Pigs can be fed westernised diets, are monogastric omnivores and actually develop all the symptoms and end- stage diseases that are important for this licence aims and objectives. Their size of organs in relation to body weight is near identical to human - this is an important consideration when studying physiology.

Upon deciding on the most appropriate animal model in which to satisfy study objectives then we will first consider if in vitro techniques are available and suitable – we are currently developing a number of these (e.g. microfluidics of drug uptake in kidneys). The proposed work will be conducted alongside these approaches. I always consider if less sentient animal models (e.g. flies, worms, fish) are satisfactory for study hypotheses, although for genuine pre-clinical work in relation to renal physiology these are rarely appropriate. Mice, rodents have only residual renal functional capacity and fail to respond to AKI in a manner similar to human. The pig is the preclinical animal model of choice for testing therapies that may rapidly move to a randomised controlled trial. For example, in terms of general metabolism (but equally applicable to organ function) the pig represents one of the few species of animal that naturally carry a significant amount of cholesterol within the low density lipoprotein (LDL) fraction (similar to humans). For more acute studies in which the similarity between porcine and human physiology is the primary outcome then certain breeds of commercial pig as provided by accredited suppliers are suitable. Pigs can naturally develop renal disease, diabetes and heart disease, esp when fed high fat or salty diets. The majority of data generated is readily extrapolated to man, more so than many other animal models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The PPL holder will always consider new, better methods that help reduce any animal suffering and improve study outcomes. For example, we altered our anaesthetic regime in consultation with the NACWO, named vet and veterinary consultants when it was apparent that a different regime produced better study outcomes (e.g. improved post-operative recovery). Equally, we sought to reduce unnecessary harm to sham-controls (i.e. no mid-line laparotomy) when it was apparent they were similar to other controls that had undergone full sham-surgery. Anaesthetic monitoring by a competent person when the pigs are under general anaesthesia will ensure welfare is not compromised. For example, this will be done by pedal reflex, corneal response and depth of breathing (mechanical ventilation at all times) to ensure appropriate depth of anaesthesia. A ventilator will help control the depth of breathing this will reduce any incidence/ likelihood of inappropriate

depth of anaesthesia and welfare issues. Post-operative monitoring follows a standardised process as developed in consultation with the NACWO, named vet and anaesthetic consultants. Pain management involves a pain-scoring table. If possible, animals will be trained to pee on demand. Animals will either be housed in groups to help reduce stress or if that is not possible and they have to be housed individually, then they will always be in sight and sound of other pigs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow any published guidance for large animals that may improve our study outcomes such as published by LASA or NC3Rs or the Home Office. For example, in regard to aseptic surgery then the guidelines as outlined in "Guidance principles for preparing for and undertaking aseptic surgery" (LASA pdf) will of course be followed.

We will ensure only the minimum number of animals are used as per trial design (pilot study or full experimental trial). The applicant routinely conducts power calculations on sample size (Genstat, VSNi Ltd) for all studies using a priori data.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PPL holder is a member of an AWERB committee and regularly hears about updates on NC3Rs, from colleagues and the NC3Rs website. Any improvements will be implemented without hesitation. For example, we altered our anaesthetic regime in consultation with the NACWO, named vet and veterinary consultants when it was apparent that a different regime produced better study outcomes. Equally, we sought to reduce unnecessary harm to sham-controls when it was apparent they were similar to other controls that had undergone full sham-surgery.

148. Reproductive toxicology

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Toxicity, Reproduction, Toxicokinetics, Safety

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate
Rats	juvenile, adult, pregnant, neonate
Rabbits	adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to assess the safety of substances that may be administered to Man. The studies performed will be designed to reveal any effects on mammalian reproduction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is generally accepted that the way in which a material is metabolised within a living body has a significant effect on how it works and its potential toxicity. Consequently, for the majority of substances forming part of the work performed under the authority of this

licence, it is imperative they are tested on living animals in order to assess for toxicity of tissue, organs and systems (e.g. the cardiovascular, respiratory and reproductive systems) following single or repeated administration. Unfortunately, the use of alternative methods, including the use of dead animals, at this moment in time cannot generate relevant data to support the submission of safety data to international regulators. Alternative methods such as in-vitro techniques will be used as much as practicable to supplement the work involving protected animals.

The testing of Pharmaceuticals as part of the safety evaluation process for clinical trial and marketing applications will generate data which will be used to make decisions on whether a candidate can be progressed to human studies. Similar assessments are also required for food and drink additives and supplements and novel foods to ensure their safe use in the human population. Study reports will be included in regulatory submissions to allow regulatory authorities (e.g. EMA or FDA) to make judgments on whether to permit clinical studies or to licence a drug. Guidance issued by the Home Office in 2005 recognises that the justification for animal-based regulatory toxicology and safety testing is the need for regulatory authorities to have sufficient information to assess the risks to which humans are exposed when test substances are manufactured/produced, transported or used. Thus, the cost-benefit assessment performed under the 1986 Act assumes, in the case of regulatory toxicology and safety testing that the principal benefit is the facilitation of sound regulatory decisions rather than the utility or profitability of the end-product. Study data will also be used to alert regulatory authorities to any potential safety concerns for substances already being administered/consumed by Man. Data are also used to inform starting or limit doses and to identify parameters which should be evaluated in clinical studies. Without these studies progression of new medicines to early human studies and to patients/marketing could not occur.

Data generated from studies performed in support of discovery and early candidate selection will be used to allow decision making on whether to develop new drug candidates and, with other preliminary studies will help to define doses for subsequent studies. For compounds which progress, these studies will be included in regulatory submissions as supporting studies. Early indications of toxicity liabilities will allow early detection of unsuitable candidates and thus development of the candidates which are more likely to progress, thus reducing associated development costs and animal use. Studies performed on ‘tool’ or competitor compounds may help to improve candidate selection and reduce resources and animals used in e.g. progressing candidates from a pharmacological class or chemical series that has inherent toxicology liabilities associated with it. These studies will help to prevent sub- optimal compounds from progressing through drug development.

Some ‘enabling studies’ will typically be performed to provide data in support of dose selection,typically tolerability and/or toxicokinetics, and allow other parts of a safety evaluation programme to proceed in an appropriate timescale with best possible outcomes.

The benefits of studies which address issues arising during the production, manufacture and marketing of substances, for example changes in production processes/locations, or impurity specifications will be very specific to the issue under resolution for example: allowing a more efficient/cost effective development process to be used, allowing use of a batch of material with a characterised impurity profile.

What outputs do you think you will see at the end of this project?

The development of safe substances such as pharmaceuticals and food stuffs (additives, supplements, ingredients and novel foods) and immune therapies (for example), is essential in protecting human health. The non-clinical studies permitted by this project are, therefore, crucial to generate data and reports for submission to regulatory authorities to guide safe product development and inform scientists of possible adverse effects.

The expected output from this project will be robust data, in the form of study reports, to enable the safety assessment. Study reports will be included in regulatory submissions to allow regulatory authorities (e.g. EMA, FDA, HSE or EFSA) to make judgements on whether to permit clinical studies to proceed, to licence a drug or to grant a marketing application.

Who or what will benefit from these outputs, and how?

Safety assessments detailed in this licence will ensure the safe use and management of products for human consumption/administration, particularly in pregnant women. In the short-term, this is achieved by providing high quality data to guide decisions regarding the suitability and the safety of the product for further development. Ultimately, these outputs will ensure that humans are not exposed to hazardous products in foods or drinks, and in the case of pharmaceuticals and therapies, the data generated will support the development of safe new medicines designed to improve the health and quality of life of patients.

How will you look to maximise the outputs of this work?

While much of the substance specific data generated is covered by confidentiality agreements, work on novel biomarkers, refinements in methodologies, protocols and techniques that permit a reduction in the number of animals required for specific study designs or to achieve specific end points are freely shared and discussed at Scientific conferences and other forums (e.g. attendance at regular NC3R meetings).

Although most studies will require the use of concurrent Controls to provide contemporaneous data for direct comparisons (to represent animals undergoing the same regulated procedures, administered the same vehicle etc), data generated from Control animals is held in reference databases to provide information relating to normal biological variation, thereby enhancing interpretation of study findings.

Species and numbers of animals expected to be used

- Mice: 30,000
- Rats: 30.000
- Rabbits: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is generally accepted that the way in which a material is metabolised and distributed within a living body has a significant effect on how it works and its potential toxicity. Unfortunately, at this time, effects on complex interacting biological systems cannot yet be replicated using in-vitro or ex-vivo methods (non-animal models). Consequently, the use of animals is still an essential part of safety testing.

All studies performed under this licence will use the least sentient species practicable for achieving the study objectives. The majority of cases will involve the use of rats and mice. In embryofoetal development studies only, a second mammalian species is required and in terms of practicality and availability the rabbit is generally accepted as the preferred non-rodent species.

Studies conducted under this Licence will allow exposure to mature adults and all stages of development from conception to sexual maturity.

Typically, what will be done to an animal used in your project?

The studies performed under this licence will use either pregnant or non-pregnant animals. Non pregnant animals are typically used on preliminary studies designed to assess the tolerance of the test material or to establish suitable dose levels for use on main studies which generally assess effects on the foetuses following exposure via the placenta.

Animals will be acquired from designated suppliers. In many cases the supplier will provide animals which have been mated at specific timepoints so that the period of gestation is known. In pregnant rats and rabbits dosing will typically start on day 6 of the animal gestation and continue to at least day 17 (rats) and day 19 (rabbits) or in some case up to the day before necropsy. Such studies will be terminated on day 20 in the rat and day 28 in the rabbit.

The test material will typically be administered using the intended therapeutic route, which is typically oral gavage, but may include injection into a muscle, vein or subcutaneous (under the skin).

During the course of the study the animals will be well cared for and will be closely monitored for reactions to treatment. Blood samples may be taken periodically to assess

proof of exposure of the test material. Other end points will also be included as required to address specific concerns (e.g. functional observation tests).

At the end of the study the animals will typically be euthanised and a necropsy undertaken. This is essential because it is important to establish if the internal organs and or foetuses have been affected in any way and this can only be achieved by examinations by qualified personnel (Foetal Morphologist/Pathologist).

What are the expected impacts and/or adverse effects for the animals during your project?

It is anticipated that some animals will lose weight, or at least fail to gain weight at a rate consistent with normal weight gain. This may be attributed to a reduction in food consumption (also a potential adverse effect), but may be present even with normal food consumption.

Animals will be closely monitored for signs of discomfort and particularly signs of pain. Any animal showing such signs will be closely monitored and will be inspected by a Vet if considered necessary. No animal will be allowed to endure pain for long periods and remedial action which may include euthanasia will always be taken.

Where pregnant animals are used it is anticipated that foetuses exposed to the test material via the placenta may experience clinical reaction that may affect their well-being. Pregnant animals will be carefully monitored throughout gestation for signs of that could indicate that pregnancy is being affected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Our experience in this field of research has determined that reaction of no more than Moderate severity will be experienced. Indeed, our records show that overall, the majority of animals (mice, rats and rabbits) experience Mild severity only, circa 70% with 30% reaching Moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is generally accepted that the way in which a material is metabolised within a living body has a significant effect on how it works and its potential toxicity. Also the potential direct effects of a test substance on living tissue are often different to that predicted by ex-vivo or in-vitro methods. Whilst consideration will always given to the use of non-animal alternatives, currently there are no alternatives that can totally replace the use of animals. Non-animal alternatives i.e. those that use cells and computers for example are typically supportive/preliminary studies that provide supportive data for pre- clinical regulatory studies and for this reason, studies involving the use of animals remain a regulatory requirement.

Which non-animal alternatives did you consider for use in this project?

Sponsors will typically utilise non-animal alternative assays as part of the development programme for a substance (e.g. in silico modelling and in vitro metabolism studies). Such assessments would not be conducted under this project, however, where available, these data would be used guide the selection of the most appropriate species and to confirm the in vivo study design (e.g. to confirm the species which show similar patterns of metabolism to those expected in man).

Whilst information from these alternative assays will contribute to the overall safety assessment, they cannot replace the need for in vivo studies at this time.

Why were they not suitable?

The use of alternative methods, including the use of dead animals cannot, at this time generate relevant data which supports the submission of safety data to international regulators. The fundamental aspects of the safety data we require involves assessing physiological, behavioural and biochemical effects following the administration of a test substance and this can only be achieved by using live animals.

Alternative methods such as in-vitro techniques will be used as much as practicable to supplement the work involving protected animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The establishment maintains detailed records pertaining to the numbers of animals used on projects each year, as well as the number of study types undertaken. By analysing annual trends and having knowledge of industry requirements, it is possible to project the

number of study types we will undertake during the life of this licence thus enabling the estimation of the number of animals required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The minimum number of animals will be used, recognising the fact that reduction is not achieved by using too few animals to achieve the objectives of the study. For Regulatory studies, guidelines require the number of groups and animals per group to be adequate to clearly demonstrate the presence or absence of an effect of the test substance; core study designs are based on international guidelines where these exist. Otherwise reference is made to internal guidance on study designs to provide the optimum number, balancing the need to achieve study objectives while avoiding excessive animal use. Project specific variations are used as required. The core study designs have been used extensively under the previous project licence and in other facilities and we have a track record of successful submissions and ability to eliminate unsuitable compounds. They are generally in line with those used throughout the pharmaceutical industry.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Statistical input is sought, where appropriate, to strengthen the overall scientific quality and relevance of the studies to be performed, with power-sample size calculations performed for specific studies if necessary to determine group size. For preliminary studies, small groups are acceptable because of the potential use of overt toxicological endpoints. Where group sizes are sufficient (rodent studies), data from definitive toxicity studies are analysed statistically.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In most cases the studies will be performed using internationally recognised guidelines (e.g. ICH and OECD) which define the most appropriate methods and scientific models to use.

The majority of animals used throughout this project will be rats and mice. On occasions however, and when scientifically justified, the rabbit will be used. The selection of an appropriate species will be a combination of ethical, scientific and practical consideration.

The species chosen will be the lowest neurophysiological sensitivity to achieve the objectives of the study and one which responds to the primary pharmacodynamic effects of the test substance; In most cases, this will be the rat or mouse.

Most pharmaceuticals need to be tested on a second species, with the second species being a non- rodent (CPMP/ICH286/95) modification). The selection of a suitable non-rodent species is of paramount importance as it will maximise human safety, clinical benefit and animal welfare.

The methods (procedures) used will be validated, well established and commonly used within the research community. The administration of test substance, removal of blood, collection of urine for example will cause no more than transient discomfort or distress. Any signs of distress will be carefully monitored including the onset and severity of treatment related effects. Appropriate and swift action will be taken to avoid any undue pain or distress.

Why can’t you use animals that are less sentient?

The studies performed under the authority of this licence are primarily to assess the toxicity of materials when exposed to foetuses as well as the parenteral animals. The use of immature life stages or species that are less sentient than these simply would not allow us to achieve the objectives of our studies.

Similarly, the duration of the studies which, in the case of multi-generation studies may be several months and studies often requiring behavioural assessments simply does not allow them to be performed under general anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures required will be undertaken by competent staff, each having undergone extensive training. Where necessary, current, industry accepted techniques for dosing and blood sampling for example, will continue be refined under separate authority i.e. under another project licence, thus ensuring existing methods remain the most appropriate for minimising pain, suffering and distress to the animals.

Animals will be monitored immediately after undergoing a procedure for any signs of adverse effects and will continue to be monitored at appropriate intervals until it is deemed that further observations are not required.

Animals will be habituated to procedures whenever considered necessary i.e. when it is deemed that by habituating animals to a procedure distress will be reduced. Similarly,

where appropriate animals may be trained to perform certain tasks thereby, minimising distress by removing the need to restrain an animal or involve direct contact during its performance.

In addition to this, the company is an industry leader in the application of microsampling techniques for obtaining blood samples in toxicology studies, which not only reduce the volumes required but also reduce the severity of the sampling procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The volumes administered to the animals and the volumes of blood taken will be in compliance with industry accepted guidelines. The primary guideline used is:

"A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes"; Karl-Heinz Diehl, Journal of Applied Toxicology J.Appl. Toxicol. 21 15-23 (2001).

The company is an industry leader in the application of microsampling techniques for obtaining blood samples in toxicology studies, which not only reduce the volumes required but also reduce the severity of the sampling procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Staff maintain a proactive attitude towards the 3R's. Several members of staff are already participants in Industry Forums which discuss the 3R's in some detail and report any advancements to relevant persons. These advancements will be discussed further and implemented into our standard practices, where appropriate. The company is an established leader in the development and application of the 3Rs in toxicology studies.

149. The reciprocal interaction of inflammation and cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Inflammation, Bladder, Colorectal, Cystic Fibrosis

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how inflammation predisposes to cancer development and how cancer causes tissue damage and inflammation, which can in turn promote progression of cancer in a feedforward loop. We will focus initially on two common cancers: colorectal cancer and bladder cancer, generating new animal models for these conditions where necessary.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inflammation and cancer interact to cause much suffering and death in the UK.

Bladder Cancer (BC) is the third most common cancer in men; is increasing in incidence;

is one of the most expensive cancers to treat; and affected individuals have some of the worst cancer experiences. The median survival for metastatic BC is 6-9 months and survival rates are not improving.

Inflammation is the immune response to tissue damage or infection. However, many cancers drive inflammatory responses (“the wound that does not heal”) and inflammation is a known driver of cancer.

In addition to well-established causes of bladder cancer such as smoking and occupational exposure to aromatic amines, chronic inflammation has been postulated as linked to the development of bladder cancer. Epidemiological studies have shown a link between risk of BC and a history of urinary tract infections (UTIs). Other triggers of chronic bladder inflammation include schistosomiasis, human papillomavirus infection and chronic chemical and mechanical irritation to the urinary bladder. The chronic inflammatory microenvironment in bladder cancer is believed to be linked to initiation, progression and treatment response. The chronic inflammatory microenvironment includes tumour associated macrophages (TAMs), myeloid-derived suppressor cells (MDSCs), mast cells, neutrophils, lymphocytes as well as inflammatory cytokines such as TNF alpha. However the molecular mechanisms underlying the link between the chronic inflammatory microenvironment and tumour initiation and progression remain to be determined. Elucidating these mechanisms can potentially lead to treatments targeting the inflammatory pathways believed to be driving initiation and progression of bladder cancer. The zebrafish model is ideal due to the capacity for *in vivo* live imaging of pre- neoplastic cells during tumour initiation and the interaction with inflammatory cells.

Colorectal Cancer (CRC) is the fourth most common cancer in the UK with survival rates for advanced cancers of only 10% at 5 years.

CRC is particularly common in people with cystic fibrosis (CF) - a well documented inflammatory condition. This is particularly true following solid organ transplantation. CF adults have an unexplained
~5-fold increased risk of GI tract cancers, rising to 30-fold in transplanted CF individuals.

Tissue inflammation and genomic instability are recognised as key enabling characteristics underpinning all cancers, facilitating subsequent acquisition of multiple cancer "hallmarks”. Mutagenic DNA damage is caused by pro-inflammatory production of reactive oxygen species (ROS) and, reciprocally, DNA damage is known to promote chronic inflammation. The cystic fibrosis transmembrane conductance regulator (CFTR) is important for ion transport at all epithelial surfaces, including the bowel. While CF is principally characterised by recurrent pulmonary infection and inflammation leading to tissue damage and respiratory failure, intestinal disruption involving chronic inflammation is a frequent feature. In mice, conditional inactivation of CFTR in myeloid-derived cells slows resolution of inflammation, indicating that CFTR has a poorly-understood role in resolving inflammation. CFTR has been identified as a candidate driver gene for colorectal cancer (CRC) in several forward genetic screens in mice, with GI tract-specific knock-out of CFTR resulting in increased adenocarcinoma in models of CRC, suggesting CFTR acts as a tumour suppressor gene in intestinal cells.

Many unknowns remain relating to the reciprocal interaction of cancer and inflammation, with a pressing need for new models to deliver new understanding. Since many immunomodulatory therapies are already available, we hope to be able to repurpose these for prevention of cancer.

What outputs do you think you will see at the end of this project?

This work will provide a new understanding in the pathological mechanism of cancer initiation and progression, as well as new information on how cancer causes tissue damage and inflammation, and vice versa. In addition to identifying the cellular drivers of several cancers, we will generate information about the function of genes known to, or suspected to, cause cancer-associated inflammation. The expected outputs and benefits of our work are:

A greater understanding of the cancer-inflammation axis and the factors triggering it. We will identify cellular and genetic drivers of the disease which will have a medium- to long-term benefit as they will provide invaluable new targets to underpin the rational design of new therapeutic approaches and to validate in patients.

A list of potential therapeutic targets from a suitable vertebrate animal model of inflammatory carcinogenesis.

An opportunity to develop more nuanced zebrafish models of cancer. Using transparent fish with a variety of visually trackable immune cell markers that switch on/off in response to stimulus could provide better understanding of the fundamental question is inflammation driving cancer, or is it a consequence of cancer?

The data generated by this programme of work will be disseminated to the scientific community via publication in international peer-reviewed journals, as well as presentation at (inter)national conferences.

Who or what will benefit from these outputs, and how?

Short-term

Development of new models, approaches and knowledge will benefit the scientific community and may lead to advances in areas unanticipated at the start of this work.

Medium-long term

Patients with cancer will ultimately benefit, although it is our aim that we would prevent cancer in patients with inflammatory syndromes such as cystic fibrosis. It is hoped that a greater understanding of the molecular mechanisms driving bladder cancer as well as understanding the link between inflammation and bladder cancer will lead to novel targeted treatments to improve outcomes for patients.

How will you look to maximise the outputs of this work?

We will liaise with patient organisations through bodies such as CRUK, Fight Bladder Cancer Charitythe Cystic Fibrosis Trust to ensure that our outputs deliver meaningful impact for patients. We aim to publish in open access journals and in preprint services such as bioRxiv.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 22000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish are a vertebrate species with a comparable immune system to that of mammals. All major components of the innate immune system are present and share homology with their mammalian counterparts. Zebrafish are an excellent model for these studies. The larval stages are virtually transparent, with zebrafish lines, such as Casper, readily available for visualisation of early internal tumour development. The transparent nature of the larvae makes them uniquely suitable for the visualisation of the cell biology of inflammatory and oncological responses within a living host.

Zebrafish are readily amenable to genetic modification, with gene knockdown and overexpression strategies easily achieved.

Typically, what will be done to an animal used in your project?

A proportion of fish experiments are performed on larvae before the onset of independent feeding – these larvae are not considered protected by the Animals (Scientific Procedures) Act.

During embryonic and larval stages, the zebrafish will be anaesthetised and fixed in agarose to enable imaging using fluorescence microscopy at approximately day 3, day 7, day 14, day 28 and day 56.

In order to determine the outcome of manipulation of the inflammatory or oncogenic environment on cancer development we will need to generate adult zebrafish bearing oncogenic or pro-inflammatory mutations or transgenes. This will lead to small numbers of animals developing cancer during their lifetime. These animals will not be subjected to further procedures, but will be observed for the development of tumours, then killed by a schedule 1 method and examined histologically.

What are the expected impacts and/or adverse effects for the animals during your project?

As above, some animals will develop tumours. Our focus on the urinary and GI tract will mean that most tumours will be in these organs. One of our zebrafish lines will have homozygous inactivation of the p53 gene which can cause peripheral nerve sheath tumours, angiosarcomas , germ cell tumours and leukaemia beginning to develop at 4 months of age and become externally visible at around 7 months of age. We will inspect zebrafish daily to identify any adverse effects which will result in schedule 1 killing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In total, approximately 37% of zebrafish with homozygous deletion of tp53 develop externally visible tumours by 12 months of age. We anticipate that we will classify these animals at moderate severity. All other animals will be mild or subthreshold.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Inflammation and cancer are complex processes involving many cell types, mediators and different tissues. When both of these processes occur in one disease, an in vivo model is required to look at the interaction of these two complex processes - tumourigenesis and inflammation. Using the zebrafish we are able to efficiently perform genetic manipulation that is not possible in any other system in which the innate immune system can be adequately studied. Where data are available in the public domain (eg. Bioinformatic and RNA seq data) or where studies have been done in other systems, these will not be repeated in our model.

Which non-animal alternatives did you consider for use in this project?

Cell culture

Bioinformatic analysis (in silico) Lab-on-a-chip

Why were they not suitable?

None of these is suitable, due to the requirements to model complex interactions between tissue types.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of adult zebrafish required are calculated based on a requirement to have enough healthy adult fish at any one time to generate the larvae required for experimentation. Although large numbers of larvae can be obtained on one spawning, fish cannot then spawn for 2 weeks, meaning a rotating stock of fish is needed to ensure embryo supply. To minimise animal use, once experiments have been performed sperm will be frozen (for future IVF) and stocks will not be maintained.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use the NC3R's Experimental Design Assistant to consult on sample sizes for individual experiments to ensure only the minimum number of animals required is used. We have performed pilot experiments in order to ascertain key timepoints. Exploratory experiments have been carried out where possible on larvae prior to independent feeding, to refine the hypothesis-driven experiments. We have searched on-line databases to identify bioinformatic data which will allow us to narrow the range of hypotheses and sometimes to refute them without experimental work. For an important problem such as cancer, these animal experiments will allow us to deliver important advances.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have sufficient pilot data to perform a priori power calculations to calculate group sizes. We will not initially exceed the predicted group sizes required to detect a 25% difference with 80% power (alpha of
0.05 as per convention). We will increase group sizes only if greater power is required, if the variance is greater than in pilot studies, or where the biological effect to be detected is less than 25%. Where we obtain data over time from the same animals, we will use statistics appropriate to repeated measures. The use of the same animals over time greatly reduces the animal number required (compared with groups of animals sacrificed at each timepoint as occurs in many mammalian studies). Where possible adult fish stocks will be shared with existing PPLs, further reducing the number of stock fish required.

Zebrafish are highly fecund, so we are able to obtain large numbers of embryos <5.2dpf from a small number of parents. We will use pilot studies to optimise the number of animals used in this project. We will share tissue where it is feasible to do so.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Fin clipping and gamete expression methods rarely involve discomfort, but for all manipulative procedures animals are suitably anaesthetised (primarily for restraint). Anaesthetic is delivered by immersion (so no instrumentation is required) using an anaesthetic protocol suitable for the procedure and following best practice.

The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal.Generation of mutant/transgenic animals with tumour propensity will be based on well established techniques for mutation and transgenesis, and the animals will not suffer directly due to the techniques. However, the appearance of tumours might lead to suffering and needs to be closely followed.

Where feasible, early genotyping using a zebrafish embryonic genotyper (ZEG) system will reduce the number of larvae raised as we will only raise those of the required genotypes.

Why can't you use animals that are less sentient?

Zebrafish are the organism with the lowest neurophysiological sensitivity that is suitable to study the innate immune system and address our proposed aims. They have a number of advantages for these studies, including optical transparency, genetic tractability and extensive genomic resources.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are in communication with other cancer research groups worldwide to ensure that we follow current best practice for identifying tumours in fish to ensure that they do not suffer.

For any experiments performed beyond the onset of independent feeding, larvae will be monitored regularly, with only the healthiest larvae being selected for imaging studies, and individual experiments will be evaluated before further larvae are used in this protocol. The advantages and risks of this approach will be evaluated after each larva is used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To the best of my knowledge there are no published best practice guidelines for the zebrafish work in this project license. However we use philosophies of experimental design advocated by the likes of Festing and Wurbel in order to refine our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am on the Impact Working Group of the NC3Rs and am in regular contact with the team. I also have access to a NC3Rs regional programme manager with whom I will consult as well as attend relevant workshops/seminars to learn about the latest developments in the 3Rs. This keeps me updated with evolving 3Rs best practice.

150. Nucleic acid sensing and interferon-regulated genes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

immune system, immunisation, virus infection, cancer, nucleic acid sensing

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to gain new knowledge on how the immune system is activated and on how it controls virus infections and cancer as well as the response to vaccines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Viruses cause diseases ranging from the common cold to AIDS, and pose the risk of pandemic outbreaks. Our body is protected from infections, including viruses, via a

protective network called the immune system. The immune system can eliminate viruses, and it is therefore important to understand how the immune response is kick-started upon infection.

The first step is that the cells in our body recognise the presence of a virus. We know that cells have specialised proteins called receptors that detect viruses. However, how these antennas sense viruses is largely unknown. By investigating the mechanisms of detection we hope to understand how the immune response is initiated during virus infection.

One of the hallmarks of the anti-viral immune response is the production of a group of molecules called interferons. The name stems from the property of interferons to interfere with and block the replication of viruses. Interferons achieve this by instructing cells to switch on their antiviral defences. Interestingly, interferons are not only essential as central players in antiviral immune responses. They are also produced during vaccination and are necessary for the development of protective immunity. Moreover, interferons are involved in cancer and may help our immune system to fight malignant cells. It is therefore important to study the effects of interferons. These new areas of research hold great promise for the development of new vaccines and novel cancer treatments. We want to obtain a better understanding of the underlying biology, which will be required for the development of new medicines.

What outputs do you think you will see at the end of this project?

The primary output of this work will be new knowledge in the area of immunology. This new information will be made available via publications in peer-reviewed scientific journals.

Who or what will benefit from these outputs, and how?

The information we will generate will be of interest to immunologists, virologists and to biomedical researchers interested in vaccination, autoimmunity and cancer, both in academia and industry (benefits expected to be evident within 2-5 years). We have chosen our specific aims with a clear view of generating data that hold translational value and may at some later stage form the basis of clinical trials. We have interactions with pharmaceutical companies working in these areas to facilitate the translation of our work.

How will you look to maximise the outputs of this work?

Over the course of this licence, we will publish our findings in academic journals. We will only publish in open access journals such that anyone interested will have full access to our data. We will also present our work to the scientific community at conferences. Where appropriate, additional channels to disseminate knowledge will be used, including Twitter and public engagement activities. We make new genetically altered animal models freely available to the scientific community upon their publication. For example, frozen sperm from previously generated mutant lines has been distributed to >20 laboratories world-wide. Our group has many collaborations, for example with virologists and oncologists, to maximise benefits in these related disciplines. Unsuccessful approaches are typically the

lack of a phenotype in a genetically altered animal line and will be included in publications. Publications will follow the ARRIVE guidelines to optimise the reporting of information.

Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice will be used to research the biology of how immune responses are initiated. Adult mice are used because they have a fully formed immune system that is similar to that of humans. Mice are also used because of the availability of genetic tools.

Typically, what will be done to an animal used in your project?

We will breed genetically modified mice that lack immune genes or have mutated immune genes. The majority of animals will be humanely killed without undergoing procedures and tissue will be used for experimentation.

In addition, genetically altered or wild-type mice may be infected with viruses, receive vaccines and/or be implanted with cancer cells. These steps typically involve a single injection. At appropriate stages of the ensuing immune responses, mice may receive injections of drugs, such as those used in people, to block molecular pathways of interest. By subsequently comparing treated and control mice, we will learn how these molecular pathways impact immune responses. The measurements made may include asking whether mice are better or worse protected from a viral infection (e.g. Influenza A virus), or we may harvest lymph nodes from killed mice and examine the quality of the immune response upon immunisation.

What are the expected impacts and/or adverse effects for the animals during your project?

We will use genetically modified mice that lack immune genes or have mutated immune genes and expect that the genetic modifications will not cause any adverse effects.

The expected impacts on mice undergoing procedures will be similar to those experienced by humans having a viral infection or receiving similar treatments. In the infection and vaccination models, some mice may suffer adverse effects that include fever, weight loss and behavioural changes, which will typically not last longer than 24 hours. Immunisations may also cause some local irritation/inflammation, which typically self-resolves within 24 hours. Mice receiving cancer cells will develop tumours, with palpable tumours typically present for less than two weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Subthreshold - 83%
Mild - 9%
Moderate - 8%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to breed genetically altered mice to obtain (from killed animals) primary cells and tissues for subsequent analysis.

We also need to use animal models of infection, vaccination and cancer because the immune response is a complex process involving many different types of molecular mediators, cells and tissues. This cannot be recapitulated outside an animal.

Which non-animal alternatives did you consider for use in this project?

We considered:

1. the use of immortalised cell lines;
2. the use of primary human cells and tissues; and
3. in silico modelling.

Why were they not suitable?

1. Immortalised cell lines are not always suitable because some immune signalling pathways are altered during the process of immortalisation. In addition, cell lines representative of some immune cell types do not exist or cannot be generated.

2. Primary human cells from healthy donors can be obtained routinely only from blood or skin. Whilst we use such human samples in some of our research, we cannot entirely rely on this, because some immune cell types and tissues (such as spleen and lymph nodes, and cells resident within these organs) cannot be obtained. For some of our research questions, human blood and skin samples cannot be used because of genetic heterogeneity and the lack of appropriate gene editing tools for human primary immune cells. Other tissues, such as tonsils, may be obtained from donors with certain disease

indications, and other organs may be obtained from cadaveric donors. We rejected these options because it is important for our research to experimentally perturb a healthy immune system and because of ethical, logistical and technical limitations.

3. We collaborate with in silico modellers; however, while such approaches are useful for prediction, they cannot test real biological mechanisms or functions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of mice have been estimated based upon the numbers of experiments required to test our hypotheses. These estimates have taken into account our experience from the last ~15 years and projected changes in project scope during the next five years. Animal group sizes are based on appropriate statistical estimates and prior experience of levels of variability.

Numbers of animals required for breeding protocols take into account animals generated with the wrong genotype as well as animals that are required for colony maintenance. Animal numbers listed in experimental protocols include those transferred from breeding protocols as well as those purchased from the core facility and commercial vendors.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. We have used statistical models to determine the minimum number of required animals.

2. We have designed experiments in such a way that many data points can be collected from the same animal. For example, we often obtain multiple tissues from the same animal.

3. Where possible, surplus cells and tissues will be frozen for future use. For example, we routinely aliquot and freeze bone marrow samples for multiple future experiments.

4. Where possible, we will use male and female animals, which reduces the number of surplus animals from breeding.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. We will use a breeding strategy - managed by staff trained specifically in maintenance and breeding of mouse colonies - that keeps the number of mice to a minimum.

2. Unwanted genetic changes will be prevented by regular crosses to a reference mouse strain.

3. We will bank sperm from our mouse strains. This will allow us to archive strains that, whilst valuable, are not currently needed for experimental purposes, rather than continue to breed them.

4. We use pilot studies with small numbers of mice, for example where we test new vaccines.

5. Fresh and frozen tissue will be shared with collaborators where appropriate, including both donations and receipts of material.

6. Procedures on animals will only be carried out if a strong hypothesis can be obtained from in vitro data, in silico predictions, clinical findings and/or genetic associations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We chose mice because this is the lowest species suitable to achieve our aims. As soon as the scientific objective of any procedure has been attained, animals will be killed, and specific humane endpoints will be applied throughout. Therefore, we will not cause lasting harm. We will use models of virus infection, vaccination and cancer that are most refined and cause the least possible harm:

We will interrogate the early stages of infection. At these time points, the innate immune system becomes activated and we will study this process. However, at these time points, virus replication has not yet resulted in tissue damage that causes profound disease. Animals will be killed before they reach this later stage.

Freund's adjuvant will not be used. This is a component of vaccine formulations that has been used in the past and caused adverse effects such ulcerations. We will use other adjuvants that do not cause adverse effects.

We will use tumour models that are easy to monitor and do not form secondary tumours (metastases).

Why can't you use animals that are less sentient?

The immune system in mice is similar to the one in humans, allowing us to extrapolate findings. This would be impossible using lower protected animals (such as zebrafish) or non-protected animals (such as fruit fly), because their immune systems are highly divergent from the one in humans, in particular in the aspects we are studying.

We need to use adult animals because the immune system is not fully developed at earlier life stages in mice. Our protocols cannot be carried out under terminal anaesthesia because mice cannot be kept alive for long enough under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will consider introducing genetic alterations only in the tissue of interest using 'conditional' genetic approaches.

We will increase monitoring of animals in cases of concern or doubt, such as in pilot studies or unimmunised control groups.

If multiple routes of administration are scientifically suitable, we chose the one that causes the least amount of pain and distress. Examples for this refinement may include intra-nasal administration instead of injection and addition of substances to the drinking water instead of repeated oral gavages. Footpad injections will not be used. Instead, we will use a refined model (hock injection) that is much less painful because animals do not have to walk on a swollen footpad, but achieves a similar scientific aim.

For tumour studies, we will explore in vivo imaging techniques.

We use anaesthetics and analgesics appropriate for mice by consulting the literature and the NVSs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the 3R resources (https://www.nc3rs.org.uk/3rs-resources). We will further consult the PREPARE guidelines (https://norecopa.no/prepare) and the "Guidelines for the welfare and use of animals in cancer research" (British Journal of Cancer (2010) 102, 1555 – 1577). Our work will be done in accordance with the LASA aseptic guide (http://www.lasa.co.uk/pdf/lasa_guiding_principles_aseptic_surgery_2010.2.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continuously seek to identify new methods for replacement, refinement and reduction. All lab members will regularly attend the animal facility users meetings to learn about the latest developments in the 3Rs. We will continue discussing our experimental approaches with facility NACWOs and NVSs, as well as collaborators, so that protocols can be constantly improved. We will regularly visit the 3R website (https://www.nc3rs.org.uk/the-3rs) to obtain the latest updates. We are closely following the developments in our area of research via publications and at conferences with a view to identify, and where appropriate implement, refinements.

151. Breeding, production, archiving and the application of assisted reproductive techniques of genetically altered mice

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- o Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Mouse, Genetically altered, Cryopreservation, IVF

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This license will permit the creation, archiving and introduction of genetically altered animal models into a world leading academic research institute for the duration of 5 years and will facilitate the efficient and ethical management of each live resource throughout the duration of various research programmes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Key objectives can be summarised as;

1. The generation of up to 40 novel genetically altered mouse lines per year over the course of the license using appropriate methods via in-house genome editing services.

2. To maintain breeding colonies of genetically altered lines for distribution to various research projects.

3. To provide the application of assisted reproductive techniques for the purposes of efficient colony management and the introduction of new mouse lines into the Biological Services Units. Rederivation techniques will also be applied to protect and improve the health status of model organisms across the academic institute.

4. The archiving and if necessary, the distribution of roughly 100 mouse lines per year over the duration of the project.

5. Where appropriate services will also be available to the wider research community. Equal harm benefit analysis will be conducted for both internal and external service provision. Any external work will be included in the aforementioned capacity.

What outputs do you think you will see at the end of this project?

The outputs from this project will be the creation of new genetically altered mouse lines that will support a wide variety of research areas. We will also ensure that animals can be maintained. with a better health status because the procedures in this licence will enable us to significantly reduce pathogens in the colonies we hold within our establishment. In addition to creation and healthy maintenance of animals we can use this licence to cryopreserve embryos and sperm to ensure that genetically altered animals can be stored for future use without having to keep breeding animals.

Who or what will benefit from these outputs, and how?

The wider research community will benefit from the outputs of this project licence by having new genetically altered mouse colonies that enable them to carry out novel and cutting edge research.

Researchers will also use animals that are free from disease which is good for both welfare and scientific outcomes. Researchers will also benefit from not maintaining excess numbers of mice in situations where they can be cryopreserved, which is also good for reducing the overall numbers of animals used.

How will you look to maximise the outputs of this work?

We have a dedicated facility for the work carried out under this project licence that actively seeks both internal and external opportunities to maximise the outputs of this project licence. Where possible, work under this project licence will be presented at national or international conferences and would be likely to reflect refinements in practice that have been developed during the course of the licence. For example, under our previous licence, we disseminated knowledge on how to reduce the number of animals that are breeding in

facilities through effective use of cryopreservation. We will use good breeding practices deveoped under this licence as a way of guiding researchers working under other project licences in how to effectively maintain their animal colonies. To further maximise the outputs of the work, we would publish any findings that would promote good practice within the industry and would actively support the dissemination of information on unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 45,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project is providing a service to other Home Office licences projects that use genetically altered mice. We use mice because the are the most commonly genetically altered species that are used for biomedical research. We need to use mice from the point of fertilsation through to adulthood. For example, we carry out in vitro fertilisation (IVF) with sperm and eggs in order to create the genetically altered animals that we require and we maintain animals through to adulthood for use in scientific procedures in other project licences or for breeding purposes under this project.

Typically, what will be done to an animal used in your project?

The majority of mice (approximately 60%) used in this project will be bred and maintained and will have subthreshold or mild symptoms resulting from their genetic alteration. They will typically have small ear samples taken for identification and/or genotyping and maintained until they are transferred to another project licence or humanely killed typically before they are 12 months of age but a maximum of 15 months of age when essential for maintaining a genetic iine.

Some animals (approximately 25%) will be used for superovulation. Female mice (dams) will be given agents that cause them to superovulate (cause them to release more eggs during a single oestrous cycle. These mice will then either be killed for egg collection or mated to produce embryos.

Some animals (approximately 15%) will be used as embryo recipients. These will be female mice that will firstly be mated with a sterile male to make them pseudopregnant (phantom pregnancy). These mice will then have embryos surgically (or rarely non-surgically) implanted in them that have been created or modified in another mouse or by intro fertilisation (IVF). Once the litters have reached weaning age, the dams will be humanely killed.

A very small number (<2%) of mice will undergo vasectomy. These male mice will undergo surgical vasectomy to render them infertile. They will be used repeatedly for making female mice pseudopregnant and will be humanly killed when they are too large or old for this use.

What are the expected impacts and/or adverse effects for the animals during your project?

Due to the nature of this project, the anticipated adverse effects within this license are likely to be very mild i.e. through breeding and maintenance of GA mice and superovulation protocols. The creation of novel genetically altered lines can cause adverse phenotypes, but adverse effects that are more than mild are not expected. Surgical protocols (vasectomy and embryo transfer) will cause a short term discomfort for animals that should not require pain relief after one day following surgery. All mice on this project will either move onto another project licence, or will be culled by a schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 85% of animals are expected to experience a mild severity. Approximately 15% of animals are expected to experience a moderate severity.

What will happen to animals at the end of this project?

Used in other projects Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice can only be bred and genetically altered through the use of live animals. Creating genetically altered animals for use as models permits the study of the functions and interaction of genes across broad subject areas, such as Cancer, Cardiovascular, Diabetes and Neuroscience studies. This project provides a service to support the production of novel and/or disease free mice that have genetic alterations that are essential for research purposes.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives are not possible because of the nature of this project and so could not be considered.

Why were they not suitable?

They were not suitable because there is no alternative to live mice for breeding purposes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals that will be used based on our experience under our previous project licence and the projected service provision over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This project does not require experimental design because the purpose is not to use animals for experimental procedures. However, some animals may be humanely killed for tissue only and used for experimental purposes during the course of maintaining mouse colonies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The centralised production, breeding and archiving of genetically altered mouse lines provides an opportunity to analyse working practices in order to use the fewest animals to achieve the intended aims.

By exploiting transgenic technology including the recent advances utilising programmable nucleases such as CRISPR/Cas9, it will be possible to generate novel mutants much more efficiently. Increases in targeting efficiency will result in fewer founder animals and reduced time frames.

Archiving mouse lines will inherently reduce the numbers of animals required for any given project and when completed pre-emptively, will allow for efficient line removal and if necessary expansion.

The archiving of mutant lines will predominantly be accomplished through the cryopreservation of sperm, which is significantly more cost effective with regard to animal usage than cryopreserving embryos. Breeding and maintenance of mutant lines for distribution to various research projects will permit centralised colony management,

reducing the breeding and managed excess required whilst ensuring the best husbandry and genetic integrity.

Distribution of novel transgenic lines to the scientific community will potentially allow for a global offset against production rates by reducing the necessity to recreate lines elsewhere.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All of the animals bred and maintained under this project licence will experience only mild (or subthreshold) symptoms of their genetic alteration. The diseases or bodily systems that they will be used to study will vary widely and these mice will move to other Home Office approved project licence for the study of these diseases or systems.

Some animals will undergo surgical procedures for vasectomy or embryo implantation which will be of moderate severity. These are not complex surgeries and the adverse effects are expected to be short- lived. Wherever possible, males that are infertile as a result of genetic alteration will be used as an alternative to surgically vasectomised males.

Why can’t you use animals that are less sentient?

As this is a service licence we would be unable to use less sentient species. However when creating novel genetically altered mice there is a robust project review before work commences.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Using an already established system for providing intesntive care post-operatively we will ensure animals recieve high levels of monitoring at all stages. Where pain management is required this will be used. If possible, genetically sterile males will be used instead of surgically vasectomised males. We will also look to increase use of non-surgical methods for embryo recipients.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance will be obtained from several resources such as NC3R's, Jax and Mouse Genetics Informatics publications.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Local NC3R's programme manager. Updates from Home Office, NC3R's, IAT and LASA. Regular review of publications associated with this work. Where there are advances which will benefit 3R's these will be assesed and utilised wherever possible.

152. Mechanisms of neural circuit development in health and disease conditions

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain development, Neuronal wiring, Gene function, Neurological diseases, Neurodegeneration

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to understand the physiological and biological mechanisms that guide brain development and maintain neuronal connections. We also want to understand the role of genes in these processes and how gene mutations lead to neurological disease conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurological conditions such as neurodevelopmental disorders and neurodegenerative diseases place a huge financial burden in our society, where societal and emotional costs are incalculable. To be able to find treatments for these debilitating conditions, we first need to elucidate the basic mechanisms that underpin the normal formation of brain structures and neural connections. We will then be able to examine how human conditions arise from mutations inside genes essential for these developmental processes.

What outputs do you think you will see at the end of this project?

Work carried out during this Project will result in outputs through the appropriate channels of conference presentation and publication (10+ and 5+ respectively), wherever possible in high impact and/or open access journals, where they will be freely accessible to other researchers, clinicians and industry.

Who or what will benefit from these outputs, and how?

Other researchers, clinicians and industry will be able to utilise our findings in developing their own research and biomedical applications. In general, the short-term (1-5 yrs) benefits will be to our and other academic researchers, including those associated with the clinic. In the medium/long-term (5-15 yrs) we anticipate our findings and approaches may influence perception, diagnosis and perhaps even treatment of human disease.

How will you look to maximise the outputs of this work?

We will establish collaborations with other researchers by sharing knowledge, experience and reagents. We will also work closely with clinicians and industry optimizing the chance of translational impact.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 19,700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using zebrafish as sole vertebrate animal model because the embryos are spawn in the water (allowing collection without affecting adult mothers), the animas develop externally and are optically clear (allowing for observation of brain development with no intervention needed). We therefore make most of our observations without any need for surgery or other intervention giving discomfort to the protected animal. Most of our experimental manipulations will be done during embryonic and larval stages. This is a period when neuronal connections are rapidly assembled in the brain and the animal

shows behavioural responses. This allows us to investigate how these connections are established and what goes wrong when genes implicated in human disease are mutated.

Typically, what will be done to an animal used in your project?

An animal used in this Project will typically undergo or have previously undergone genetic modification. This is important for generating fluorescent reporter transgenic lines essential for monitoring the cell behaviour and function. We also plan to establish lines with mutations in genes previously found to be associated with human disease. This is an important part of our research in understanding the molecular and cellular mechanisms that are responsible for the disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals used in this Project are expected to experience minimal pain and suffering as a result of our manipulations. However, in certain cases when a genetically altered animal is created to mimic a human disease condition, it is inevitable that fish might experience some clinical symptoms. We will aim to reduce such clinical symptoms by maintaining our genetically altered lines in healthy heterozygous forms. Occasionally, our experimental manipulations can also produce side effects. We will make sure that any individual showing signs of discomfort is monitored regularly and, if the symptoms persist, we will kill animals by Schedule 1 methods.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (80%) of animals used in this Project will experience pain or distress that is no greater than mild. We anticipate that a maximum of 20% of animals used in this Project will experience a moderate severity. In the rare event that fish need to be kept until the end of a procedure, it is first monitored for sign of pain and/or distress (lack of swimming activity, appetite or sexual behaviour). Any individual presenting any signs of pain or distress that is not rapidly curable will be killed under Schedule 1.

What will happen to animals at the end of this project?

Killed
Used in other projects
Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the main goal of our research is the understanding of the cellular and molecular mechanisms required for development and function of the brain in the vertebrate embryo, alternatives not using animals at all are not yet available. The originality and strength of our study is the ability to follow neuronal cell behaviour and function in vivo, using imaging of fluorescent transgenic zebrafish. In vivo studies are the only way to identify the cellular behaviour at the source of developmental defects.

Moreover, using in vivo studies allows the examination of the behavioural manifestations of genetic lesions, allowing us to perform small molecule drug screening to identify compounds that could ameliorate the symptoms, offering opportunities for novel drug development.

Which non-animal alternatives did you consider for use in this project?

Some of the molecular candidates involved in the formation of neuronal circuits will be assessed in primary neuron culture. We are currently starting to develop these culture technologies, hoping to get these to be used for some of our scientific questions, instead of the fish.

Why were they not suitable?

We did search for more alternatives, using FRAME and other sources suggested on the NC3Rs website, without success.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimation of fish usage is non-trivial, since multiple confounding factors make simple calculations impossible, and instead force reliance on previous experience within the wider fish researcher community. The key point is that the overwhelming majority of our animal usage is in generating or maintaining genetically altered (GA) lines. In the first case, stochastic effects are important in affecting i) how many founder fish actually have germ-line integration of the transgene, and then transmit to the next generation, as well as ii) the extent to which positional effects alter the behaviour of the transgene from that intended. In both cases, a further stochastic effect that is of major significance is that of the unpredictability of sex ratios. Furthermore, for almost all work, the key issue is a regular supply of good quality embryos for experimental study; this necessitates maintaining larger

than minimal numbers of fish so that individuals are not usually used more than once per week. Over-usage would be problematic from a welfare point of view since it could well result in stress. We note that the harmless nature of the GA in the majority of the lines when kept as hemizygotes or heterozygotes goes a long way to reducing to a minimum the suffering caused. The numbers requested in this license for each protocol have been estimated in accordance with these principles.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Almost all (approximately 90%) manipulations and observations will be performed on zebrafish embryos or early larvae at stages prior to the stage when they are capable of independent feeding, and hence of stages that are outside of the Animal (Scientific Procedures) Act. However, in the remaining cases (approximately 10%) it will be necessary to rear experimentally manipulated fish after they become protected by the Act. Where possible our emphasis will be on assessing effects as early as possible, so that older, larval and adult stages will be only used where completely necessary.

We will take advantage of the optical clarity of fish larvae to allow the use of new microscopic methods to image brain development or brain disorder models. The aim of much of our work is to use transgenes that do not disrupt normal processes to report on those processes as they happen. So, although the animals are transgenic and therefore fall under the Act, they will not suffer in any way compared to non- GA fish. Creating stable transgenic lines is, by itself, a way to reduce the number of animals used. The establishment of healthy viable adults carrying a transgene allows us to reduce the number of embryos studied compared to the quantity we would have to use in a transient system.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of our animal usage will result from generation and maintenance of mutant and transgenic stocks. We will use the latest transgenesis/mutagenesis techniques so as to ensure that the minimum numbers of founder fish are generated, and will take advantage of developments in inducible gene expression (e.g. CreERT2) to ensure that transgenes are expressed wherever possible only when needed. Where possible, we will perform genotyping at the embryonic and larval stages to only raise fish of the required genotype, and where feasible we will use transient CRISPR mutagenesis approaches to minimise the need for generating and maintaining mutant lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish as a model system during this Project. Fish are the least sentient of the vertebrate models suitable for genetic research. The Project will use the latest in vivo technologies used by other researchers in the field to minimise any animal suffering, such as well-established gene editing and imaging techniques. Our methods will allow us to generate transgenic lines reporting the expression of transgenes in specific cell types within the brain, and mutant animals carrying mutations in genes required for neuronal development. We also plan to use imaging techniques to monitor neuronal cell behaviour and function and assays to investigate the behavioural manifestations of these genetic manipulations.

Why can't you use animals that are less sentient?

We chose the zebrafish as sole vertebrate animal model because the embryos are spawn in the water (allowing collection without affecting adult mothers) and are optically clear (allowing for observation of brain development with no intervention needed). We therefore make most of our observations without any need for surgery or other intervention giving discomfort to the protected animal. We anticipate that the majority of our procedures will not exceed mild severity limit and will not generate pain or distress (a maximum of 20% of animals are expected to exceed that limit, and no animal will experience a severity above moderate limit). In the rare event that a fish needs to be kept until the end of a procedure, it is first monitored for signs of pain and/or distress (lack of swimming activity, appetite or sexual behaviour). Any individual presenting any signs of pain or distress that is not rapidly curable will be killed under Schedule 1.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all our studies we will address effects as early as possible and we will use anaesthetics whenever appropriate. Non-invasive methods will be used wherever possible. As stated in Protocol 1, the majority of lines carrying mutations will be kept as healthy heterozygotes and are expected to only show phenotypes when homozygous. Therefore, this will reduce any potential suffering of animals. Any individual presenting signs of distress or pain persisting in the hours following each treatment will be culled under Schedule 1.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will constantly look for published literature to ensure experiments are conducted in the most refined way. We will use pilot studies to refine protocols being developed/modified in

the lab. We will refine the use of specific anaesthetics as their advantages and disadvantages are understood. Where revised methodology has become available, we will endeavour to update our protocols accordingly.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will have regular meetings with our regional program NC3Rs manager and attend meetings/events organised by the NC3Rs.

153. Development of an implantable device for the treatment of brain tumours

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain, Cancer, Technology, Therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.
What's the aim of this project?

To develop and test an implantable device, which has been designed to deliver chemotherapeutic drugs for the treatment of brain tumours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With more than 11,000 new cases each year in the UK, brain tumours are a common disease which significantly impacts the life of affected patients. On average, only 12% of patients survive for five or more years after the diagnosis.
Depending on each individual case, brain tumours are treated by a combination of chemotherapy, radiotherapy and, if possible, surgical removal. A fundamental limitation for the success of chemotherapy is the blood-brain-barrier, a membrane that separates the sensitive brain tissue from the blood and any toxic substances that may be dissolved in it. It plays a pivotal role in protecting the brain from toxic substances but also significantly

reduces the amount of cancer drugs which can be delivered into a brain tumour through the blood. Additionally, reduced blood flow to solid brain tumours further complicates the process of delivering enough drug to have a positive effect. The highly toxic nature of chemotherapeutic drugs limits the volumes that can be safely given to a patient because they can cause damage in healthy tissues as well as the tumour being targeted.
A different approach for enhancing transport through the barrier is avoiding it entirely by delivering cancer drugs directly into tumours. Convection enhanced delivery, for instance, is a technique where a thin tube is inserted into a brain tumour through which a cancer drug solution is injected. By creating a constant overpressure of the solution, the drug is forced into the tumour which allows better drug distribution than simply soaking the tumour in drug solution. However, convection enhanced delivery is significantly limited by the tendency of the drug to flow back out of the tumour through the hole created to insert the tube. To avoid this problem we will develop a device that can be implanted inside a brain tumour and will deliver anti-cancer drugs without pushing liquid into the brain. The anti-cancer drug, dissolved in fluid, will flow into the implanted device through an input tube. Once inside the device, an electric current will be used to separate the drug from the fluid so that only the 'dry' drug is delivered to the tumour. This is known as iontophoretic drug delivery. The fluid, now cleared of anti-cancer drugs, can be taken away through an output tube. We anticipate that this approach will solve the problems caused by convection enhanced delivery.

Iotophoresis has been an active topic of research for over a hundred years and was traditionally used to increase absorption of a topically applied drug through the skin. This allowed for the safe and painless delivery of drugs, through tissues that are typically impermeable, without the need to puncture the skin with needles and potentially invite infection. Traditional iontophoretic devices consist of a counter electrode and a working electrode, the latter of which is separated from the target tissue by a reservoir of the chosen drug. When a current is applied across the electrodes the drug is driven out of the reservoir directly into the target tissue. Between 1900 and 2019 almost 2800 publications have been published on iontophoresis and in the year 2020 alone there were 20 papers. The vast majority describe iontophoresis as a method for moving substances through skin but we hope to show that is can be used to deliver drugs within the body, with great accuracy and in a way that doesn't increase local pressure.

What outputs do you think you will see at the end of this project?

The output will be an effective, safe implantable device which will deliver drugs directly into tumours. We will also publish our findings in scientific journals which will include details on our design process and experimental methods.

Who or what will benefit from these outputs, and how?

At the time of writing there is another device in development within our group which aims to utilise the same delivery method for anti-seizure medication into the brain to treat epilepsy. The lessons we learn from the development of the cancer treatment device, from the choice of materials to the implantation method, will feed directly back into the decision making process for manufacturing and testing the epilepsy treatment device and all future devices with similar function. We will also be able to compare the function and efficacy against devices that have been, and are being, developed by other groups around the world.

In the long term, the publications that arise from the data collected during this project are likely to show, for the first time, that drug delivery devices of this type can be used in the treatment of brain tumours.
Many anticancer drugs, including cisplatin, cannot penetrate the barrier that separates the brain from the blood and therefore cannot be utilised in this role. If we are able to show that our device can shrink tumour size or reduce toxic damage to non-tumour tissues above and beyond what we would see with the current best available treatment, then we can move forward with the development of a device for human applications. Direct delivery of anticancer agents into brain tumours has the potential to improve the poor survival outcomes associated with brain tumours that are difficult to surgically remove.

How will you look to maximise the outputs of this work?

We will use the data generated, both significant and non-significant, under this project license to inform a number of research papers that we aim to publish in high-impact scientific journals. This should ensure that the outcomes of this work are recognised by a multi-disciplinary audience.

This work is part of an Interdisciplinary Research Collaboration (IRC) involving researchers from five leading UK academic establishments. At every step of the process there is constant communication between the researchers and the clinicians ensuring that our results feed directly back into the hospital setting.

Species and numbers of animals expected to be used

- Mice: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For this study we will use adult mice with a well characterised background and no deliberate alterations to their genetic makeup. These mice are ideal for our studies because the tumour cells that will be grown under the skin come from mice with a similar genetic background. It is unlikely that the tumour tissue will be rejected by the host so there is no need to use mice with compromised immune systems in order to grow the tumours. The animal facilities at our establishment are very well adapted to caring for small rodents and no major special provisions will need to be made prior to our experiments.

We will use adult mice because the device we are developing will ultimately be used in humans. Testing its function in anything smaller than adult mice will likely prove irrelevant and make the surgical implantations unnecessarily difficult. Whilst it would be beneficial to test the device in a much larger animal (e.g. pig) we believe that the information we get from mice will be sufficiently translatable into the clinical setting.

Typically, what will be done to an animal used in your project?

Diagram showing the 3 scenarios likely to be experienced by the animals.

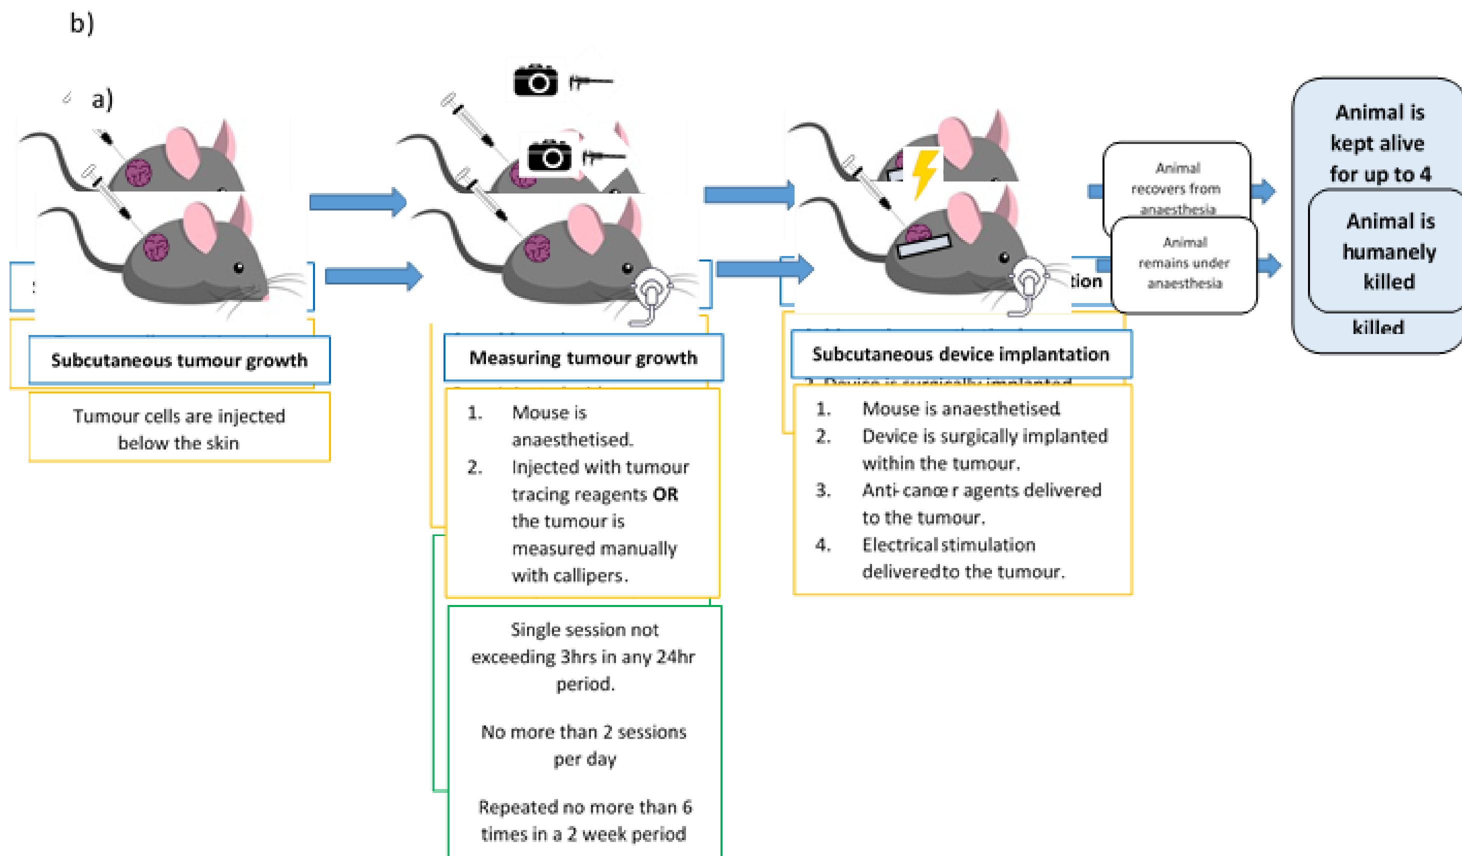

Figure a) Mice will have tumour cells injected subcutaneously which may require general anaesthetic and pain relief. The tumour will be allowed to grow to critical size and measured, using either specialised imaging hardware, for which the mice may be anaesthetised and injected with tumour tracking reagents, or manually with callipers, which may also require general anaesthetic for accurate recording. Once the tumour has reached the correct size the animal will be anaesthetised and the drug delivery device will be implanted within the tumour tissue. Anti-cancer agents and control substances may be applied to the tumour tissue alone or in combination with local electrical stimulation. Before the mice recover from the anaesthesia they will be humanely killed.

Figure b) Mice will have tumour cells injected subcutaneously which may require general anaesthetic and pain relief. The tumour will be allowed to grow to critical size and measured, using either specialised imaging hardware, for which the mice may be anaesthetised and injected with tumour tracking reagents, or manually with callipers, which may also require general anaesthetic for accurate recording. Once the tumour has reached the correct size the animal will be anaesthetised and the drug delivery device will be implanted within the tumour tissue. The animal will recover and spend up to 4 weeks carrying the inactive device under the skin before being humanely killed. We will analyse the samples from the implantation site to determine how the local tissue environment responds to the device over time.

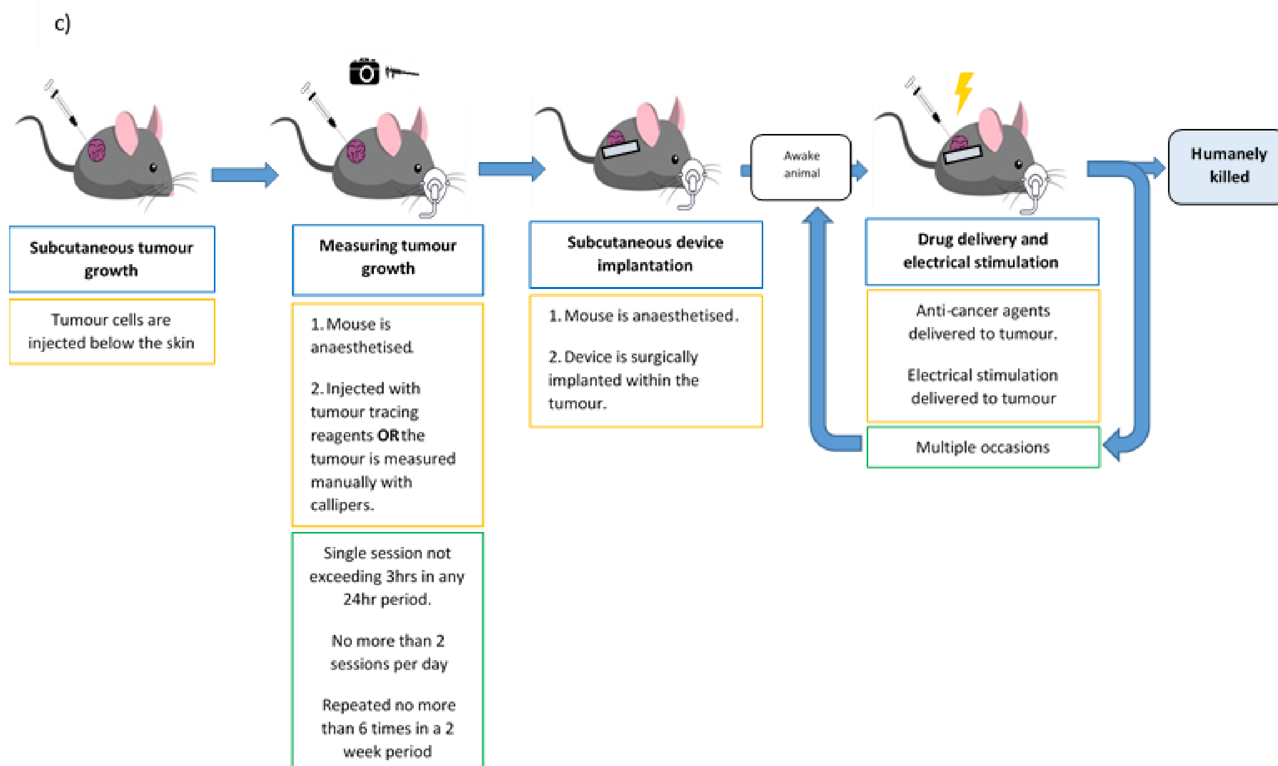

Figure c) Mice will have tumour cells injected subcutaneously which may require general anaesthetic and pain relief. The tumour will be allowed to grow to critical size and measured, using either specialised imaging hardware, for which the mice may be anaesthetised and injected with tumour tracking reagents, or manually with callipers, which may also require general anaesthetic for accurate recording. Once the tumour has reached the correct size the animal will be anaesthetised and the drug delivery device will be implanted within the tumour tissue, again requiring pain relief during recovery. After recovering from anaesthesia, anti-cancer agents and control substances may be applied to the tumour tissue alone or in combination with local electrical stimulation. The device will be operationally tested for a short time (up to one week) or over longer timelines (up to 4 weeks). At the end of the experiment the animal will be humanely killed.

Ideally, we would want to test the device in a brain tumour and brain with similar dimensions to that of a human, better replicating the target tissues and producing more relevant information. However, for the initial validation phases we believe that we can address gain valuable information using brain tumour cells grown under the skin of mice.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect that the mice may experience mild and transient pain following surgery, however this will be countered using pain killers before and after surgery. Any further surgical complications, although unlikely, will be monitored for and advice will be sought from the Named Veterinary Surgeon should welfare concerns occur.
Humane endpoints refer to one or more physiological or behavioural signs that have been determined to signal when an experimental animal's distress should be terminated or reduced. This is typically achieved by ceasing a painful procedure, administering pain killers or humanely killing the animal.

We don't expect any serious adverse effects to the animal's general well-being during the tumour growth phase as tumour volume measurements will be carried out periodically to

ensure that humane endpoints are not exceeded. Most of negative clinical signs associated with tumours in mice present as weight loss and any mice that lose 15% of their pre-implantation weight will be humanely killed.

It is possible that adverse effects will occur in response to administration of the anti-cancer drugs, such as local tissue damage due to direct contact with the agents or an allergic reaction. Adverse effects that are expected include typical signs of toxicity associated with administration of anticancer agents. These may include acute effects such as inactivity or tensing of the abdominal wall to protect inflamed and painful organs. Adverse effects may also include chronic drug effects such as gut toxicity, caused when the toxic drug kills off the friendly bacteria that inhabit the gut and is most likely to manifest as weight loss. Chemotherapy is cleared from the body through the kidneys which can have a damaging effect on them, the resulting water imbalance that often presents as dehydration or, in some case, water retention. The extent of the damage is largely dependent on the individual dose, frequency and cumulative dose of the drug and also manifests as weight loss.

Platinum-based chemotherapeutic drugs such as cisplatin have been linked to permanent hearing loss in human cancer survivors and studies have shown that the same symptoms can effect mice enrolled on cisplatin treatment regimens. While not immediately threatening to the lives of the mice, it may interfere with their normal social behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Moderate severity, 100% of mice

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is critical that animals are used in the validation of this device because it is not yet possible to simulate the complex tumour environment outside of a living animal. Our aim is to get the device into the clinical setting where it can help patients with potentially life threatening diseases. Testing the safety of medical devices in animals before they are introduced in human clinical trials is required for both ethical and legal reasons.

Which non-animal alternatives did you consider for use in this project?

Several experiments have been conducted to gather as much preliminary information as possible without the use of live animals.

To measure the speed that the drug moves through the tissue after being released by the device, we cast the device in gel designed to be similar in density and mineral content to living tissue. The drug, bound to a coloured dye, was then released into the gel at varying rates and the speed that the drug travelled through the tissue was measured.
While the gel is a useful model for tissue, we also conducted similar tests using chicken breast and pig brain, purchased from the local butchers to get a better picture of how the drug moves through tissue in relevant biological material.

We have also run simulations, using computer software, that mimic the chemical and physical processes that will occur in the activated device.

Why were they not suitable?

Due to the delicate nature of the brain, the potentially damaging effects of chemotherapeutic drugs and the complex nature of cancer, there are no non-animal alternatives that would provide the peace of mind required to safely move the device into human trials. Non-animal alternatives are suitable for providing preliminary information which allows us to reduce the numbers of animals and refine the experiments but they do not satisfy the need to replace animals entirely.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates of animal numbers are derived from a combination of 2 factors: our experience in developing implantable devices - particularly that derived from our previous licence, and our engineering knowledge on the typical number of new versions necessary to develop a successful device. Over the course of this licence, we expect to develop a progressively improved drug delivery device. From our previous experience, we expect to have to go through approximately 20 new versions of devices before arriving at the final design. From our experience, each new version requires approximately 25 animals to test and obtain decisive feedback on. While difficult to predict the exact numbers at this stage, this calculated estimation provides a good approximation to the number of animals we expect to use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible we intend to randomise the allocation of animals into either control or treatment groups to minimise systemic bias and improving the reliability of the results. We also intend to utilise blinding to ensure that the person analysing the results isn't subject to unconscious bias, further increasing reliability and reducing the requirement for repeated experiments. We will use an experimental design assistant (https://www.nc3rs.org.uk/experimental-design) and PREPARE guidelines (https://norecopa.no/prepare) to aid in planning the experiments. Our group constantly reviews the work in the field of bioelectronics to avoid unnecessary repetition of animal

experiments. We will use the online platform SyRF (http://syrf.org.uk/) to aid with our reviews.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be used to assess feasibility and outcome measures of the experimental plan, mainly regarding new treatments. Previous experience has shown that many potential problems can be identified and rectified in small pilot studies. This means that eventual definitive studies with larger groups of animals have a high probability of success, and large studies will not need to be repeated due to unforeseen study failures.
In order to ensure that the results are reported to the highest standard we will adopt the advice given in the ARRIVE guidelines. By doing so we hope to improve the reproducibility of our animal work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To test and validate the device in a relevant system we will need to generate a model of glioma. Ideally, we would want to test the device in a brain tumour and brain with similar dimensions to that of a human, better replicating the target tissues and producing more relevant information. However, for the initial validation phases we believe that we can address our objectives using brain tumours grown under the skin of adult mice.
In order to refine our protocols and reduce that chance of causing unnecessary pain to the animals we will work in a step wise fashion, collecting as much information from low risk methods, before progressing onto methods with a higher risk of complications. We will first test the device in mice that have been terminally anaesthetised, almost completely removing any pain, suffering or distress that could be experienced before the animal is humanely killed. Once we know that we can implant the device safely we will move into tumours that have been implanted under the skin for the next stage of testing. This will allow us to test the ability of the device to deliver drugs to a living tumour and its suitability as a long term wearable device without any risk of neurological complications.
The tumours will be implanted under the skin while the mice are under general anaesthetic with both pre-operative and post-operative pain relief. This ensures that animals don't experience distress but also improves the reproducibility as even small movements during implantation can have negative results on tumour uniformity.

Growing tumours in mice requires close monitoring as the cancers can expand rapidly and spread to other tissues in the body. To counter these risks, we will perform regular volume measurements using non-invasive calliper measurements or bioluminescent imaging . This allows us to take accurate measurements without using procedures anymore invasive than an injection and ensures that we don't allow to the tumours to grow beyond the humane

endpoints. Measurements will be taken under general anaesthetic to reduce movement and ensure the greatest accuracy.
Mice are a very useful species for cancer research because the disease is so well characterised after decades of research and publications. We know which procedures are likely to cause pain, which signs to look for and how to address any problems. By building on the work of others, we are able to learn from the lessons of the past and improve our methods for the benefit of the animals and our research.

Why can't you use animals that are less sentient?

Adult mice represent the smallest and least sentient animal that we could test our device, intended for human use, while still collecting relevant data. Using younger mice would likely make our surgical interventions more technically difficult than necessary and pose more risk to the animals.

We will use mice that have been placed under terminal anaesthesia for the initial stages of device validation, giving us the opportunity to test the function of the device in living tissues without the risk of complications that may cause suffering. As the device is being developed for chronic human use we will need to move testing into awake animals in order to show that it can be worn for extended periods of time, without malfunctioning or impeding the normal movement of the wearer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The mice will be housed in groups, between three and four per cage, to stimulate their normal social behaviours. This is beneficial for the animal's mental welfare and, because distressed animals can become anti-social, allows us to visually assess their general health.

Following surgery the mice will have their surgery sites visually inspected and be weighed at least twice a day for the first 3 days, then once a day for as long as necessary. Weights and observations will be recorded on post-operative data sheets, ensuring a comprehensive account of each mouse's recovery. Mice that show signs of chronic distress such as erect hair, hunched posture, anti-social behaviour and weight loss of 15% of pre-treatment body weight will be humanely killed. We will also refer to the mouse grimace scale to recognise pain, assess its severity and take steps to relieve it.
Special nesting material and easy-to-eat food will be provided after surgery, as well as heat packs attached to the outside of the cage to aid recovery. Due to their large surface-area to body-volume ratio, small rodents are particularly vulnerable to hypothermia following surgery and the use of heat packs will prevent this.

We will utilise bioluminescent imaging to track the tumour growth over time. This technology requires the tumour cells to be genetically altered so that they carry the gene responsible for emitting light in fireflies. This gene will cause the tumour to glow inside the mouse, producing light that can be detected using a sensitive camera. Computer software will then determine the size of the tumour with greater accuracy than can be achieved using manual methods. The mice will need to be injected with a harmless reagent to stimulate the bioluminescence and briefly placed under anaesthetic for a clear image to develop, but the increased level of accuracy will make sure that the tumours aren't allowed to grow larger than necessary.

We will use non-tail handling methods, such as cupping and tube handling, (https://www.nc3rs.org.uk/mouse-handling-tutorial) and enrichment aimed at improving their quality of life. Every animal will be given at least a week to acclimatise to the new facility before any procedure is carried out. All our work is structured in a stepwise approach to only progress with interventions which are more likely to be successful. To achieve this aim, we will carry out initial work in mice under terminal anaesthesia.
To ensure that we are providing the best and most up-to-date care for the animals during the tumour implantation and growth stages, we will defer to the “NCRI Guidelines for the welfare and use of animals in cancer research” by P. Workman et al.
To deliver the best surgical outcomes for the animals and our research we will review the guiding principles listed in the "LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery 2017".

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will have regular discussions with the Named Persons and animal technicians to review current approaches and whether there are any new 3Rs opportunities.
We have subscribed to the NC3Rs e-newsletter, providing monthly updates that focus on funding opportunities, 3Rs events and publications.
We will also look at attending NC3Rs events and workshops to keep abreast of 3Rs advances and approaches.

Any new advances that may impact how we work or provide new approaches will be communicated with everyone working on this project.

154. Understanding epithelial tumour initiation

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cancer initiation, Prevention, Epithelial cells, Development

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify the early cellular and molecular events that drive epithelial tumour initiation. This information will enable us to detect tumours early and prevent their progression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a devastating disease. Every day in the UK, 1000 men and women are diagnosed with cancer and 450 die from the disease. Progress has been made in developing better drugs to treat cancer. However, the most impactful intervention one can make for cancer patients is to detect the tumours early. The evidence is clear, the earlier a tumour is detected the higher are the chances of surviving the disease. For example, data from Cancer Research UK shows that breast cancer patients for which the tumours were detected early they have 90% chance of responding to treatment and surviving cancer-free for more than 10 years. In contrast, patients for which cancers were detected at a late stage of the disease they have less than 10% chance of surviving cancer-free for more than 10 years.

In aim of this project is to increase our understanding of how tumours develop. In particular we want to identify the early changes that occur in the tissues before tumours grow. This information will allow us to develop accurate early detection methods and hopefully new methods of how to prevent tumours from developing all together.

What outputs do you think you will see at the end of this project?

Advancing our basic understanding of how cancers develop. It is only now that we have the technical ability to study the early steps of tumour initiation. We will share any large datasets we generate in this project with the scientific community so it can be used by others in their research. Identification of new markers that can be used for the early detection of tumour initiation. These will be reported and shared through peer review publications.

Developing new genetically engineered mouse models that can be used to accurately study tumour development.

Patent and grant applications based on our findings to enable the development of early detection and therapies.

Who or what will benefit from these outputs, and how?

Scientists studying cancer biology. The large datasets and mouse models generated from this project will benefit their research. We deposit all our data in public repositories and also generate free user friendly websites that accompany the publications of these studies so everyone can access and benefit from the data.

Cancer Patients. The identification of new markers that can be used for the early detection of cancer will improve the clinical care provided for cancer patients. We aim to validate our findings in the mouse and pursue the translation of our findings as soon as possible.

How will you look to maximise the outputs of this work?

Data generated from this project will be presented at national and international conferences as well as shared through publications and pre-print outlets such as BioRxiv.

We will also continue to make user- friendly websites to access the single cell genomics data generated form the mouse studies.

It is important in science to also share unsuccessful approaches to minimize unnecessary animal use by others. We will aim to publish any unsuccessful and technically challenging approaches using BioRxiv so others can benefit from our experience.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Despite the significant improvement in cancer care over the last decades, we still have little understanding of the events surrounding tumour initiation. Most cancer studies to date, both in mouse and in human, have focused on characterising the tumour and how to shrink it. Now with the advances in sequencing technology we have the ability to study the very early steps of tumour development using genetically altered mouse models. This is important as it will reveal the earliest markers of cancer development, which can then be used for the development of: 1) early detection methods and 2) therapies that can prevent cancer development. These kind of studies are only feasible in the mouse, particularly when studying solid tumours (eg. Breast, Ovarian, Lung and Intestine). We will generate mice that are predisposed to developing cancer and investigate their tissues at the cellular level using novel sequencing technologies, prior to the detection of physical tumours. This analysis will reveal the very early cellular changes that occur in a tissue before tumours arise. It is impossible to perform these kind of pre-cancer studies in humans.

Typically, what will be done to an animal used in your project?

We will need to generate and maintain genetically altered animals.The majority of our work will be focus on tissue specific tumour initiation which will be achieved using tissue specific gene deletion/induction as this will minimise unwanted harm. The animals will be monitored for tumour development and in some cases treated with potential therapeutics. In addition, as most of our focus will be on the early steps of tumour initiation, we will have only a small proportion of our animals with fully developed tumours. In general mice in the project could be used for:

the generation of new or re-derivation of genetically altered animals obtained from public repositories or research labs.

the breeding and maintenance of genetically altered animals that can be used in the experimental protocols.

the treatment with tumour inducing substances or cell labeling substances or contrast agents for Xray/CT scaning using one the following methods (Steps 3-5) :

- oral gavage (a tube inserted via the mouth into the stomach to deliver a soultion).

13. subcutaneously (i.e under the skin).
14. intraperitoneally (i.e. into the body cavity).
15. intravenously (i.e into a vein)
16. implantation of a slow release pellet subcutaneously under anaesthesia.

It is not possible to fully predict the nature or severity of any potential defect from new genetic mutations. We expect if these new mutations predispose animals to tumour development, most of them (80-90%) will develop within 1year. In few animals (10- 20%), it may take up to 2 years of ageing for this new mutation to cause tumour development. Tumour inducing agents are highly mutagenic and hence increase the chances of tumour development. We expect 100% of mice treated with tumour inducing agents to develop tumours within 1 year. Transgene inducing/deleting reagents, in rare cases, may cause skin inflammation, thickening or flaking, hair loss or altered pigmentation, benign dermal cysts, skin erosions or tumours. General anaesthetic might be used if subcutaneous injections or implants are used (30% of animals). Animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Surgical procedures will be carried out aseptically. In the unlikely event of post-operative complications, animals will be killed unless, in the opinion of the NVS, such complications can be remedied promptly and successfully using no more than minor interventions. In the case of wound dehiscence, uninfected wounds may be re-closed on one occasion within 48 hours of the initial surgery.

Mice might undergo direct injections of viral particles that can induce breast cancer.

More than 99% of animals are expected to make a rapid recovery. Analgesic agents will be used to minimise pain wherever possible. In rare cases (<1%) it is possible that adverse effects from anaesthesia could occur. The procedure is not expected to result in any frequent or chronic adverse effects. By removing the dead skin from the nipple non-surgically, we expect that the already low risk of infection will be further minimised. Mastitis is a possible adverse effect of injecting into the mammary duct. However, the risk of mastitis is greatly reduced by using a blunt needle which is as short as possible and is not inserted into the mammary gland. The fluid pressure is sufficient to carry the viral particles into the gland with the needle positioned at the tip. Mice that show signs of redness/inflammation (mastitis) following completion of an intraductal injection will be given a mild anti- inflammatory and monitored closely. Mice that display persistent mastitis (not resolved 72 hours after injection) will be killed by schedule 1 method. Viral constructs (for example constructs inducing oncogene expression) might lead to the development of tumours.

- Viral reagents might be delivered via inhalation to induce gene expression, deletion or editing directly in the lung.

Delivering the viral agent (eg. Adenovirus or Lentivirus) for tumour induction is done under general anaesthetics. This is a non-invasive procedure where a small drop of viral agent is applied at both nostrils. Tumours - Tumour incidence varies with method of induction and genetic background. The majority of studies do not require advanced tumour development therefore 75% of tumour bearing animals will be killed by a Schedule 1 method before moderate adverse effects are exceeded. 25% of animals will harbour advanced tumours. General anaesthetic will be used but animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Any animals that fail to do so or exhibit signs of pain, distress or of significant ill health will be killed by a Schedule 1 method.

- Mice might be injected with cancer cell lines to perform xenograft tumour growth assays. Cells mignt be injected subcutaneously or through the tail vein.

Post-surgical infection is unlikely (1%) as aseptic techniques are used. However, in case of an infection developing mice will be killed by a Schedule 1 method. General anaesthetic will be used but animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Any animals that fail to do so or exhibit signs of pain, distress or of significant ill health will be killed by a Schedule 1 method. Wild-type cells injected subcutaneously are not expected to develop tumours.

However, tumour cells or cells carrying novel cancer mutation may develop tumours.

At the end of all experiments mice will either be humanely killed, or tissues and organs collected under deep, terminal anaesthetic unconsciousness‘ or similar.

What are the expected impacts and/or adverse effects for the animals during your project?

To be able to study the early steps of tumour development we will need to breed mice that will develop solid tumours. We will focus on breast, ovarian, lung and digestive tract tumours. For some mouse lines they will be administered with non-toxic gene inducing agent via injection, water or food. In some cases mice will be treated with carcinogenic agents to induce tumour initiation. In all cases tumours will develop within several months. As most of our focus will be on the early steps of tumour initiation, we will have only a small proportion of our animals with fully developed tumours. In some cases, a potential therapeutic agent or preventative agent (eg. Vaccine) will be administered in cancer prone mice to determine their effect on tumour initiation.

General anaesthetic will be used for surgical procedures. Animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Surgical procedures will be carried out aseptically. In the unlikely event of post-operative complications, animals will be killed unless, in the opinion of the Named Veterinary

Surgeon, such complications can be remedied promptly and successfully using no more than minor interventions. In the case of wound dehiscence, uninfected wounds may be re-closed on one occasion within 48 hours of the initial surgery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Mild 40%
Moderate 60%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer is a complex disease that develops in intact tissues. Studying primary human tumours at the molecular levels have been very informative as demonstrated by the international cancer genome consortium (ICGC) and the cancer genome atlas (TCGA) and ICGC studies. However, it is necessary to have a realistic model, which is amenable to genetic, and biochemical studies whilst maintaining tissue architecture. The mouse allows us to perform such detailed genetic and biochemical studies whilst maintaining the 3D tissue organisation and normal physiological environment. We will aim to use laboratory based cell lines whenever possible to perform validation and biochemical studies. However, cell lines have their limitations as they are a) self-selecting populations of cells that can survive on plastic and b) grow in a 2D environment. We will switch to animal experiments when the data at hand clearly supports the need for it.

Which non-animal alternatives did you consider for use in this project?

Cell lines and primary organoid cultures. Organoids are small, three-dimensional tissue cultures that can be grown in a dish in a lab into such an ordered pattern that they mimic a lot of the complexity of an organ and remove the need to repeatedly collect animal tissue.

Why were they not suitable?

The mouse allows us to perform such detailed genetic and biochemical studies whilst maintaining the 3D tissue organisation and normal physiological environment. We will aim

to use cell lines whenever possible to perform validation and biochemical studies. However, cell lines and organoids have their limitations as they are a) self-selecting populations of cells that can survive on plastic/matrigel and b) grow in a 2D environment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We aim to identify the earliest cellular and molecular events that occur prior to epithelial tumour development. To achieve this we will use Genetically Modified (GM) animals which we have extensive experience in using. The experimental design overlaps considerably between the various epithelial tissues. Calculations were also informed by reference to the National Center for the replacement, refinement and reduction (NC3Rs) experimental design assistant. Mice will be randomly assigned to experimental or control groups whilst maintaining a comparable age, size and sex if possible (this is not feasible for breast cancer studies). The team of researchers will each be assigned a role to ensure that experimental and control groups remain blinded to the researcher designing the experiment. We have also performed this type of analysis previously and based on that published analysis we now have an informed estimate of the number of animals needed. In some instances pilot experiments might be needed to determine the number of mice necessary to achieve robust statistical results when experiments are ready to be conducted in full.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For new and pilot studies we will consult the NC3Rs experimental design assistant following the PREPARE guidelines. In addition, we consult with our bioinformatics collaborators ensure experiments are powered appropriately for downstream computational analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of our GM animals have complex genotypes we have carefully planned breeding strategies to maximize the number of suitable experimental animals and control littermates. All animals will be humanely killed at the end of experiments and tissue samples taken for further experiments. Where possible mouse tissues will be shared amongst the research group. Where appropriate pilot studies will be conducted to determine feasibility and efficacy. Depending on the tissue and scientific question, mice

will be randomly assigned to experimental or control groups. In addition, we try and run most experiments with at least two team members to enable blinding of the groups thus minimising bias.

Finally, when ever possible we always try and store and share tissues with the extended research community to maximise the amount of data and information collected from each mouse used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use the mouse to model and study the early steps of cancer development. We will generate genetically altered mouse models that represent the types of cancer seen in the clinic. We will breed these mice and monitor them for tumour development and tissues will be collected from these animals and analysed to identify the earliest signs of tumour development. Importantly, these models generate tumours with predictable latency and growth thus allowing termination of the experiment at an earlier stage when tumours are still relatively small. Thus, our tumour models mean that most mice are likely to exhibit only moderate adverse effects. The small number that exhibit severe effects will be killed immediately. We will use tissue specific genetic alterations which will minimise unnecessary harm for the animal and model the disease more accurately.

Why can't you use animals that are less sentient?

Cancer is a complicated disease that starts well before a tumour is detected. It is also a fact that cancer cells do not grow in isolation but do so by interacting with and manipulating the healthy cells in their surroundings, which is called the cancer micro-environment. By understanding, how cancer cells manipulate the micro-environment during the early stages of cancer hold the key to the development of new methods of early cancer detection and therapeutics. Therefore, it is not possible to use more immature stages or terminally anesthetised animals to answer this important and complex biological question. Mouse physiology is sufficiently similar to that of humans thus, enabling us to model human disease with a high degree of accuracy. This is facilitated by detailed knowledge and comparison of mouse physiology and genetics.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will aim to house the mice in social groups of up to 5 to enhance their social interactions and experience. If mice undergo surgical procedures we will administer pain medication and use post- operative bedding, heat mats if anesthesia was prolonged and provide mash for easy access to food. Animals are expected to make a rapid and unremarkable recovery from the anesthetic within two hours. In the uncommon event that animals fail to do so or exhibit signs of pain, distress or of significant ill health they will be killed by a Schedule 1 method unless a programme of enhanced monitoring and care is instituted until the animal fully recovers. Any animal not fully recovered from the surgical procedure within 24 hours (eating, drinking and return to normal behavior) will be killed by a Schedule 1 method.

Tumours - Tumour incidence varies with method of induction and genetic background. The majority of studies do not require advanced tumour development therefore 75% of tumour bearing animals will be killed by a Schedule 1 method before moderate adverse effects are exceeded. 25% of animals will harbor advanced tumours. Tumour burden will be measured using non-invasive methods such as Calipers. We will also explore the use of more advanced and quantitative non-invasive devices such as the Biovolume 2000 (https://www.biovolume.com/).

Pain management - After consultation with the veterinarian and if needed, pain management treatment could be provided in flavored jelly, paste or milk shake formats.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We adhere to the guidelines published in Workman et al (2010) Guidelines for the welfare and use of animals in cancer research. BJC 102, 1555 - 1577. We also consult the PREPARE guidelines when designing and planning animal experiments. It is also important that we report how animal experiments were conducted so that others can learn from our experiences and minimise potential animal suffering. For this we adhere to the NC3Rs ARRIVE guidelines on reporting of In Vivo Experiments. For surgical procedures we adhere to guidance from LASA such as the 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery (https://www.lasa.co.uk/current_publications/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are advised of advances in the 3Rs via regular email correspondence with our dedicated technician who regularly attend relevant 3Rs meetings. We also keep up to date through the use of the NC3Rs website pages (https://nc3rs.org.uk/resource-hubs) and 3Rs tools in-house and external resources such as Norecopa https://norecopa.no/databases-guidelines. In addition, we also regularly consult the Jackson Laboratories website which is

a valuable online resource that include the latest updates in animal husbandry and care. (https://resources.jax.org/)

155. Imaging neurons to understand memory formation and loss

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- o Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Optics, Brain, Memory, Synapse

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project comprise of two parts. The first will involve the development of novel, high- resolution, optical imaging instrumentation to conduct miminimally inavasive in vivo imaging in the mammalian brain. The second will apply the technology to address neurobiological questions, specifically the role of synapses in memory formation and loss, that would be difficult, if not impossible, to address in the absence of the new tools.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The fulfilment of the project aims will produce two important bodies of work. The instrumentation we build has a direct impact in the area of human neurosurgery. At present we are funded to develop a prototype of a minimally invasive device for brain surgery. Critically, the applications for our technology do not solely rest with brain imaging, they are likely to be suitable for any live tissue work where access is challenging, but minimising tissue damage is a priority.

The second area where we will make an impact is the application of the new technology for the study of mammalian synapses. The loss, gain and the structural rearrangement of synapses is observed in almost all neurological conditions including Alzheimer's Disease, schizophrenia and autism. Each of these diseases come with a huge societal burden. For example, current published data report that there are nearly 6 million Alzheimer's sufferers within the USA with the number projected to rise to 13.6 million by 2050. Thus the need to better understand what drives the changes at the synapse could barely be greater.

By imaging synapses in vivo, we are confident that these crucial structures are examined in the correct biological context. Thereby the scientific observations we make can be quickly and appropriately applied to the normal or pathological status of synapses in humans.

What outputs do you think you will see at the end of this project?

The outputs will take a number of forms. First we will publish our work in peer reviewed journals. This will represent the primary mode for dissemination of new information. Second, we will patent or licence relevant material when appropriate do so. This will be most relevant for the optics developments. Most technological developments, including software, will be quickly released to the scientific community, with ready access to the materials and techniques via a website that we support.

Who or what will benefit from these outputs, and how?

This work will develop optical technologies that will allow high-resolution image collection to be performed not only within superficial regions of the mammalian brain but also areas deep within it. These advances stand to afford substantial benefit to a large community of researchers and clinicians.

Many neurological conditions have their origins in brain areas that are inaccessible to high-resolution brain imaging. Examples include Alzheimer's Disease, where synapse loss within the hippocampus, a deep brain structure, is thought to be an early indicator of disease onset. Other deep brain areas, such as the nucleus accumbens, are linked to the changes that accompany the onset of addiction, a huge societal problem, and yet study of these hugely important brain regions is hampered by the lack of tools that would permit optical interrogation of their neurons and synapses in vivo. The development of the optical tools within this project will therefore extend benefit to a wide community of researchers whose work will be enhanced by new instrumentation of this type.

As part of the project we will also make our own contribution to the study of synapses with a view to better understanding changes that take place as the mammalian brain learns new information and critically the reverse, the changes that occur as information is lost. Information loss is particularly important as there are occassions where it is desirable and necessary to forget and occassions where forgetting represents a serious health concern, such as with dementia. An understanding of these biological processes is a crucial step towards the development of diagnostics and interventions that can serve to ameliorate or perhaps cure such pernicious diseases.

Finally, the value of the instrumentation extends beyond pure research tools, with the significance for human diagnostic having already been recognised. We are presently fully engaged with the neurosurgery community and building an instrumentation for use in humans.

How will you look to maximise the outputs of this work?

As a group we collaborate extensively with experts in the field of adaptive optics, MMF technology, statistics, neurosurgery, and synaptic plasticity. We share with these groups our progress and this information exchange is reciprocated. We would not hesitate to seek further assistance and collaborators should we require support in a specific area, nor will we restrict assistance to those who wish to share in our experience.

As an illustration of the extent to which we actively seek to share our developments we are presently seeking grant support (Wellcome Trust) to offer workshops where other scientists can visit the laboratory to learn about implementation of the techniques we are developing, this support would also secure development of on-line resources.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used as this is an animal capable of robust, demonstrable learning. It’s brain architecture is similar to that seen in humans, this includes the presence of dendritic spines at excitatory synapses.

Dendritic spines are known to be of importance in human neural pathology and are the first structures to change in memory related diseases. Our primary interest is in normal, mature synapse function and so we will study healthy adult animals, in this way we will not conflate our results by those that reflect developmental or disease processes.

Typically, what will be done to an animal used in your project?

The ambition is to image neurones and their synapses deep within the mammalian brain for the purpose of understanding the changes that occur at synapses during memory formation and memory loss. In order to gain optical access to the brain animals will undergo a single surgical procedure to permit either the insertion an optical fibre or fibres, or to remove a small piece of the skull to be replaced with a transparent cranial window. All surgical procedures will be conducted whilst the animal is under general anaesthetic. Once fully recovered from the impact of surgery and anaesthesia animals will be undergo cycles of imaging for periods not exceeding 3 hours, where typically structural, and sometimes functional, information will be gathered. Whether the animal is anaesthetised during these imaging cycles will vary. For animals for whom the head is to be held a light plane general anaesthesia will be used. However, for some animals the imaging technology will have reached a point in its development to be sufficiently refined as not to require restraint of the animal nor anaesthetic. In all cases imaging can take place across several weeks. The interval between each round of imaging may be as short as a single day, although the interval may also be longer. The interval between imaging cycles will be determined both by the biological question and the level of impact that an imaging session has upon an animal. Imaging in most animals will occur without intervening interventions, such as administration of substances, although some animals may receive a substance or be sampled (blood or swab) in order to measure the level of a hormone. For some animals behavioural training between imaging sessions may also occur with a view to understanding what impact this has upon synapse form and function. At the end of the image collection cycles all animals will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

All animals will undergo a surgical procedure under general anaesthetic. While the impact of these procedures is expected to be modest it is recognised that the animal may experience some post- operative impact that could include, pain, inflammation, blood loss, or a period of weight loss induced by the anaesthetic. Each of these could potentially drive a change in the animal's normal behaviour. The impacts described are expected to be short in duration, i.e. will not extend for more than few days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

50% of mice will be subthreshold.
50% of mice will experience moderate severity.
What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Learning and memory are processes that are driven by the behaviour of the animal. In order that we may make accurate attributions to neural function in relation to changes in the behaviour we must be able to relate brain activity to behaviour. Thus we look to study brain function in animal models where we can simultaneoulsy measure brain activity and behaviour. The optical technologies that we will develop and refine may ultimately be suitable for use in humans. The size of the human brain is very large relative to our instrumentation ensuring that the invasive impact of the device is minimal (negligible). However, assessment of its utility requires that we first examine the tool(s) in the living mammalian brain tissue of animals, thereby helping ensure that our technology is fit for purpose.

Which non-animal alternatives did you consider for use in this project?

All of the early stages of the development of our optical tools are conducted without the need for animals, or indeed biological tissue of any type. The optical performance of a device can be assessed by physical means and only once the device adequately fulfils stringent optical requirements do we consider implementing the technology in the context of tissue imaging. This stage begins with cadaveric material and studies of ex vivo tissue and only once these are successful do we commence work in vivo.

Why were they not suitable?

Model systems are not suitable for the final stage in our studies for a number of reasons. The first is that the structures we wish to understand, synapses, are subject to many competeing physiological parameters, many of which will exert an influence upon the biology of the synapse. One example would be the cyclic presentation of hormones. Something, that is hard to artifically recreate. The second relates to the type of questions we wish to ask, specificlly about the performance of synapses in the formtion and loss of memory. To achieve this demonstrable learning, recall and forgetting will need to be demonstated, something that can only be determined in a behaving animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have been conducting related experiments under licence. The new licence looks to develop this program of work. We are therefore familiar with the number of animals required to support this type of work as well as the numbers used in direct imaging experimentation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will implement a staged process in our investigations that ensures of use of animals is kept to a minimum. Step one assesses the optical performance of instrumentation without the need for animals. Key optical performance parameters will need to achieved prior to moving to step two. In this step we examine the performance of the technology in ex vivo tissue taken from animals under schedule 1.

Success at step two then will allow us to move to step three where we test the technology in vivo in animals under terminal anaesthesia. Only if successful at step three will we move to move to step four, the neuroscience experimentation component of our studies. Here again we follow a staged process, with combinations of options chosen to maximise the amount of information collected from each animal.

As a fundamental goal of our optical technology is to permit repeated measurements to taken from a single animal we radically reduce animal numbers by the nature of our experimental design. Data are collected from single animals before and after learning, therefore we always have a within animal control. In this way the need for examination of large populations of animals to ‘smooth’ biological noise is much reduced. A further constraint, that helps reduce animal numbers relates to the complexity of the optical hardware, we build bespoke optical devices and so typically have only a single device for expeimental use. This consideration, combined with surgeries, places a very real brake on the number of experiments we can perform. The measurements we take are usually simple to interpret, requiring minimal statistical power. In essence images are compared and assessed for quality against those those produced from ex vivo tissue. The observations we wish to make following behavioural training will seek to identify macroscopic changes in synapse number, size or transmission performance and also require relatively modest statistical power as the baseline condition represents data from the same neuron(s) prior to training.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The care and maintenance of our animal breeding colonies is monitored by expert NACWOs and animal facility staff. Excellence in animal husbandry techniques help ensure that the number of animals we breed aligns with best practice for sustaining a healthy colony.

Almost all instrumentation development commences with the generation of computer models to assess the design and likely success of the imaging tool. Devices are then built and then, as discussed in the previous section, images are taken first of calibarated beads and then with ex vivo tissue. Only once these images are fully validated is any attempt made to move to in vivo imaging.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We wish to use mice and take advantage of the vast array of genetic tools available for mice, in particular transgenic lines expressing genetically-encoded fluorescent reporter proteins in defined neuronal population. The optical methods we use to interogate neuronal function are designed to be minimally invasive, this is desirable from an experimental refinement perspective as this approach is least likely to peturb the biology, but critically in this context the size of our optical fibres, or the optical access techniques to be applied will help ensure that minimal physical damage to the animal occurs and in consequence the least pain and distress.

Why can't you use animals that are less sentient?

We describe how animals that have been terminally anaesthetised will form a crucial part in our study. However, a key objective within the work requires that animals have undergone demonstrable learning and exhibit memory. These biological phenotypes require that the animals are sentient in order that these behaviourally driven qualities may be observed. While it is true that less sentient species are capable of learning and memory, whether the neural mechanisms involved are comparable with those seen in humans is contentious. What is less contentious is that the capacity for sophisticted learning decreases with decreased phylogentic sophistication. We have therefore chosen a species that shares many parallels in brain structure and neural performance with humans. The life stage chosen for our studies are adult animals. We judge this appropriate as immature animals are subject to synaptic plasticity, a normal part of their development. We wish to be sure that we do not conflate changes in synapse number, type or function

that arise in development with an adult process, as it is the adult synaptic changes that we believe to be most relevent to human diseases we seek to understand.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Surgical interventions:

The hallmark of our experimental protocols will be the use of optical fibres or cranial windows to achieve chronic cellular and sub-cellular imaging of neurons. Previously, others have reported imaging of deep brain structures like the hippocampus after surgical aspiration of the overlying cerebral cortex. Our approach is fundamentally different in that we aim to cause as little damage as possible to the brain and will use probes that can be as small in diameter as a human hair or optical methods that obviate the need for aspiration. For example, the diameter of the MMF device permits direct insertion into the brain and generates so little damage that imaging can be performed almost immediately thereafter.

We will consult closely with the university veterinary services to improve and refine surgical protocols. Any significant refinement in our methods will be initially tested in dead animals (killed by schedule 1 methods) or under non-recovery anaesthesia. We will be using state-of-the-art surgical equipment and designated rooms, with optimal aseptic standards and animals are administered post-surgical analgesia. Animals in our study express fluorescent reportors removing the need for the injection viral or fluorescent agents.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We receive all updates for NC3Rs – National Centre for the Replacement, Refinement and Reduction of Animals in Research. https://nc3rs.org.uk These include webinars, links to specific relevant publications e.g. Minimising mouse aggression, Sci reports (Oct 2019) as well as principle and practice videos.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As part of our Establishment's Gold Standard practice all licence holders must attend termly animal welfare meetings. These groupings are organised to map onto local AWERBs, ensuring that participants share common research practices. A specific agenda item for these meetings explores advances in the 3Rs, ideas are exchanged and best practice discussed. Three crucial communities also present at these meetings are the vets, NACWOS and the Regional Programme Manager NC3Rs

– National Centre for the Replacement, Refinement and Reduction of Animals in Research, all of whom provide updates and advice for implementation of any advance.

156. The biology of body weight and body composition

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Obesity, Cachexia, Body composition, Diabetes

Animal types	Life stages
Mice	adult, pregnant, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how body weight and body composition are controlled and how disturbances in this control lead to disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding the processes that govern body weight is highly relevant to clinical practice as disorders that arise when these processes go wrong cause a great deal of illness and suffering. Obesity, defined as excessive storage of energy as fat, is a serious issue that drives medical conditions, with obese individuals at increased risk of developing problems with their heart, blood vessels, kidney and liver, as well as being more likely to be affected by a number of different cancers. These problems bring added personal burden to the

affected individual and the healthcare support needed to treat these diseases costs a lot of money. In 2017 Public Health England reported that the UK-wide NHS costs attributable to overweight and obesity would reach £9.7 billion by 2050.

At the other extreme, cachexia is a syndrome of negative energy balance where muscle and fat mass are progressively lost. It affects over a third of all cancer patients and is strongly associated with both reduced tolerance to anti-cancer therapy and reduced survival times.

What outputs do you think you will see at the end of this project?

In undertaking these studies, we will generate new **data on the biological process that control body composition. These data will combine with our on-going studies in human populations and will be presented in peer-reviewed publications and shared with colleagues in academia, medical sciences and industry.**

Who or what will benefit from these outputs, and how?

In the short term the major beneficiaries will be the metabolic scientific community. We also expect our research to be of benefit to the fields of cancer biology and cardiovascular disease.

In the longer term we expect our research to be of benefit to the pharmaceutical industry, where the genes and processes we identify will provide new targets for the creation of drugs to combat body weight-associated diseases with the ultimate goal that will, even in a small way, improve human health.

Finally, we believe that work under this licence will have a role in shaping and training the next generation of researchers working on understanding how "whole body physiology", the important science of understanding how each of the multiple component parts of the body communicate to each other to allow the body as a whole to survive and thrive.

How will you look to maximise the outputs of this work?

We will share our data and ideas with national and international collaborators and will publish our work in open access publications. We will look to share all the data we generate. We believe that it is as important to share outputs and insights that show a pathway or molecule does not have a key role just as much as it is to highlight significant insights from more novel results. We also have an active engagement with the public via lay science pieces, national newspapers and Twitter.

Species and numbers of animals expected to be used

- Mice: 17,200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Human metabolic disease typically comes about because of the complex cross talk and interaction between external factors (like diet, activity and environmental conditions) and internal factors such as levels of hormones in the blood and chemical signals in the brain. We believe that mice have the necessary, very similar organ structure and hormonal systems to humans that means studying them is going to be a really informative way to improving understanding of the "chemicals of life" like sugar and fat that are knocked out of balance in human metabolic diseases like obesity and diabetes.

Mice also offer a system in which precise changes in genes and proteins of interest can be made to really focus in on the detail of how the component parts of a mechanism all link in and work together.

As the majority of human metabolic disease affects adults, most of our work will be in adult mice. However, we recognise that these diseases only emerge after many years of exposure to particular diets and lifestyles so to be able to replicate this in a model system we will need to study younger animals.

Typically, what will be done to an animal used in your project?

The majority of the work will focus on studying animals that have been designed to either make a gene not work at all (“loss of function”) or work at a higher rate of activity (“gain of function”). We particularly want to know how these changes in gene function alter the responses to environmental challenges and drugs used to treat disorders of body compositions.

These procedures can be broadly grouped into 3

Procedures needed to create the model; the genetic engineering done in the laboratory sometimes need additional delivery of other compounds to complete the process. Whenever possible these reagents will be given by the oral route (either by mixing in the diet or by a tube inserted via the mouth into the stomach) but sometime may need to be delivered directly into the body by injection. These injections may be intravenous (into a vein), intraperitoneal (into the body cavity) or subcutaneous (under the skin). As we are focused on body weight, we will frequently change the dietary intake of an animal, both in terms of constituents and amount consumed. This can mean supplying a diet that will make the animal put on weight as well as restricting food to bring about weight loss.

- Challenges to test the system; animals will be given drugs, naturally occurring hormones and biological active reagents such as antibodies. These will mostly be delivered by injections into a vein, into a body cavity or under the skin but sometimes may require the placement under the skin of small pellet-like, devices that act as a depot for drug delivery over several weeks. Because we understand that the brain has such a crucial role in controlling body weight, we will sometime need to undertake surgery to enable us to deliver drugs and hormones directly into regions of the brain that we know control how we eat or expend energy. When we do this the mouse will be under a general anaesthetic and will be unconscious. A mouse will only usually have this kind of surgery once and the procedure takes around 20 minutes. We use a specially designed operating table that enables small sterile tubes to be placed into specific regions of the brain accurately and quickly and the mouse is usually fully recovered and back to eating and drinking within 2 hours.

- Processes needed to measure and analyse the response; animals will be placed in carefully designed study chambers and imaging scanners to measure their behaviour and response to these challenges. These special study chambers look very much like the houses the animals normally live in through the week but with some simple modifications to enable, for example, sampling and measurement of the oxygen levels in the air circulating in the chamber or measurement of how much food and water the mouse has consumed. As such, the mice can easily spend several days in these chambers without undue stress. Similarly, when the mouse needs to have a scan to check how much fat and lean tissue they have, they will be placed in specially designed tubes made of material identical to that found in the home cage to enable them to remain still and secure and quickly have a scan without the need for sedating drugs. Finally, these response measurements will sometime involve taking small amount of blood from superficial veins.

A typical experiment will involve a small series (2 or 3) of short interventions over 3-4 weeks. For example, we will give an animal a highly palatable diet for 2 weeks, treat it with a drug for a week and see what effect that had on the food intake, the body weight and the energy expenditure of the animal.

What are the expected impacts and/or adverse effects for the animals during your project?

Most experiments proposed will lead to no more discomfort than that experienced by any rodent bred in captivity and residing in a modern animal facility.

Some animals will experience transient (seconds) discomfort when given injections or when having blood samples taken. The injections will often be of naturally occurring hormones, or compounds closely related to them. On occasion, animals may be given compounds that are recognised to produce circulating levels of hormones that are seen in acute illness. These may reduce the animals' drive to seek out and eat food in the hours after they have been given.

When given a different diet or treatment, some animals will gain or lose weight. This will be within closely monitored parameters that take into account other important aspects of their appearance and behaviour. This weight change will typically occur slowly over weeks.

A minority of animal will also undergo surgery that will require a general anaesthetic. Inevitably, as with any operation, animals will have some discomfort in the immediate hours after the operation at the site of the incision. However, this will be minimised by administration of painkillers under instruction from a veterinarian. The general anaesthetic needed for this surgery may also make the animals less active and less hungry in the first day after the operation but we expect them to recover their appetite and vitality within 48 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Breeding protocol 95% Sub-threshold, 5% mild
- Other protocols
- Mild- 65%
- Moderate-35%
- Severe- 0%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Human metabolic disease is the end-result of a complex interaction between multiple external environmental factors and internal hormonal, chemical and neuronal messengers. This cannot be meaningfully replicated in anything other than animal models and although we could use non- vertebrate animals which are of lesser sentience than rodents to help in our studies, none have the necessary complexity in organ structure or wider networks to adequately address the scientific questions posed. Further, the need for targeted genetic sophistication and the need to access deep internal tissue such as a brain requires a model organism system.

Which non-animal alternatives did you consider for use in this project?

We look to use animal alternatives where possible. We use cell culture models for looking at specific mechanisms that occur in isolated cell populations. Results from these experiments can both be informed by our animal work and help us to design better animal experiments.

When looking to ask a question about the function of a gene found in the brain we have used neurons grown in a cell culture medium rather than use mouse brains. For example, through our links with colleagues who study human genetics, we have identified a number of possible genes that are linked to obesity. We also know from published work that these genes are expressed in the brain. These make them exciting candidates for future projects but before we do any work in mice, we want to be really sure they are working in the way we predict. To do that we have altered the function of these genes in neurons grown in a dish to see what happens, replacing the need to do these preliminary studies in animals Further we have collaborated with colleagues who have gut “organoids” to test ideas on hormone action in the gut. Organoids are small, three-dimensional tissue cultures that can be grown in a dish in a lab into such an ordered pattern that they mimic a lot of the complexity of an organ, and remove the need to repeatedly collect animal tissue. Finally, with correct ethical approval and process in place, we have access to post-mortem material from humans to enable us to map out the location of genes of interest without using animals at all.
Why were they not suitable?

While cells and organoids grown in a dish are useful they can never generate the **integrated data essential to this project. We cannot record from a nerve cell how fat it has become or if it is hungry, or determine how much an organoid has eaten. As such they not a sophisticated enough model platform to enable us to study the complex interplay between multiple organs that leads to metabolic disease.**

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

These numbers are largely based on the level of work over the previous two licenses and the amount of funding we have in place and expect to use to fulfil our aims and objectives.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To avoid wastage of animals, appropriate background research will be done prior to all experiments. Whenever possible, we will look to work with existing colonies of animals rather than breed new colonies. We will allow other trained researchers to work with the colonies in our unit rather than moving mice, reducing the number of mice that are both bred and transported.

Studies will be of appropriate size to detect significance, with animals randomly assigned to matched study groups and, whenever possible and practicable, investigators blinded to the nature of interventions. Protocols will include a series of analyses and steps on a single animal, rather than single analyses on multiple animals. We aim to balance impact upon an individual animal with scientific output but reason that this approach significantly reduces the number of animals used.

We think carefully about which other organs researchers in the laboratory can work on, such as heart and adipose tissue, and harvest these from the same animals. This reduces the numbers of animals used overall, increases the amount of data obtained from a single animal and allows us to examine links between different tissues/organs by combining data from the same animals, thereby enhancing the quality of the information produced.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use pilot studies for any new agent we are investigating. These are used to check the safety of drugs in a small number of animals before using them in a larger cohort but also give a real world output on effect size to design the larger study.

We routinely freeze down and store either eggs or sperm from all of the different colonies of mice we study. This means we only breed animals when we need them for experiments, rather than having to maintain a permanent colony for use in potential future experiments. We collaborate with other groups across the UK, Europe and the USA and share samples we have banked to these collaborators for their own purposes, maximising the benefit from previously conducted studies.

We are also aware that we live in an age when more and more experimental data are placed in open access platforms that are easily accessible on-line. We continue to work closely with our experts in information technology to look through these large data sets to find information that will actively shape our experimental design.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice.

We will typically use a mixture of wild-type, genetically altered and naturally occurring genetic mutant animals. Genetically altered animals are those that are carrying a specific and deliberate change in their genetic code that has been engineered to be **there through laboratory manipulation of DNA.**

We will use altered diets to change body weight. These are formulated to be accessible and palatable to mice.

In terms of the tests we carry out to measure circulating chemicals, either in the resting background state or after the system has been "switched on" with a challenge, we have refined protocols which deliver the smallest volume and require the smallest sample sizes possible to generate meaningful data.

Imaging and calorimetry systems are widely used apparatus that have been continually refined and redesigned over years to minimise stress. Calorimetry systems are cages plumbed in to closed circuit gas analyser systems which enable measurement of what gas a mouse had consumed and what gas a mouse has produced. In doing so, this enables a calculation to be made of how much energy that mouse has used up. While previous calorimetry systems had rather barren grid floors, continuing refinement in design and material has now made it possible to have a calorimetry system based around the existing base floor unit of the home cage.

To more accurately record food intake and metabolism, we will sometimes need to single-house mice. This can be stressful but we will minimise the time each animal is housed alone and, where possible, animals will be re-housed in groups with their original cage-mates following a period of single-housing. In addition to shelters, nest boxes and nesting material, tubes to act as hiding tunnels, shredding toys and wooden chewing toys for animals to gnaw upon will also be supplied. These will be modified as necessary to accommodate head placed cannula in any animal that has undergone surgery and had an indwelling cannula sited.

Finally, we have a number of specialised techniques that we will perform at the end of the experiment on terminally anaesthetised animals to minimise their pain suffering and distress. Animals that are under "terminal anaesthesia" remain in a state of deep sleep and unconsciousness throughout until they are humanely killed at the end of the experiment.

Why can’t you use animals that are less sentient?

We use less sentient animals where possible and our research group has used flies to study specific research questions.

However, as our interest is in modelling human disease states, a mammalian system is the most suitable.

We do use terminally anaesthetised animals for some procedures, but under such conditions we cannot measure processes such as food intake and energy expenditure that can only be measured in live animals over days.

How will you refine the produres you're using to minimise the welfare costs (harms) for the animals?

We have made several refinements to our techniques over the past years. Specifically; More prolonged period of acclimatisation in an enriched environment with “same-user handling” in period prior to studies where stress is anticipated and where stress will affect data output. This has been particularly useful in studies of the stress hormone corticosterone where, without a period beforehand where the animals are used to being handled, the stress signal from the test itself may have swamped the true biological signal. Whenever possible, mice will be housed in social groups.

For calorimetry data we have taken advantage of in-house, mathematics expertise existing within our institute to factor in the inevitable change in body weight seen in the study period. This improves the quality of the data and removes the need for the animals to undergo a repeat period in the calorimetry system.

For food intake studies we have made our own dishes to capture spillage and made measurement of food intake a much faster and accurate process, maximising data yield from the time animals spend single-housed. Whenever we are using any drug that we wish the animal to take by mouth, we will work with our teams in the animal units to introduce appealing and attractive flavouring (like Strawberry Nesquick) to be delivered alongside the drug.

We will look to use close observation of both body weight and body condition scoring to get a more complete readout of an animal's situation to enable us to detect problems early and avoid harm. The body condition scoring system is a simple, rapid and noninvasive method for assessing health status and wellbeing.

In any post-operative period we will pay close attention to ensuring the environment meets the needs of the animal by the addition of a heated environment, post-operative bedding and more palatable mashed food.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Laboratory Animal Science Association (LASA) guiding principles documents of aseptic technique (https://www.lasa.co.uk/current_publications/)

ARRIVE (Animal Research: Reporting of In Vivo Experiment) guidelines for preparing papers for publication (https://www.nc3rs.org.uk/arrive-guidelines)

PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for planning animal research and testing (https://www.ncbi.nlm.nih.gov/pubmed/28771074)- used for planning our experiments
Smith et al. Classification and reporting of severity experienced by animals used in scientific procedures: FELASA/ECLAM/ESLAV Working Group report. Lab Animal 2018 Feb;52(1_suppl):5-57. doi: 10.1177/0023677217744587.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institution has a regular advisory board meeting to facilitate meaningful dialogue across the license holder, researchers and technicians. Through these meetings we are able to find out about latest practical guidance from relevant national bodies such as the LASA (Laboratory Animal Science Association) and the RSPCA (Royal Society for the Prevention of Cruelty to Animals).

Accessing NC3R website (https://www.nc3rs.org.uk) as a resource for guidelines, practical information, links to publications and training materials.

Advances in the 3Rs will be disseminated to those operating under this licence through the weekly laboratory meetings.

157. Repair and protection of the retina and optic nerve

Project duration

5 years 0 months

Project purpose

- Basic research
  - Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Blindness, CNS disease, glaucoma, nerve regeneration, neuroprotection

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To test new treatments for enhancing protective and regenerative machinery in the optic nerve. These treatments aim to treat loss of vision due to glaucoma, and to regenerate fibres in the injured or diseased central nervous system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The aim of this work is to treat disease or injury to nerve cells (neurons) in the optic nerve and retina. The intention is to develop new treatments for the degenerative eye disease, glaucoma. Additionally, the findings will be relevant to treating many neuronal diseases or injuries in the brain or spinal cord.

Glaucoma is one of the leading causes of blindness worldwide. Glaucoma is a neuro-degenerative disease which causes the nerve fibres (axons) between the retina and brain to deteriorate. This ultimately leads to the death of the nerve cells (neurons) in the retina which extend their axons towards the brain. Currently treatments to protect retinal neurons are not very good, and there are no treatments that allow regrowth of damaged axons back towards the brain. Adult retinal neurons are similar to neurons in the brain or spinal cord, in that they do not regrow after they are damaged by injury or disease.

The aims of this work are to identify and test new treatments that will (1) prevent retinal neurons from dying during glaucoma or after other injury or disease to the optic nerve, (2) enhance the regrowth of damaged fibres. Our work has shown that axons in the optic nerve, brain and spinal cord do not regrow after injury or disease because the cellular machinery for protection and regeneration is not abundantly there. We have discovered some treatments that allow this cellular machinery (components that trigger growth or survival) to be directed into the nerve fibres. This enhances the ability of nerve fibres to regrow, and prevents retinal neurons from dying. We have tested many treatments using models of injury and disease in cell-culture dishes, reducing the need for animal experiments, but ultimately, we need to test these treatments using animal models of retinal and optic nerve injury or disease, so that we can see whether they are worth developing to treat patients.

We also need to fully examine specific protective and regenerative molecules (cell components) into the optic nerve. We know about some of these molecules, but we need to understand associated processes much better in order to identify better treatments.

What outputs do you think you will see at the end of this project?

As with our previous work in this area, we will publish our results in high-impact peer-reviewed journals. Our latest manuscripts were published in broad-appeal and clinically relevant journals, meaning the work is read not only by clinicians interested in potential new therapies but also by scientists from many different disciplines interested in scientific advance.

We would also aim to identify potential treatments that are novel and unexpected and suitable for business development. Suitable therapies with high potential for clinical translation will be considered for patent applications.

Who or what will benefit from these outputs, and how?

Our research appeals to scientists investigating novel treatments for glaucoma, and repair of the injured or diseased retina and optic nerve. Clinicians in this field are also very

interested in our work, keenly anticipating potential new therapies. The work is also of interest to the central nervous system (CNS) repair community. Interventions which enable axon regrowth in the optic nerve are usually efficacious in the brain and spinal cord, so researchers looking to repair the injured spinal cord are also very interested in our findings.

Ultimately, our research is aimed at developing new treatments for eye disease. The intention is for our work to benefit the vast number of patients worldwide who are suffering from loss of vision due to degenerative disease in the retina and optic nerve.

The work will also be widely disseminated to the scientific community through publications and the findings will be presented at local, national and international scientific meetings.

The data will also be used in support of future funding applications and potentially for patent applications for development towards clinical treatments and enterprise.

How will you look to maximise the outputs of this work?

We collaborate with many scientists throughout the world and build on our findings through further experiments which are better performed by these additional experts. Our recent papers were published together with many labs worldwide, and we are part of global research consortia. In addition to publication in high-impact journals, the work is also presented at conferences worldwide, within the eye research community, CNS repair community, and at specialist cell biology meetings aimed at understanding relevant cell biological mechanisms. Papers are usually published as open access articles, and can include positive and negative (unsuccessful) findings.

Species and numbers of animals expected to be used

- Mice: 900
- Rats: 550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use mice and rats, which have not been genetically modified. The group has extensive experience with both species and all new ocular drugs require testing in a mammalian system..

Mice and rats are used because their eye anatomy is similar to that of the human eye, including the response to injury. We use two models of optic injury and disease. The injury model is well characterized in mice, as is the disease model in rats. Rats are required for the disease model, because the larger globe size is necessary to accurately model

disease pathology. It is also useful to show that our novel protection and regeneration strategies work in more than one species.

These models need to be investigated in adult animals, because the response to injury is very different in young animals, and the disease we are modelling does not occur in young patients. The young central nervous system has a limited ability to regenerate after injury, whilst the adult central nervous system has almost none. It is the injured or diseased adult central nervous system that we are aiming to repair.

Typically, what will be done to an animal used in your project?

We have spent many years investigating the mechanisms that control the ability of nerves to repair after injury or disease, using cell culture models of injury, and we continue to generate new targets for repair using these models, which we make into new therapies. The animals used in our projects will typically receive an injection into the eye. This is a not painful, and is routinely used for many current therapies to treat patients with glaucoma and other eye diseases. The injection is intravitreal, which is a shallow injection through the white of the eye, to deliver a small amount of liquid into the vitreal humour inside the eye.

Animals are then left for a few weeks to allow for the treatment to work in the eye. The animal will then receive either an optic nerve crush (to model injury) or a laser injury to the eye, which results in raised eye pressure, mimicking disease. The optic nerve crush is performed under anesthesia, and involves moving the eyeball forward of the socket to expose the nerve behind. The nerve is crushed with fine forceps, and the eye returned to its usual position. The nerve does not sense pain, so the crush is not painful afterwards. Animals are left for some time (typically two to six weeks) for regeneration to occur. The animals are then killed, and we analyse regeneration in the optic nerve, and protection from cell death in the retina.

For the disease model, the animal is anesthetised, and a laser is used to cause a very small injury (similar to cauterising) to a specific area around the edge of the eye. This slows down the normal drainage of eye fluid, leading to a build-up of eye pressure, (similar to glaucoma). The injury heals, meaning that the pressure build up is transient, so after a week the injury is repeated. 42 days after the initial injury, the animals are killed, and the optic nerve and retina are analysed for degeneration,

regeneration, and protection from cell death. During the course of this disease model, eye pressure is measured regularly with a tonometer (which is like a blunt pen that is gently pressed against the eye), and eye function is measured by electroretinography ERG, a non-invasive assessment of retinal function using light and electrodes placed on the eye.

For ERG recordings an electrode is placed in contact with the surface of each eye, wire loops placed around the circumference of the eyes and an electrode placed into the tail or skin of the animal. This is done under anesthesia. During the same anesthetic, imaging

may be done, using a camera to image through the cornea to observe the retina at the back of the eye.

Tonometer measurements involve touching the cornea with a small probe which provides an instant resistance measurement based on the eyes intraocular pressure. This does not require an anesthetic.

What are the expected impacts and/or adverse effects for the animals during your project?

Neither the injury procedure nor the disease model are expected to cause adverse effects. The injections into the eye should not cause any complication, and the in life assessments are not painful and do not cause adverse effects. The group has several years' experience with these techniques and rarely encounter problems.

The eye procedures can cause temporary swelling and tenderness, but this should rapidly resolve itself. The animals will be very closely monitored after the procedures to ensure these effects subside, and if necessary, animals will be treated for pain or inflammation. Vision loss occurs rapidly after the optic nerve injury, and more slowly in the disease model. Loss of vision is limited to one eye, so the animals do not become blind from the procedures.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

C57BL/6 (a wildtype mouse strain) – mild (50%) moderate (50%).

Wistar, Sprague-Dawley, Lister Hooded (wildtype rat strains) – moderate (100%).

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We have worked for many years using cell culture models to study the molecules that control the regenerative capacity of the central nervous system (CNS: brain, spinal cord and optic nerve). We continue to use these systems, which have proven to be incredibly valuable for identifying new targets for stimulating regeneration after injury or disease, as

well as protecting injured or diseased neurons from death. Our in vitro studies have discovered treatments that are effective at preventing cell death in the retina as a result of injury, and that they are very effective at stimulating regeneration of the fibres that connect through the optic nerve to the brain.

Whilst we have been very efficient at modelling CNS injury, the eye and optic nerve cannot be modelled in cell culture systems. In order to test whether our new gene therapy tools could be useful for treating patients, we need to find out if they can protect and repair in intact eyes and optic nerves. It is therefore necessary to investigate our new treatments using animals.

Which non-animal alternatives did you consider for use in this project?

We use cortical neuron cultures to model CNS neurons, and we are developing new human neuronal culture systems using inducible stem cell derived neurons. We also plan to pursue other cell culture injury models, including scratch assays, where we use a needle to injure a "hedge" of axons and monitor regrowth afterwards.

These are all well respected models of CNS injury. To model eye injury and disease we are working with collaborators who are experts in the retinal explant model.

Our philosophy remains to conduct cell culture experiments to identify new treatments, and to only use animal models for confirmation of therapeutic benefits.

We additionally considered culturing retinal ganglion cells (RGCs) in dishes, but these are notoriously difficult to culture, and they do not behave similarly to RGC neurons in a real-life situation (in live animals).

Why were they not suitable?

Whilst we use cell culture models to study mechanisms of nerve injury and neuroprotection, these models are not sufficient for this project because the cells we are targeting are influenced by many conditions which are not represented in cell culture. For example, the retina and optic nerve contain many cell types in addition to neurons, including immune cells, and to investigate whether our new treatments are beneficial in a meaningful fashion, we need to understand the regenerative or neuroprotective effects in a complete biological situation, where the RGCs are also influenced by the many other cell types. None of the available cell culture models completely model the situation in the injured or diseased eye or optic nerve, but we will continue to use cell culture systems to model aspects of injury or neuroprotection as closely as possible, and all off the new treatments we test have been previously studied in cell culture models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Sample sizes are calculated from previous similar experiments and from pilot data to minimise group sizes required to demonstrate clinically relevant effects. Pilot studies are always carried out using a small cohort of animals (3-6 animals) before beginning a full study.

Testing of preliminary novel treatments are typically performed on group sizes of 3 to 4 animals due to the reproducibility of the procedure and results. Controls are needed in order to correctly analyses effect size. In the case of our novel therapies, these usually mock delivery systems.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For each of the procedures, there is a lot of prior experience within the group, and statistical advice has been obtained from the biostatistics unit. Experiments are conducted to the PREPARE guidelines, and will comply with the ARRIVE guidelines for publication.

Sham surgeries have previously been used to control for unexpected inflammation which may cause an unpredictable response, and are not required for acceptance as a published article. We are quite confident our surgeries only have the desired effect and are keen not to use excessive animals where possible to comply with the 3R's.

Any new surgery, and any new Procedure Individual Licence (PIL) holder will undertake preliminary experiments to generate data relevant to the technique and research question. Additionally, doses will be calculated from effective non-toxic concentrations in tissue culture studies to minimise dose ranges needed to be testing in animals.

The minimum number of control groups will be used for each experiment in order to reduce numbers whilst allowing for the experimental data to be statistically meaningful. For new treatments, we know from previous studies that phosphate-buffered saline (PBS) injection and mock delivery injection can be used interchangeably (as results are almost identical) so only one type of control will be included alongside test compounds.

To ensure accuracy of data, we will also use blinded experimentation for the majority of studies whereby each animal is given a number and the investigating scientist is blinded to which procedures or treatments each animal has received. Unblinding only occurs after the final analysis of tissue and data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will maximise data by analysing as many parameters as possible, using as much tissue as possible. Whilst we may be aiming, for example, to analyse regeneration in the optic nerve, we can also retain complete eye and brain tissue for complete analysis of all the pathways potentially involved / affected.

We will list excess organs, where possible, on the animal facility mailing list. We have shared organs with other groups in the past and will continue to donate extra tissues.

Injury or disease procedures will only be performed on one eye per animal, with the other eye serving as the uninjured control. This also helps to optimise the number of animals per experiment, rather than using additional animals as controls.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

CNS axon injury model: - Mouse optic nerve crush injury.

The optic nerve crush injury is a widely used and widely accepted model of injury to the axons of the central nervous system, as well as being accepted as a model for measuring neuroprotective effects. Effects identified using this model are good indicators of targets or treatments for protecting and repairing both the injured and diseased CNS. Of the available models of CNS injury, it is one of the least severe, but returns many beneficial results.

The optic nerve crush procedure has been used for many years. It causes damage to the axons of the optic nerve which is highly reproducible, and leads to a progressive loss of RGC neurons in the retina, which again is highly reproducible. The optic nerve relays visual information from the retina to the brain. The injury process involves exposing the nerve behind the eye, followed by crushing with a pair of fine forceps for a defined period of time, usually a few seconds. The nerve and surrounding tissues are then replaced, and the injury site heals without assistance.

All of our work identifying potential treatments for repairing or protecting the injured or diseased CNS begin using cell models in a culture dish. The optic nerve crush injury is challenging, but is far less severe or invasive than other brain or spinal cord models of CNS injury. Use of the model allows validation of our treatments, whilst assessing

regenerative and protective effects for the injured or diseased visual system. The optic nerve crush model is a highly beneficial system for identifying, validating and comparing multiple and varied treatments.

A laser intervention to raise intraocular pressure and model glaucoma. An established model in rats.

A laser is used to damage to the trabecular meshwork, the eye's drainage system. This causes a blockage which reduces aqueous outflow from the eye, causing eye pressure to build up transiently. This is reproducible, so has a high degree of success, and has been used extensively by the group. It is only successful in rats, and performs best in non-pigmented animals. The laser settings and parameters required have been standardised and optimised over many years. This will keep complications to a minimum, however if these arise they can normally be treated by maintaining eye lubrication.

The combination of these two models means that we can test potential therapies in both injury and disease scenarios, and in two different species. This is important to demonstrate that treatments can be moved towards developing treatments for humans, and for generating data that can be used for patent applications. For this it is necessary to use accepted pre-clinical models.

Why can’t you use animals that are less sentient?

The objective of this work is to identify treatments for the adult human central nervous system, focusing primarily on repairing the injured or diseased visual system. Adult mammals are required for this work primarily because of the similarity of the visual system to humans, but also because of the comparative regenerative ability of the adult central nervous system (CNS). The regenerative ability of the mammalian CNS declines rapidly with maturity, so that infants have some ability for regrowth after an injury, whilst adults have very little capacity for regeneration. It is critical to use adult animals that exhibit this feeble regenerate ability in adults. Degenerative diseases such as glaucoma also mostly occur in adult and aged patients.

Because we are measuring regeneration, it takes a long time for effects to occur (weeks), so it is not possible for animals to remain under terminal anaesthesia. It is crucial that the injury and disease models have relevance to human disease, because the ultimate aim of the work is to identify strategies that can ultimately be developed to treat human patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is a concise application, with minimal injury and disease models, which will be performed by a limited number of researchers. We will use a recently developed scoring system for recording surgical procedures, on a range of 1-10. Scores below 7 will be followed up with additional care post-surgery, and notes will be made of any particular areas of concern. Animals will be examined throughout the study for evidence of damage

and given post-operative eye-gel, or antibiotic if required. Weight and behaviour of animals of concern will be additionally monitored for a 7 day period. Investigators will be required to maintain these records to improve their techniques, and confirm optimal care of animals.

Researchers train routinely on dead animals to allows them to perfect their surgeries and techniques (dead animals are sourced from excess stock in house, which were destined to be killed). This reduces variability in their studies and helps reduce animal usage through failed procedures and minimises suffering.

For injury or disease models, analgesia is provided during the procedures to limit suffering, and maintained for a day afterwards.

A shared spreadsheet will be maintained within the group which details the course of all animals through all procedures performed. This spreadsheet will record each animal, every procedure performed on that animal, the actual severity reached, additional comments to the study and how the tissues were used and stored. This system has worked very well in the past and we have improved our recording and monitoring of animal welfare.

We will ensure optimal communication between the researchers and the technicians in the animal facility, to educate facility staff and managers about the techniques we are using, so that abnormal or adverse effects can be rapidly identified and treated.

Our wider research group has extensive previous experience with the techniques and procedures in this licence application, and has a comprehensive list of potential adverse reactions that could potentially arise from either these or other procedures involving the eye. This will be made available to all the investigators training for or using the procedures, as well as technicians and researchers who are looking after the animals, in order to aid in identification of adverse effects and to minimise potential harms.

Animals will be housed in groups to enable social interaction and grooming. Animals used in these procedures do not normally fight after surgery and open wounds are not expected. We have experienced minimal signs of stress or discomfort from our procedures in the past and expect a good quality of life for the animals on this licence.

We are also developing new tools which allow for a reduction in the number of eye injections.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow ARRIVE and PREPARE guidelines. Current publications on the LASA website will also be read. There are also best practice guidelines issued by ARVO, the Association for Research in Vision in Ophthalmology. They have issued a “Statement for the Use of Animals in Ophthalmic and Vision Research” which is available on their website. New researchers will be directed to these resources to encourage current best

practice. Further resources regarding veterinary ophthalmology are available through BRAVO, the British Association of Veterinary Ophthalmology although these relate mostly to up to date approaches for treating animal eye disorders.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have a strong record in cell based models of CNS injury, and will continue to develop these to be as relevant to human injury or disease as possible. In routinely keeping up to date with neuronal cell biology literature we will also be alert to new developments in cell-based neuronal models, with developments arising from studies using stem cell derived neurons, human "mini-brain" organoid type cultures, and patient-derived neuronal cell models of disease. We will also continue to monitor the

NC3Rs website for developments, as well as the Norwegian 3Rs website "Norecopa"and will incorporate new approaches into our research. Up to date surgical advice is available on the LASA website, as well as best practice guidelines from ARVO, the Association for Research in Vision in Ophthalmology, available on their website.

We are also collaborating with labs worldwide who use human and animal models of retinal disease, and will keep up to date with developments in their labs, and incorporate these in our collaborative projects.

158. Analysis of skin carcinogenesis in transgenic mice

Project duration

2 years 0 months

Project purpose

- Basic research

Key words

cancer, transgenic, skin, oncogenes, tumour supressor genes [TSG]

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project uses genetic engineering technology to create transgenic mice that develop benign or malignant skin cancer, and is geared to finish on-going work delayed due to Covid, which are now in the latter stages. Exploiting the latest in techniques, tumours are only induced after topical treatment of skin with steroids to activate the genetic mutation[s]. Thus, any disease is highly localised to specific skin sites and the model can assess effects of several mutations in pre-cancerous stages that lead to malignant tumours in efforts to identify the real mutations and validate the mechanism of how they drive cells through each stage of cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The incidence of skin cancer is rising steadily, and the most significant stage in clinical terms for the patient is the conversion of non-malignant, benign tumours [called papillomas] to malignant ones called carcinomas and their risk of spreading called metastasis. This research study will involve studying the activation of cancer-causing genes [called oncogenes] or inactivation of cancer preventing genes [called [tumour suppressor] genes (TSGs)] in the skin of genetically modified]mice [called transgenic mice]. Using this real life transgenic mouse approach can therefore test which are the key genes thought to be responsible for causing tumours [the “driver” mutations] and by studying their co- operation, we can assess the stage at which mutations in these genes become active to cause cancer. The genes chosen to study represent common genes that are known to help regulate skin cell growth and therefore are likely to go wrong in cancer; and no longer provide the protective systems that naturally have evolved to cope with every day mutations occurring daily sun exposure. Studies of these transgenic mice will aid in identifying the relevant molecules involved in causing cancer and thus become a target for the studies aimed at stopping skin cancers from forming, which may be equally applicable to other cancer types such as breast, colon and lung cancer.

What outputs do you think you will see at the end of this project?

This study is designed to develop genetically modified animals that directly test which genes can drive cancer development in a real-life situation and thus identify targets that can be modified to slow or stop the cancer process and now are mounted by the mouse skin to help prevent benign tumours from forming or stop their progression to become malignant cancers- which is the most important stage.

This mouse model of cancer formation has a particular strength in its ability to investigate the events that underlie both the early stages to form benign tumours and what causes their progression to become malignant. Hence, a study of how the mutations cause progression will both identify the suspected driver genes and test if key tumour suppressor genes [TSGs] can stop the process or slow it down. As a bonus, this type of study will advance the understanding of how these genes work in normal processes such as normal skin growth and how the epidermis (the upper part of the skin) helps maintain the integrity of the skin.

All methods required to regulate expression of genes in the epidermis are well established and have been successfully exploited in the past to identify and test the driver mutations and explore how they interact to create cancers.

Who or what will benefit from these outputs, and how?

This mouse skin model of multistage cancer formation is considered one of the classic ways to study cancer and it is envisaged that these results will be relevant to other cancer types; e.g. breast, lung and colon. All the results are maintained on database available to other researchers; and all biopsy specimens are stored as frozen samples or fixed tissues ready for new experiments.

The mice are available to other scientists investigating cancer and anti-cancer therapies. All methods required to establish genetically modified transgenic mice are well established and have been successfully exploited to validate mutations and explore their effects.

Ideally, in the long term, identification of the pathways involved in cancer formation could lead to the discovery of new strategies for skin cancer, one of the most common cancers in the world, which may be equally applicable to non-skin cancers.

Further, the animals themselves would provide a good way to stringently test new treatments that target these known mutations, in a real-world situation, prior to clinical trials in humans.

How will you look to maximise the outputs of this work?

Findings will be presented to other scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings. Under the previous project, six papers have been published and peer reviewed data has been presented at many international scientific meetings.

The Institute has a data repository that includes full text of my published journal articles and all conference proceedings. In line with RCUK requirements these data remain accessible for 25 years.

The mice and tumour biopsies are also shared between collaborators in the UK, Europe and the USA.

Species and numbers of animals expected to be used

- Mice: Breeders 1,200;
- experimental 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse skin model of multistage cancer formation is considered one of the classic models for cancer research. Development of skin cancer in mice has a particular strength in its ability to investigate each stage of tumour progression, from early pre-cancers [termed skin hyperplasia] to benign tumours [termed papillomas and keratoacanthomas] that may regress or progress into fully malignant tumours (termed squamous cell carcinomas [SCC]).

Being located on the skin, due to the ability to target expression of mutant genes specifically to the skin, these tumours are easily observed and any changes are easily followed over time.

This has allowed scientists to analyse how tumours progress in adult animals; and test which mutations can drive each stage of cancer formation- or not and identify which tumour suppressor genes [TSGs] fail.

In particular, this allows a focus of this project to assess what causes a benign tumour to become malignant- which is the most important stage for any cancer patient.

Typically, what will be done to an animal used in your project?

Individual transgenic mouse genotypes have been established on the previous project licence and transferred to this project licence. These are routinely bred to create new genotypes. In these mice, one of the genes is a gene switch regulator which is turned on when skin is painted with a steroid. In adult mice which have been bred to contain both the gene switch regulator and a target gene, expression of the target gene only occurs in areas of skin treated with a steroid.

This genetic engineering can therefore activate a mutant cancer causing [oncogene] gene or inactivate a target TSG expression or activate new TSG expression in attempts to inhibit cancer growth.

Thus, potential tumour formation can be highly localised by painting an ear tip or lower back and may develop tumours at these sites; or tumour growth may be inhibited depending upon which genes are turned on.

Typically, juvenile mice [@ 24-28 days] are tagged at the ear and a tiny piece of tail tip is removed for DNA analysis to identify which mice contain the correct genes. These breeders are maintained for up to 6 months.

Once tagged mice are identified with the correct genes, they are anesthetised and treated topically with the steroid at the ear tip and also on the lower back; which has been shaven.

These mice are then maintained for up to 6 months to assess tumour inhibition or benign tumour progression.

What are the expected impacts and/or adverse effects for the animals during your project?

Adult animals that have been topically treated with the steroid on each ear tip and lower back are most likely to develop tumours at these sites; as seen in earlier studies. Initially, this manifests as a scaly, thickened skin and then may form a small, wart-like tumour by 8-9 weeks of age. This may or may not convert to become a malignant tumour over subsequent 4-6 weeks.

These inducible mutations are applied to mice that express a cancer initiating gene or a cancer promoting gene exclisively in the epidermis-the outermost layer of the skin - but not in any internal tissues. In addition, these foundation mice do not express these genes in the tail but can over a period of months develop benign tumours at the ear tag site as benign tumours are induce by the tiny ear tag wound. These small benign tumours do not progress to become malignant and thus provide the ideal foundation to assess which new gene[s] will cause malignancy or ideally identify the genes that can inhibit this event- as for any patient, the conversion of benign tumours to malignant is the most significant event in their disease.

Thus the goal of this project is to assess which genes drive formation of these tumours and another goal is to add or remove genes that inhibit this process- and thus some inhibited mice may be maintained for up to 6 months to assess if this approach was successful.

By employing the ability to induce mutations at specific times via topical steroid treatment, the majority of breeders [>80%] established in the previous PPL did not display a harmful phenotype; with the remaining 20% possibly exhibiting a benign ear tag tumour by 3 -6 months of age.

Tail tipping is carried out under general anesthesia using aseptic technique to provide a tissue sample for DNA analysis, as sampling from this location does not induce tumours whereas sampling from other anatomical locations can induce the formation of tumours in the strains of transgenic mice employed.

Any mouse developing an unexpected harmful phenotype will be humanely killed by Schedule 1.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

- Mild (80%),
- Moderate (20%)

What will happen to animals at the end of this project?

Killed

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objectives of this project cannot be achieved without the use of live, genetically altered [GA] animals. It is the goal of the project to establish mouse skin models to verify causal roles for relevant mutations that drive tumour progression and identify sentinel systems that have evolved to inhibit cancer.

Which non-animal alternatives did you consider for use in this project?

Experiments involving tissue culture using mouse or human skin cells and transformed by introduction of genes [transfection] have been performed. Transformation is assessed by growth from low numbers, ability to migrate across the dish, seed new colonies and resistance to cell-death.

Why were they not suitable?

Unlike cell culture systems, mice (including those genetically altered) offer the possibility to determine the influence of factors critical to cancer progression such as a blood supply, the immune system, and the growth controls of cells that together with the physical barriers of tissues help to prevent the invasion by tumour cells. However, experiments will utilise skin cells from transgenic mice for tissue culture experiments and the results compared to the mouse data to assess whether cultured cells accurately mimic progression of tumours observed in animal models sufficiently well to replace the need for monitoring malignant progression in adults.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Considerable experience has been gained in previous experiments over the past 25 years that have distilled the numbers required up to 15 animals per genotype in repeat experiments for up to 6/7 months. Given the requirement for topical treatment to activate the mutations, e.g treating each ear tip and a small dorsal area, this has the capacity to produce up to 90 biopsies from these 30 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whilst generating these cohorts requires breeding of multiple GM lines, breeding strategies are carefully structured and rigorously monitored to ensure that only the

minimum numbers required for statistical power are generated. In addition, given the requirement for topical steroid treatments, animals carrying multiple target transgenes can be routinely maintained without phenotypes; these act as a foundation source reducing overall numbers required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Untreated breeders act as additional controls and since several genotypes have already been characterised repeating these comparison controls is unnecessary; thus further reducing numbers required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse skin is considered one of the classic models to study cancer formation. This has been combined with production of transgenic mice to assess effects of mutations in genetically modified animals produced by standard techniques. A major strength of this approach employs a skin-specific, inducible gene switch system that prevents disease during animal development or unnecessary disease in internal organs. Thus, during breeding and juvenile development, tumours do not appear; and moreover, as tumours can be highly localised [e.g. treatment of ear tip] disease is further minimised.

Another major advantage of skin models is their accessibility, which not only facilitates induction of localised disease via topical treatments, but also allows macroscopic observation of tumour formation or tumour progression without invasive procedures.

Why can’t you use animals that are less sentient?

The objectives of this project cannot be achieved without the use of adult, genetically altered [GA] animals. It is the goal of the project to establish inducible transgenic mouse skin models to verify causal roles for multiple, relevant mutations that drive stage-specific tumour progression, explore the subsequent mechanism and identify putative compensatory sentinel systems that have evolved to inhibit carcinogenesis.

Mice are the mainstay of this kind of approach with many relevant models published with which to compare data and acquire appropriate reagents from colleagues.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This project employs a skin-specific inducible gene switch system that avoids disease during animal development or unnecessary disease in internal organs. Thus, during breeding and juvenile development, tumours do not appear; and moreover, as disease can be highly localised [e.g. treatment of ear tip] suffering is minimised.

The accessible nature of skin models allows careful monitoring of all potential tumours without invasive procedures and permit experiments to be terminated as soon as significant data has been obtained.

Animals are regularly monitored and for individuals with possible malignant tumours animals are monitored daily and adverse effects closely monitored to ensure no tumour exceeds the recommendations of Workman et al, 2010 and that we implement pre-set humane end-points.

In addition, to help control pain animals about to undergo the genotyping protocol via ear tagging and a tail tip biopsy are placed on analgesia in the drinking water for 24hous pre and post the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Workman et al 2010. BJC www.NC3Rs.org.uk

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

www.NC3Rs.org.uk; consultation with Named Animal Care Welfare Officers NACWO

159. Mechanisms regulating neural stem cell activity and neuronal production

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Stem cells, Neurogenesis, Quiescence, Ageing

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify mechanisms that control the activity of neural stem cells and the process of neurogenesis in the embryonic, adult and ageing brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neural stem cells play a central role in the generation of neurons and glial cells during brain development and in the adult brain. Defects in neural stem cell activity in the embryo has been linked to neurodevelopmental disorders and defects in adults and in particular in ageing and diseased individuals, to cognitive impairments and mood disorders. Identifying the mechanisms that control the activity of neural stem cells and the process of

neurogenesis is essential to elucidate the aetiology of these disorders and understand how the brain is formed and maintained.

What outputs do you think you will see at the end of this project?

The project will result in an improvement of our understanding of the mechanisms that control the activity of neural stem cells and the process of neurogenesis, and how these mechanisms change between embryonic and postnatal development, adulthood and ageing. The outputs will take the form of publications in peer-reviewed journals and presentations at academic conferences but will also include dissemination to the lay public via popular science initiatives. Materials, data and methods will also, where appropriate, be accessible online.

Who or what will benefit from these outputs, and how?

The main beneficiaries of our research in the short and medium term will be other scientists working in the fields of brain development, brain plasticity and brain ageing. For example, scientists may investigate whether the mechanisms we uncover are deficient in neurodevelopmental pathologies (e.g. lissencephaly), neurodegenerative pathologies (e.g. Akzheimer's disease) and mood disorders (e.g. depression). In the longer term, these studies may lead to the identification of new targets for the development of new pharmaceutical and therapeutic interventions in these pathologies.

How will you look to maximise the outputs of this work?

We will share our data, analysis tools and resources with other scientists, using one to one interactions and collaborations, repositories and our lab webpage, which will reduce the number of replicated experiments in the field. We will disseminate our research by publishing results in peer reviewed journals. We will also present our work to academic peers at scientific conferences (national and international) and engage with public partners to disseminate our results.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will perform our study in mice because of the number of available mouse lines that are genetically suitable, the ease of generating new mutations or manipulating gene expression acutely in this species, and the comparison with previous studies in the scientific literature. Also the brain of mice is sufficiently similar to that of humans to make

its study worthwhile to learn about mechanisms of brain development and function in humans. We will use embryonic, postnatal, adult and aged mice, since we are investigating the changes that occur in neural stem cell activity and neurogenesis during the lifetime.

Typically, what will be done to an animal used in your project?

Some animals will receive injections of substances to induce gene deletions or measure cell proliferation. Some animals will receive several injections with the same or several substances, at variable intervals. They will then be humanely killed at various times after these manipulations in order to study their brain tissues.

Some animals will undergo surgery where a window is opened in their skull for injection of substances into the brain to manipulate gene expression locally. Adverse effects after the surgery may reach moderate levels of severity for a short period of time, but all animals will receive pain relief and will be closely monitored until they recover completely. At variable time after this, they will be humanely killed in order to study their brain tissues.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals will undergo surgery of moderate severity. After recovering from general anaesthesia, mice will be less active for a day or two after surgery. Animals might lose some weight but will typically regain that weight within two to three days. Some animals will also be allowed to age (up to 24 months) and as a result may experience certain discomforts associated with the ageing process. At the end of experiments, or if mice show signs of ill health, distress or suffering that are not improved or resolved within a timeframe approved by the veterinary surgeon, they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 60% of mice will experience a severity category 'Mild'
- 40% of mice will experience a severity category 'Moderate'

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice will be used in this project. Neural stem cells can be maintained in culture and we perform such experiments, but their behaviour in vitro is substantially different from what it is normally, as the cells in vivo are embedded in a tissue comprising multiple cell types that interact with stem cells and influence their behaviour. This stem cell niche is too complex and not sufficiently characterised to be reconstituted in culture, and in vivo experimentation in whole animals is therefore unavoidable to reach a thorough understanding of how neural stem cell behaviour is regulated.

How ageing affects neural stem cells and neurogenesis can only be studied in vivo as there is strong evidence that the ageing process, both healthy and pathological, involves interactions between brain cells and the immune and vascular systems, which again have not been reconstituted ex vivo.

The proposed studies could not be undertaken in non-mammalian species because their neural stem cells and niche environment are too different from neural stem cells in mammals and particularly humans (for example, non-mammalian species do not have restricted stem cell niches in the parts of the brain called dentate gyrus and subventricular zone as both humans and mice do).

Which non-animal alternatives did you consider for use in this project?

This project will be done in parallel with studies using non-animal alternatives, including Mouse Neural Stem Cell (NSC) cultures.
Human Induced pluripotent stem cells (iPSC)-derived neural cultures, including brain organoids
Human foetal brain material from the Human Developmental Biology Resource.

Why were they not suitable?

The cell culture models will provide us with useful information. Mouse NSC cultures will be used to get insights into the intracellular mechanisms (e.g. transcription factors, chromatin remodelers) that regulate neural stem cell behaviour. NSC cultures are a reductionist model that allow access to fundamental properties and constituents of neural stem cells that are maintained in this artificial setting (e.g. transcriptional and epigenetic mechanisms controlling NSC activity and quiescence). Other NSC properties differ between culture and in vivo settings, including their interactions with other niche components (absent in culture), their behaviour (e.g. NSC divide asymmetrically in vivo but symmetrically in vitro) or population dynamics (NSC numbers and activity rates change with age in vivo while NSC cultures cannot be maintained long enough to assess these changes), and must therefore be studied in vivo. Human Induced pluripotent stem cells (iPSC)-derived neural

cultures will be used to determine how much similarity or divergence exist between human and mouse neural stem cell and the mechanisms that regulate their activity. However any in vitro result will need to be validated by studies of neural stem cells in mice in vivo because the cells are substantially different in the two environments.

Moreover, in vitro experiments do not allow the study of interactions between neural stem cells and their niche environment, crucial for the regulation of neural stem cell activity, and interactions with the immune and vascular systems, crucial in brain ageing.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on previous experience when dealing with complex genetic crosses in mouse breeding as well as estimates on the number of experimental animals required based on expected effect sizes and variablity (SD) from the literature, past work, and in vitro pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Several factors will lead to a reduction of animal numbers, including reducing variation and good experimental design involving the use of appropriate statistics. In particular, statistical tests will be used to ensure that we use the minimum number of animals possible to reliably interpret our data.

We will design our mouse breeding strategies carefully to minimize the number of generations necessary to reach the desired combination of transgenes/ mutations, and to maximise the proportion of offspring carrying this combination of transgenes in the litter. Where appropriate, we will use otherwise unwanted offspring as negative controls.

We will also interrogate gene function by performing as much as possible acute manipulations of gene expression, e.g. by injecting viruses or CAS9/gRNAS to avoid the extensive breeding required to generate and maintain mouse mutant lines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding and holding lines as frozen down embryos and sperm will be used to minimise the number of mice being produced for these studies. However, generation of

surplus GA mice is sometimes difficult to avoid, e.g. when the genotype of interest is homozygote and breeding generates heterozygotes in addition to homozygotes, in numbers too large to be all used as breeders. Where possible, genetically altered lines will be maintained in a homozygous state, thereby obviating the generation of a large excess of offspring with inappropriate genotypes. In other cases, homozygotes will be generated from heterozygote intercrosses, with littermates genotyped as heterozygous or wild type used as age-matched controls. Genetically modified lines will be sourced from repositories to avoid remaking of lines whenever possible. Pilot studies will be undertaken to ensure the correct time course and experimental paradigms for our experimental purposes before larger scale studies are undertaken. Tissues sampled from the animals used in this project will be shared among lab members and with researchers in other labs when applicable.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice have been chosen for this work as the least sentient species to model the human nervous system well enough for our work to be relevant to understanding of human brain development and adult neurogenesis. Mice are essential because the experiments require the use of the latest and most refined gene manipulation technologies to identify and label cell subtypes and allow cell specific gene overexpression and downregulation approaches, and these approaches are available in this species.

Our transgenic mouse models are not expected to exhibit any harmful phenotype. Acute manipulation of gene expression in the brain by stereotaxic injection of various substances (viruses, shRNA, gRNA) will require opening of a cranial window under general anaesthesia. For this surgical step, appropriate anaesthetic/analgesic regimens and post-operative care will be used to minimise pain and surgery will be performed following aseptic technique to reduce the risk of infections. The initial surgery is the only step in which any pain may occur. Any surgical procedures will undergo regular review to identify further refinements to minimise animal suffering including optimisation of implants and anaesthesia/analgesia regimens.

Some of the mice will be analysed by perfusion of the brain tissue under terminal anaesthesia followed by histological analysis. Other mice will be analysed by harvesting the fresh brain tissue after schedule 1 killing, followed by biochemical analysis. The analysis will therefore generate minimal suffering.

Why can't you use animals that are less sentient?

Mice will be used for this project as they represent the least sentient species appropriate for this type of work. Other species which are less sentient (such as fish or amphibians) cannot be used because they do not show sufficient similarities to humans (e.g. they have large adult neural stem cell populations that are significantly different from those found in mammals as their brains continue to grow throughout life).

Some experiments will be conducted in animals at embryonic or early postnatal stages, but other experiments will require using adult and ageing animals because part of the project focuses on stem cell activity and neurogenesis during adulthood and in old age.

Some of our experiments will be done using tissues from animals that have been euthanised or terminally anaesthesised. However, in order to examine the impact of gene expression manipulations, other experiments will be performed on anaesthesised animals followed by recovery for various duration until the time of analysis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animal facility staff run a comprehensive health-monitoring programme whereby animals health and welfare are checked and recorded on a daily basis. The animals will be maintained under conditions where their health status can be protected as far as is reasonably practicable. We use refined holding techniques for the animals, as well as group housing and enrichment. We use appropriate anaesthetic/analgesic regimens (including pre- and post-operative analgesia) and aseptic technique to minimise pain and will refine these with advice from the Named Veterinary Surgeon to ensure that we are using the best possible option given our experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Resources hosted on the NC3Rs website, in particular:
- ARRIVE guidelines on experimental design and reporting results.
- PREPARE guidelines for planning animal experiments
- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs from several sources:
- Liaison with our animal care staff and NC3Rs representative
- Technological advances in the published scientific literature
- The NC3Rs website

160. Information processing in neural circuits

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

neural circuits, sensory processing, mental illness, novel therapies, optical methods

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to find out how activity in identified neural networks enables internal representation, processing, and storage of sensory information in the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Improving our understanding of how the brain processes information coming from our senses is in the first instance a matter of considerable, fundamental scientific interest. In the longer term, the insights gained from this project should allow us to identify new

therapeutic targets for mental illness that affects sensory processing (e.g. schizophrenia or ADHD) and storage of sensory input into memory (e.g.

Alzheimer's disease and dementia).

What outputs do you think you will see at the end of this project?

The project will generate output in the form of peer-reviewed research findings; non-specialist public communications; leads for novel treatment strategies for mental illness.

Who or what will benefit from these outputs, and how?

The main beneficiaries will be other researchers studying how the brain processes information from our senses in health and disease. Through the development of potential new treatment strategies, researchers in industry and ultimately the general public stand to benefit from the outputs of this project.

How will you look to maximise the outputs of this work?

We have been very successful in the past to maximise outputs and their impact through varied multi- and inter-disciplinary collaborations. These collaborations typically produce benefits and outputs bigger than the sum of their individual contributions.

Species and numbers of animals expected to be used

- Mice: 8500 (some animals may be purchased-in instead of bred under authority of the license)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The brains of mice process information from their senses, such as touch, taste or smell, very much like in humans. The use of mouse models for behavioural testing has been refined over many decades.

Uniquely, mouse models combine these properties with the possibility to use very specific, targeted way using genetic modifications. These modifications allow, for example, to manipulate brain activity in a very precise manner or model human neuropsychiatric disease through the transfer of human disease risk genes to the mice. To map connections between brain areas, we will require the use of early life stages. All behavioural experiments will be carried out in adult animals.

Typically, what will be done to an animal used in your project?

Part of the project will involve the generation of genetically altered mice to allow us to investigate the functions of particular molecules and cell-types in sensory processing. These animals are expected to be not fundamentally different in the way they behave from wild-type controls and thus expected levels of severity will be mild. In about 5% of the animals, we will need to trim some of the whiskers of the animal to be able to relate neural signals to touch sensation in specific whiskers. This has minimal effect on animal well-being. In about 30% of the animals it will be necessary to inject substances into the brain to deduce anatomical structures and function or implant electrodes or viewing windows. This will be carried out under general anaesthesia typically lasting no longer than 90 minutes, in aseptic conditions, with about 5% of the animals being humanely killed before regaining consciousness (e.g., where tracer substances require very short incubation time) and the other animals being recovered with appropriate post-operative care and only causing moderate amounts of discomfort to the animals in the study. The behavioural tasks we will use to record conscious, sensory perceptions are painless. In some cases, it will be necessary to motivate the animals to perform these tasks by rationing their food or water during testing. This may result in a temporary weight loss, but this will always be monitored carefully, and extra food or water provided if this occurs. Rationing results in lean, motivated animals and will typically last about 14 weeks. The availability of modern techniques for monitoring or altering neural activity in particular regions of the brain make it possible to carry out all of this work in a manner that should cause only moderate amounts of discomfort to the animals in the study. For example, surgical operations for implantation of ultrafine microelectrodes or for inserting genes into the brain will be carried out under general anaesthesia, in aseptic conditions, and with appropriate post-operative care. The adverse effects that may occur following surgery include transient pain and bleeding, but their incidence is likely to be less than 5% of the animals undergoing surgery. Chronic implants for recording neural activity or for delivering flashes of light for the purpose of altering that activity are small and light- weight, and do not materially affect the animal's quality of life. A relatively small percentage of animals (about 12%) will be used in tests where the head needs to be fixed to enable stable recordings of brain activity. These recordings typically last about 45 minutes per day and are repeated daily for 2-3 weeks. In these tests, the animal is supported on a moveable platform that allows the animal to perform behavioural tasks, for example, navigating through a virtual maze projected onto screens. This method is now very established and well tolerated by mice displaying the same behaviour as when walking freely and should cause only mild amounts of discomfort to the animals in the study. Animals will be killed humanely at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals will experience transient, post-operative pain, typically lasting no longer than 1-3 days during which pain relief will be provided. Some animals will be fitted with chronic head implants (typically just a small, light-weight and thin, implanted window in the skull) for typically about three months or until the scientific end is reached. In our experience, these implants do not noticeably affect animal welfare or behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals (>50%) will be used for breeding and experience sub-threshold severities. Of those animals used in procedures beyond breeding, about 5-10% will experience Mild severity and about 30-35% Moderate severity.

What will happen to animals at the end of this project?

Killed
Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our project investigates how the brain processes information from the senses. Currently, this can only be studied by using the brains of animals or humans, as our understanding of brain function is too rudimentary to generate realistic mathematical models for testing. Brain imaging measures in humans lack the sensitivity to observe changes in the properties of individual, identified brain cells in response to sensory stimuli. Moreover, a key aim of this project is to try manipulating brain activity in a very controlled, targeted fashion using genetic modifications to specific brain cells, which is not available in humans. Additionally, we aim to relate brain cell activity to the underlying neural circuitry at a microscopic level. This requires the use of post-mortem histological measurements, which would not be ethical or practical to carry out in humans.

Which non-animal alternatives did you consider for use in this project?

We considered lower animals (e.g., c. elegans), human cell in vitro models and mathematical models of brain function.

Why were they not suitable?

Lower animals or human brain cell in vitro models do not nearly model human brain function in health and disease sufficiently as well as the mouse. Too little is known about brain function in general, to make mathematical models a suitable replacement given the project aims.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Yes. Calculations have been carried out to determine the necessary number of animals for each experiment, ensuring significance of our results but also minimising the number of animals used. We are additionally able to keep animal numbers to a minimum by using cutting edge methods, such as optical recordings of many hundreds of identified brain cells at a time, that yield large amounts of data and experimental designs that allow multiple measurements to be made from each animal.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We estimate effect sizes and adjust required numbers of animals to the minimum required to test our working hypotheses. Furthermore, we employ within-subject experimental designs wherever possible to reduce the number of animals required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will work closely with our animal facility to ensure efficient breeding strategies. Additionally, we will use pilot studies when using new approaches to estimate effect sizes. We will also continue to make use of computer modelling of brain activity to reduce the conditions we need to be explore in experiments, thereby reducing the number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used because they are the animals with a sensory system that is comparable to that in humans.

The impact on animal welfare will be minimised by carrying out procedures in state-of-the-art facilities and using best practice methods. Breeding and colony maintenance, including genetically altered mice, will follow the Home Office assessment framework for efficient breeding and maintenance. We will only use genetically altered mice that exhibit a mild phenotype (e.g., with no effects on feeding or welfare) or no measurable behavioural phenotype (e.g., mice producing a fluorescent marker in certain brain cells). Where animals undergo surgical operations, these will be carried out very carefully under anaesthesia and aseptic conditions, and the animals are given painkillers and will be closely monitored until they have fully recovered.

Sometimes it will be necessary to regulate the food or water intake in mice in order to motivate them to perform behavioural tasks for a food or water reward. We have very strict guidelines in place to mitigate any harm from this food or water regulation, as well as for the behavioural tasks used.

The use of state-of-the-art methods will help reduce the impact on animal welfare while, at the same time, increasing the amount of scientific insight that can be obtained from each experiment. These methods include, for example, the introduction of genetic modifications to specific neurons, allowing us to change their activity in a precise fashion.

Animal welfare is regularly monitored. Clear instructions for all protocols ensure that procedures are aborted before exceeding set limits for impact on animal welfare.

The data obtained from these experiments will be used to refine computer models of the brain that will help to guide subsequent experiments and contribute to a reduction in the number of animals needed.

Why can’t you use animals that are less sentient?

Our project aims to unravel the biological principles of sentience, so the basis for feeling and perceiving things using our sense, itself. Therefore, a minimum level of sentience is required in the animals used in the project. Furthermore, we hope to extrapolate our findings in mice to the brain function of humans, particularly in neuropsychiatric conditions, and therefore require animals with a minimally similar brain architecture.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We employ increased monitoring whenever there are possible welfare costs to the animals. For example, animals receive daily post-operative care, including pain relief where necessary, for at least one week after surgery. We also have strict, staged SOPs for habituating animals to handling staff and experimental apparatus, thereby minimising potentially stressful situations for the animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We regularly review our procedures and SOPs against the published literature, particularly peer- reviewed protocols (e.g., Nature Protocols) and use the published resources on the NC3Rs website.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We keep abreast about advances in the 3Rs through regular newsletters from our Home Office Liaison, NVS, and NACWO. Group members involved in the project also attend relevant workshops and online courses. Furthermore, 3Rs and license matters are reviewed and protocolled in a separate agenda item in our weekly labmeetings.

161. The regulation of platelet function as a central mechanism for the control of cardiovascular function and development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Platelets, Thrombosis, Heart attack, Stroke, Obesity

Animal types	**Life stages**
Mice	adult, embryo, juvenile, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand the roles of specific proteins (e.g receptors, enzymes such as kinases, phosphatases, cyclases, ion channels and other intracellular cell signalling proteins) in (A) the regulation of the function of platelets, and the implications of these in blood clotting and thrombosis, and

(B) their roles in additional processes in which platelets are implicated including obesity, vascular and lymphatic development, vascular remodelling, and inflammation. Using our increased understanding of the processes that control platelet function in health and

disease, we aim to establish more effective strategies and medicines to prevent thrombosis and other conditions in which platelet function is implicated.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

When blood clotting occurs within blood vessels, a condition known as thrombosis that is often triggered as a result of blood vessel disease, this prevents the flow of blood to tissues and organs that lie downstream. Thrombosis is the principal cause of heart attacks and strokes. Platelets are blood cells that initiate blood clotting, whether to prevent bleeding or cause thrombosis. While considerable success has been achieved in recent decades in the development of drugs that target platelets to prevent thrombosis, currently available treatments are ineffective in many patients, while others suffer serious side effects including bleeding. Understanding of the complex mechanisms that regulate platelets in health and disease is important for the development of more effective, more refined, and more specific and safer anti-platelet medicines to prevent or treat thrombosis. The ability to adjust platelet reactivity in an individual, potentially through targeting multiple processes, will enable more precise control increasing efficacy thereby reducing the likelihood of thrombosis, while maintaining effective blood clotting where this is needed. This project is expected to result in the identification of new drug targets, understanding of the effects of genetics and chronic conditions such as obesity on pre-disposition to thrombosis, and characterisation of combinations of mechanisms that may be modulated by new medications.

This work complements extensive analysis of the regulation of blood clotting in humans by the applicant, and the development of new analytical and mathematical modelling methods to provide treatments targeted to specific patients (precision medicine).

What outputs do you think you will see at the end of this project?

At the end of this project we will expect to have

1. Identified new mechanisms, and the proteins in platelets that control these, which control the functions of platelets, and therefore regulate blood clotting.

2. Established which of the mechanisms identified in (1) are essential for proper blood clotting, and which may be involved in abnormal blood clotting which leads to heart attacks and strokes.

3. Determined which of these mechanisms or proteins may be effectively targeted in the development of new medicines to prevent heart attacks and strokes.

4. Discovered the effects of obesity and associated metabolic disease during pregnancy on platelet function and therefore levels of blood clotting in offspring when also exposed to a high calorie diet. This will provide mechanisms to help design new therapies to combat the impact of poor diet in pregnancy on future generations.

Who or what will benefit from these outputs, and how?

The key benefits will be to human health. Cardiovascular diseases (CVDs) are the single largest category of disease which leads to poor health and death in the UK. In the last year around 166,000 deaths were caused by CVDs, with a large proportion due to abnormal or un-necessary blood clotting. This equates to a heart attack every 8 minutes in the UK. The knowledge gained from this work will lead to the development of new medicines or measures to reduce the risk of developing CVD, and better therapies to treat those already affected. This work will be associated with extensive population and clinical studies, which allow our discoveries in mice to be transferred to human benefit. Following the identification of new target proteins or processes within platelets that may form the basis of new anti-thrombotic strategies, we would anticipate the development and preclinical testing of new drug candidates to take between 5 to 10 years. Platelet regulation is complex, and some experiments may lead us to conclude that a mechanism should not be targeted to prevent disease, and knowledge of this will be equally important for researchers of blood clotting to understand.

Abnormal platelet function can cause serious disease symptoms that are less obviously related to the mechanisms that cause heart attacks and strokes but are nonetheless life-threatening. Our work has identified why and how blood clots form in the lungs and other organs of patients with severe COVID-19 infection. We have indentified abnormalities in the immune responses of these patients to the COVID- 19 virus that trigger excessive clotting. Importantly we have also identified existing drugs that specifically prevent the abnormal clotting in the laboratory, and are currently testing the effects of these in clinical trials. This example demonstrates how our research may lead to new treatments that we hope will prevent deaths that are caused by abnormal blood clotting.

We will disseminate all of our research findings to other scientists working in this field through research publications and conference presentations, maximising the potential contribution and translation of our work for human benefit. Where appropriate we will also discuss our work with the general public, engagement with which has increased substantially due to the COVID-19 pandemic.

How will you look to maximise the outputs of this work?

A number of avenues will be used to maximise the outputs from this work. This will include publication in high ranking scientific journals, and presentation at internationally leading research conferences.

Within the research group we are experienced in the art of drug discovery through high throughput screening and the development of biologics, and therefore will be able to take

promising aspects of the work forward in the development of new medicines. We interact extensively with industrial researchers in the pharmaceutical and biotechnology sectors, and have well developed networks to explore the development of therapies based on our work. Examples of this include work to explore the potential re- purposing of existing new drugs used in the treatments of haematological cancers for the prevention of thrombosis, refinement of drugs to reduce myeloma treatment-associated thrombosis, and the repurposing of immune-modulating drugs to prevent COVID-19 associated thrombosis (with clinical trials underway).

Due to the important potential impact on human health that is associated with our research, we frequently engage with the media to inform the public of our research and the importance of measures that may reduce risk of CVD. Continued interaction with the media in association with this project is envisaged, particularly where the outcome of work (for example experiments to determine the effects of maternal obesity on blood clotting levels) may lead to new public health advice policies.

Species and numbers of animals expected to be used

- Mice: 5,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To determine the roles of specific platelet proteins and the processes that these control in bleeding and clotting diseases we presently have no alternative than to test this using animals, noting that all research prior to this is conducted using blood obtained from humans. The similar circulatory systems in humans and mice, and very similar physiology of blood platelets between the species has led to the mouse being adopted internationally as the most appropriate animal in which to study platelet function in the complex circulation in health and disease. This also holds the major of advantage of being able to use genetically altered mice, which allows questions to be addressed that would not otherwise be possible. This is because platelets lack a nucleus, which prevents their production in cell culture or the use of molecular biology techniques to manipulate the levels of specific proteins, or introduce mutant forms of a protein. The experimental approaches that we have established using mice have become acknowledged as the principal pre-clinical experimental approach in the development and testing of drugs to combat thrombosis and related disorders. We have led the establishment and refinement of these experimental approaches in the UK, working closely with colleagues internationally who were responsible for the development of some of the laboratory technology that we have implemented, and others who have also adopted these techniques in locations around the world. The wide adoption of this approach

internationally allows us to compare our experimental outcomes and data with the wealth of published literature, and collaborate more effectively with other researchers.

The breeding of mice involves the use of young adult mice, and the generation of juveniles that are either used for further breeding or within our experiments. Bleeding assays may use adult mice at any age, although most of our techniques to analyse thrombosis require young adults to be used.

Typically, what will be done to an animal used in your project?

The most commonly used procedure in this project (up to 5000) will involve the breeding of mice that have been genetically altered, so that either specific cells or all cells in the body either lack a specific protein, gain a specific protein or a protein is replaced with a mutated form of a protein. This allows us to understand the role of this specific protein in health and disease. In most cases pregnancy progresses normally (21 days) and mice grow and suffer no illness, pain or stress. In some cases altered blood clotting may cause adverse effects such as uncontrollable bleeding, so mice are observed very carefully, even though breeding of mice is routine and straightforward. Genotyping is performed to assess the genetic makeup of mice, and for this a small piece of tissue is obtained from the ear, which is considered a minimally invasive way to obtain genetic material. Where ear notching is used for indentification, removed tissue will be retained, resulting in no additional procedures being required for genotyping.

The mice that we breed, and sometimes mice imported from other laboratories are used to determine whether thrombosis is reduced or increased and whether normal blood clotting is compromised.

Bleeding assays (up to 1500 mice over 5 years) are performed by making a small incision at the tip of the tail and measuring blood loss or the time that it takes for bleeding to stop. This takes no more than 30 minutes to perform and mice that continue to bleed after 20 mins are killed humanely. This surgical procedure is performed under general anaesthesia and in most cases mice are not allowed to wake up following this. Rarely, animals may be allowed to recover and used subsequently to measure thrombosis. Thrombosis, another surgical procedure is also measured under general anaesthesia without recovery (up to 1500 mice over 5 years). This may be achieved in a number of ways, following dissection of specific vessels to that they can be observed using a video microscope, and thrombosis is triggered either by using a laser, or by application of chemical to a vessel, or by physically manipulating a vessel. Thrombosis is measured and evaluated by microscopy and sophisticated software for analysis of data. This type of analysis allows multiple measurements from a single mouse, in experiments that last up to 2 hours in duration.

In some cases mice will be treated before blood sampling, or analysis of thrombosis or bleeding, with anti-thrombotic drugs or other agents that are expected to modulate platelet function. These drugs will be injected either into an exposed vein or canulated carotid artery, under the skin or into a body cavity, or administered in drinking water or by oral

gavage. Mice may also be fed a high calorie diet to induce obesity, prior to analysis of platelets.

What are the expected impacts and/or adverse effects for the animals during your project?

In most cases the breeding of genetically modified mice will result in mice that may have mildly defective blood clotting, but are essentially healthy. On occasions it is possible that a genetically modified mouse may suffer from unhealthy bleeding or thrombosis, although in our experience this is very rare. Should this occur and exceed acceptable limits of severity (mild or moderate), mice will be killed humanely as soon as possible.

The experiments that we do with the genetically modified mice to test bleeding or thrombosis will be performed under general anaesthesia, so the mice will not feel anything and in most cases will not be allowed to wake up after the experiment. Some mice used to test bleeding or thrombosis will have been pre-treated with medicines of other agents that are expected to modify platelet function or number, which may result in reduced or increased platelet function and/or blood clotting. This may result in an increased chance of extended bleeding (particularly during procedures) or thrombosis that would cause the mice some pain or distress. Our experience suggests that this would be a rare occurrence, affecting less than 10% of mice treated in this way. Other mice used in these procedures will have been treated to induce obesity. This will result in weight gain or conversely a failure to thrive and consequently a reduction in weight and potentially hair loss and skin irritations. Our previous work indicates that elevated calories eaten by pregnant mothers and their offspring increase the levels of platelet function. Based on previous experiments we do not expect increased levels of platelet function to be associated with any clinical signs in the mice.

On rare occasions (<10% of mice used to measure bleeding) mice will be allowed to recover following analysis of bleeding and subsequently used in experiments to measure thrombosis provided that their health has returned to normal, and that they exhibit no continued effect of the bleeding tests (e.g. re- bleeding) and that they continue to thrive.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The largest scale procedure conducted in this project is the breeding of genetically altered mice (5000 mice), a protocol that has a MILD severity limit.

The measurement of bleeding and thrombosis is conducted under general anaesthesia. All thrombosis testing and most bleeding testing are done without recovery. Less than 10% of mice in which bleeding tests have been performed will be allowed to recover before use in thrombosis tests. The mice used for these protocols may be administered agents or drugs

that modulate platelet function or number. A MODERATE severity category is appropriate, and therefore the severity limit for tests of bleeding and thrombosis is MODERATE although for >90% mice, only MILD severity is experienced.

Some mice will be fed on a high calorie diet during pregnancy. The offspring resulting from these (and females that are not fed a high calorie diet) may also be fed a high calorie diet. This may result in weight gain or loss, and failure to thrive. Adverse effects are expected in no more than 5% of animals and will be used on a protocol with a MODERATE severity classification.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Platelets control blood clotting which is important in preventing uncontrolled bleeding. These cells also trigger unwanted blood clots within the circulation (thrombosis) which causes heart attacks and strokes, as well as a number of additional life-threatening conditions. While we do obtain a great deal of information about platelets and their roles using human blood samples in the laboratory, determination of the role of specific proteins in the control of platelet function and thrombosis development can only be done within an intact circulation. This is because blood within blood vessels is exposed to special conditions such as blood flow and chemical messages from other cells including those of the blood vessels. These tests are particularly important because they will lead to us identifying proteins or processes that may be targeted to prevent heart attacks and strokes. Abnormal bleeding is a potential side effect of targeting proteins that modulate platelet function, and therefore it is also important to established whether bleeding is altered in our mice, to indicate whether specific proteins might make good 'drug targets' which do not cause adverse bleeding.

Sometimes we need to study platelets from mice that have been genetically altered (transgenic) to lack a specific protein, or to produce an abnormal version of a protein. These mice may be used to measure thrombosis or bleeding (as above) or blood samples may be obtained from these mice and studied in the laboratory. Our need to breed transgenic mice stems from the fact that there are no reliable methods of generating platelets in the laboratory from bone marrow cells or cell lines. This means that the only source of genetically altered platelets is from an animal model (work is underway in some laboratories to overcome this limitation and produce platelets for patients, but realising this ambition will require several more years of research). Previous studies have utilised genetically altered mice to identify and delineate the processes involved in platelet

activation. Data obtained from the use of genetically altered mouse models in this application would therefore be directly applicable to published studies.

We have previously shown that platelets in offspring may be programmed by the diet of their mother during pregnancy, making the platelets more likely to cause clot formation, particularly when the offspring are themselves exposed to a high calorie diet. The precise mechanism and duration of this effect is not understood. This has substantial implications for human health, but experimentally modifying the diet during human pregnancy would be neither ethical or practical, and therefore we have established a mouse model to investigate this aspect of our work. The changes produced during pregnancy are complex, and cannot be recapitulated by cells in culture, and therefore we need to induce obesity and metabolic changes during pregnancy in mice. The specific use of mice allows us to take advantage of the similar composition of blood vessels and blood in mice and humans, and to use established models of thrombosis and bleeding (see above) which may be compared with extensive published scientific studies.

Platelets are also involved in a number of important system effects in the body including the development of certain types of vessels (blood and lymphatic) and the control of inflammation in blood vessels and tissues. While much of the underlying biological studies are performed using cells in culture, cell lines and human platelets, the specific processes that regulate these functions require confirmation and detailed study in a whole mammalian system.

Which non-animal alternatives did you consider for use in this project?

Extensive work with human platelets and other blood cells is always performed before we consider using mice to study these cells and their impacts on health and disease.

While presently studies in animals are not completely avoidable we have been working to reduce our reliance on animals in our research, and as a consequence we have been able to make considerable reductions in our planned work with animals in the next 5 years, to approximately 50% reduction in comparison with the project that this replaces. This has accured for a number of reasons that span the 3Rs principles. The over-riding development in our work has been our ability to exploit our current understanding of platelet regulation to develop a more patient-facing and translational focus. This reflects that maturity of the science in this area and a range of technical innovations, including our development of new assay systems, clinically relevant tests and computational and software resources that employ machine learning to analyse complex data. Indeed, these developments have enabled us to respond rapidly to the COVID-19 pandemic resulting the discovery of why seriously ill patients develop blood clots, and the establishment of a clinical trial to test drugs that may alleviate this.

Within the group we have a strong focus on why we do what we do, to assess what is really necessary in order to achieve the aims of our research while ensuring the highest quality of outputs. This is aided by substantial animal research expertise and knowledge of

governance in this area, supported by a team member who has received specialist training in the care and welfare on animals used for research. As scientists we have increasingly pushed back against manuscript reviewers that request work to be repeated but with small changes or the use of a different experimental model or mouse strain. These types of requests are often ill-considered and simply following these views is not appropriate from an ethical perspective. Models are models. They do not necessarily replicate perfectly human disease and biology. So attacking a problem using multiple animal approaches potentially just results in multiple different outcomes and confusion. Therefore, where we consider animal experiments to be necessary, careful planning and selection of appropriate approach is essential, prior to initiation of the work. This may involve pilot studies to establish which approach is apprioriate to test our hypotheses. These principles guide our approach as a group to experiments using animals and decisions are made following considered discussion within the group (e.g. at lab meetings) ensuring accountability and the development of a mindset that challenges and does not follow trends in research without question.

We have also been working for several years on computational approaches which we hope in the future to allow us to further reduce our reliance on animals in our research. We have developed a suite of mathematical models that are able to simulate the activation of platelet function, and the impact of anti-platelet drugs on this. This work, which has been developed with support from the British Heart Foundation is called the Virtual Platelet, and will allow us to conduct experiments “in silico” for the purpose of understanding the basis of variability in platelet function in the population, for drug discovery (including understanding the impact of targeting more than one molecule simultaneously) and diagnosis on the basis of platelet dysfunctions. These models currently include simulations of both human and mouse platelet function, which further allows changes in platelet function in humans measured in vitro to be related to potential impact on thrombosis risk or size. Data collected within this project will contribute to the development and testing of these mathematical models. Importantly these models will also allow us to test hypotheses for which lab-based experiments would not be possible, feasible or ethical using animals. This will in the future allow us to reduce our reliance on the use of animals in our work - a goal which, along with improving the translation of our research to benefit patients, motivates this work.

We are also involved in the development of 'vessel on a chip' experimental approaches to study platelet function ex vivo supported by research funding from several organisations.

Why were they not suitable?

Whole systems approaches are the only way currently to test the importance of specific proteins and their mechanisms of regulation of platelet function, with respect to diseases in which platelets are involved because of the complexity of the processes that require the many interrelated body systems to be functioning normally. We are making good progress in the development and 'characterisation of vessel on a chip' devices and their characterisation. Although these techniques have not yet reached sufficient maturity and

consistency for routine use, our current data suggest that this will be a realistic means to reduce, refine and replace the use of animal in platelet research in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

During this study we anticipate investigating the role of 10 proteins or processes in detail that are required for the control of platelet function. Five of these will be expected to require cell-specific (platelet/megakaryocyte) gene deletion, which required a larger breeding colony to obtained suitable genotypes and litter-mate controls. The numbers for maintaining strains are based on the use of published best practice guidelines for optimising colony size and using techniques such as cryopreservation of gametes and embryos where appropriate and possible. This will allow colonies to be maintained a suitable level when required to supply sufficient numbers of offspring for required experiments. Experiments will be designed to minimise animal numbers through the use of tools such as the Experimental Design Assistant (NC3Rs), power calculations and with experience of carrying out similar experiments under previous projects.

During the last project we have refined our scientific approaches to maximise the use of in-vitro and in- silico methods (as these have come available). This has allowed us to reduce the type and number of in-vitro animal studies that need to be done. In addition, we have optimised the number of animals needed for breeding and maintaining animal lines through further improvements in the health status of the colonies and archiving lines whenever possible. The latter has been done with facilities that allow access to these lines by other researchers in due course, and thereby reduce the necessity for others to re-create these lines.

Through this continuous application of the strategies to minimise the use of animals, we have been able to make a 50% reduction in use of animals from the previous project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In most cases the levels of differences observed between different genotypes of mice within the context of the experimental approaches used are relatively high, and therefore it is possible to test hypotheses with small sample sizes. This is supported by power calculations for the specific experimental question and design and extensive experience in the use of the models proposed. Where new transgenic mouse lines are used we will

employ the Experimental Design Assistant developed by NC3Rs to formulate the most effective design which minimises animal use without compromising statistical power.

The following measures form routine components of our experimental design:

- Power calculations will be used to ascertain the minimum number of animals required to be used in a single experiment, to detect meaningful physiological effects. For the techniques within the project a power of 90% is realistic while minimising animal usage.

Mouse usage will also be minimised in the following ways:

- Use of efficient statistical designs to increase precision, e.g. use of litter mates as controls

- Use of efficient breeding protocols that minimise the production of unwanted animals

- Utilisation of heterozygous surplus mice to renew the breeding pairs used

- Use of modern efficient laboratory tests that allow fewer animals to be bred

- Researchers will be blinded to mouse genotype or treatment and animal selection randomised.

- We will seek statistical advice to help with experimental design and during data analysis to maximise the quality of data, while minimising variability. We have access to excellent statistical design and analysis expertise at this institution and within the applicant's BHF Programme Grant Team. Mathematical modelling for experimental design is also available within the applicant's research group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where new experiments are to be performed, and where new strains of mice are to be used, a pilot study will be conducted in accordance with N3CRs guidance (https://nc3rs.org.uk/conducting-pilot- study), in order the test the appropriateness of experimental design, the development of effective instructions to project researchers, determination of skills required and suitability of available equipment. This will enable the variability of results to be determined allowing power calculations to be performed for appropriate sample size determination, identify unexpected adverse effects and define early humane endpoints.

Experiments will be coordinated to ensure resources such as specialist analytical equipment are available to maximise use of samples and tissues. Where appropriate tissues will be frozen and stored for use in future studies or by others.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice (unaltered inbred strains and genetically altered mice) will be bred during this project. The offspring (and for unaltered inbred strain breeders at the end of their breeding life) will be used in protocols to assess the effects of genetic alterations on bleeding times, experimentally induced thrombosis and the modulation of platelet number. The effect of obesity and associated metabolic dysfunction on these outcome measures will also be assessed.

All mouse strains used in this project will either be transferred from the previous project or will be sourced from commercial suppliers or collaborators. We do not anticipate generating new lines under this project. As a result any adverse effects that may result from the genetic alteration will be well characterised. The majority of genetically altered mice used in our studies (and all mice used to date) exhibit no adverse effects, despite platelet function in some cases being altered substantially. This likely reflects the fail-safes that exist within blood clotting systems, to ensure that blood clotting occurs when it is really needed. In some cases removal of a gene systemically may be known to cause substantial harm or may be incompatible with development or survival. In these cases conditional deletion techniques are used to target deletion to the bone marrow cells that form platelets (megakaryocytes) and therefore also platelets, or other blood cells or blood vessel cells.

Mice will be used to assess bleeding and thrombosis, both of which will be performed under general anaesthesia. For analysis of thrombosis this will be without recovery, and for bleeding this will usually be without recovery. This ensures minimal levels of pain and suffering throughout these procedures. In some cases mice will be pre-treated with drugs or agents that either alter platelet function or the numbers of platelets in the circulation, before analysis of bleeding or thrombosis. All injections will be performed in accordance with minimal severity guidelines (e.g. Morton et al., 2001 Laboratory Animals, 35, 1-41). The injection should result in only transient pain and distress and no lasting harm.

Substances to be administered are not expected to cause pain or inflammation at the site of injection and any physiological effects are not expected to result in clinical signs. When a substance is to be administered to a particular strain for the first time, a literature search will be performed to see if information about the potential effects of the combination is available. Also a pilot study will be done so that any potentially significant adverse effects

can be assessed. These animals will be frequently monitored and those experiencing any unexpected adverse effect, will be killed humanely.

Finally, in some mice we will induce obesity through high calorie diet before mating and during pregnancy, while others will receive a normal diet to maintain normal weight and metabolic profile. Offspring from normal weight and obese mothers will also receive either normal or high calorie diet. A high calorie diet carries a low risk of causing a failure to thrive, and poor coat and skin conditions , although in our experience this is rare, and obese mice may display early stages of type 2 diabetes

(insulin resistance and elevated blood glucose levels). This approach has been refined in previous studies by colleagues, to minimise sample sizes and levels of suffering.

Why can't you use animals that are less sentient?

Similarities in the cell biology of platelets and the circulatory systems of humans and mice have led to mice becoming the non-primate model of choice in which to most closely replicate human blood clotting and thrombosis while also be amenable to the use of genetically altered mice. Less sentient animals such as zebrafish are used to study the molecular mechanism that control blood clotting, but it is not possible to study injury or vascular disease as would be experienced in the circulatory system of humans, and therefore for the study of bleeding and thrombosis a mammalian model is required. Our continued use of mice and refined experimental procedures will allow our work to continue to be set in the context of, and compared with, extensive literature of studies conducted using similar approaches, and to allow comparison with existing data from our own research.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our methodology will continue to be refined, with recent examples including new analysis techniques and statistical approaches that increase the information that may be gained from intravital microscopy analysis of thrombosis. This will include the continued development of the Virtual Platelet, and the establishment of more appropriate mouse models of platelet regulation that incorporates underlying insulin resistance that is present in many patients for whom anti-platelet therapy is required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs website is used by my group as the primary source of published guidance which draws on extensive published academic studies and tools for appropriate experimental design. While we do look at primary literature to support for example refinement in techniques, the NC3Rs has compiled some excellent resources and continually updates and presents the latest evidence to support best practice. A good example of this is the Mouse Grimace Scale, and guidance on humane euthanasia which

are used in our work, and is supported by e-learning resources. Researchers will also refer to the PREPARE guidelines (https://norecopa.no/PREPARE) to assist in the preparation of new experiments and associated experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will continue to use the NC3Rs website as a first source of information and training. This is an excellent resource in terms of training, best practice and emerging refinements that may be considered. Members of the group will be expected to attend webinars, including training in the use of the experimental design application and recordings of relevant previous sessions. These include efficient management of genetically altered mouse colonies, organ on a chip technology, the use of the PREPARE and ARRIVE guidelines 2.0, best practice in experimental design, and mouse handling made easy: reducing anxiety in mice and their handlers.

We have a learning platform (hosted on the Microsoft Teams platform) which is dedicated to dissemination of 3Rs-relative materials, advice and training and new developments to animal centre users, which is coordinated by a dedicated information officer and overseen by our veterinary surgeon. This is also used as a channel for information from the Home Office to users, and for sharing of good practice locally.

162. Molecular determinants of brain development

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain, development, neurogenesis, migration, circuits

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand the roles that different genes play during the development of the brain, both in normal conditions and in the case of neurodevelopmental disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The brain is the most complex organ in our body. It contains millions of neurons that establish trillions of contacts between them to ensure proper function. In addition, a similar amount of non-neuronal cells also play essential roles by supporting neuronal function in different ways. Putting together such a complex organ requires precise regulation of multiple processes. Many different genes are involved in the different stages, from the

production of the neurons to the recognition of the correct partners for circuit formation. Understanding how the brain is formed is important because defects during development have significant consequences on brain function that negatively impact the quality of life of those who suffer them and their families.

What outputs do you think you will see at the end of this project?

We expect to generate new information about the role of different genes during development of the brain, particularly of the cerebral cortex. One of those genes will be PCDH19, a gene mutated in a form of epileptic encephalopathy. We will publish our results in peer reviewed journals and present them in conferences in the form of posters or talks. The work conducted under this project licence will also be published in PhD theses.

Who or what will benefit from these outputs, and how?

Psychiatric and neurological diseases pose a heavy burden not only on society, but also on the health systems of many countries. The estimation of the European Brain Council as of 2010 was a yearly cost of €798 billion for the treatment of brain conditions, which represented 35% of Europe's total disease burden ("Cost of disorders of the brain in Europe 2010" (http://ebc- brussels.org/wpcontent/uploads/2015/07/Cost-of-Disorders-of-the-Brain-in-Europe-EurNeuro2011.pdf). Importantly, those numbers are now considered to be an underestimation and studies are ongoing to update them, exemplifying the importance of research into brain development and function.

The research proposed for this project comprises basic neurobiology, but it could also eventually be relevant from a clinical point of view in the future. The expected results would translate into two potential benefits:

First, it will generate new knowledge about the function of several genes, involved in distinct processes during cortical development, contributing to our understanding of brain development and function. This will benefit other researchers working on the field, but also clinicians dealing with patients affected by neurodevelopmental diseases, by providing new candidate genes for diagnostic screening.

Second, it will shed light on the pathophysiology of EIEE9, a human disorder caused by mutations in the PCDH19 gene (one of the genes that we will study), and potentially of other disorders, providing information to affected families to help them understand the disease.

A good understanding of the different molecules and processes involved in the development of the brain, specifically the cerebral cortex, is also essential when new risks are identified that can severely affect the mental health of the population (like the recent Zika virus epidemic). Such knowledge also forms the basis for the development of targeted interventions, in the form of drugs, behavioural, or others.

How will you look to maximise the outputs of this work?

There are several ongoing or planned collaborations that will help maximise the outputs of this work, including researchers at universities in the UK and Europe. The different collaborations focus on distinct aspects of the project, from neurogenesis and fate determination to circuit assembly and function, and we expect them to significantly enhance our outputs.

In addition, we will disseminate our findings through peer reviewed research papers in scientific journals and at meetings and conferences, some of them including clinicians and affected families (in the case of PCDH19). Furthermore, we will continue our ongoing involvement in public engagement, which focuses on children and young adults, mostly (but not exclusively) from disadvantaged backgrounds.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For this project the chosen species is the mouse. Most of our work focuses on the cerebral cortex, so we need to use a model animal with a cortical structure similar to that of humans, if we want to gain relevant insight that can be at least partially translated to human development. Mice are the lowest vertebrate group that has a six-layered cortex and are close enough to humans to reveal principles of brain development. Because mice have been extensively used as model animals in this field, there is a wide body of research to build upon and findings can be related to previous results.

A considerable part of our work is carried out in embryos, as this is the stage at which the processes of neurogenesis, fate determination and most of migration occur. However, to study the consequences that any alterations during development have on brain function, we need to use postnatal and adult animals.

Typically, what will be done to an animal used in your project?

The main techniques to be applied to the animals in this project are:

- breeding of genetically altered animals

- administration of substances by injection or in the drinking water: this can be done to a pregnant animal to have the substances reach the developing embryos, or to an adult animal to directly label specific cells. Injections to pregnant animals are a quick procedure; for adult animals they may require anaesthesia to direct the injections to specific location within the central nervous system.

- tissue collection for identification and analysis purposes: these are very short procedures. For analysis, they are carried out either after humane killing of the animal, or after terminal anaesthesia to the animal.

- in utero electroporation: this surgical procedure is performed on pregnant dams. It typically lasts less than 30 minutes and animals recover quickly after it.

- behavioural analysis: these procedures are mild and have minimal effects on the animals.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects that we expect are:

- transient increase in stress from behavioural analysis
- transient pain from tissue collection for identification/analysis
- postoperative discomfort
- very rarely post-operative complications

Most of the above-mentioned effects are expected to be of mild severity. Surgery is considered to have a moderate severity limit, but refinement methods should minimise any discomfort or pain to the animal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect a majority of animals to be in the sub-threshold and mild categories. These are the animals that are used for maintaining the colonies, that only receive an intraperitoneal injection, or that are used in most behavioural analyses. Our experience from the last 6 years is that about 75% of animals fall in those two categories. An additional 10% are animals under the non-recovery category.

Regarding moderate severity, the proportion we expect is less than 10%. Those are mainly the pregnant animals undergoing surgery for in utero electroporation and adult animals that receive injections in the central nervous system.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The developing cerebral cortex is a very complex structure. It receives cells and signals that originate outside the cortex, and its cellular and spatial organisation, which is crucial for proper development, changes as development proceeds. At present, there are no non-animal models that can replicate these complex conditions. Also, to gain insight into the development of the human brain, a mammalian species needs to be used because lower vertebrates do not have a six-layered cortex.

Which non-animal alternatives did you consider for use in this project?

We have considered laboratory approaches which do not use live animals such as using mouse or human embryonic stem cells differentiated into neurons and the use of cerebral organoids.

Why were they not suitable?

The non-animal alternatives mentioned above will be used whenever a basic mechanism is studied that does not depend so heavily on the complex architectural and signalling arrangements of the live animal cortex. Mouse embryonic stem cells differentiated into neurons are already being used in the lab to study biochemical processes and neuronal responses. However, organoids still suffer from a lack of reproducibility and neither of the two alternatives allows for the study of behavioural changes resulting from developmental impairments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number has been estimated taking into account:

- the diversity of mouse lines needed to fulfil the objectives of the project
- the average number of animals used per year in the last 6 years
- the number of researchers in the group currently working with animals (2)

- the number of researchers that will join the group during the duration of the project (between 1 and 3)

- the ongoing and planned collaborations with other research groups

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All calculations were made using the NC3Rs Experimental Design Assistant and current data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To ensure that animal numbers are kept to a minimum, besides experimental design, the following aspects will be considered:

1) Animal breeding will be optimised to reduce the number of surplus animals created that are not used in experiments. All researchers working on the project will watch the webinar “Best practices for efficient mouse colony management” that is available from the Jackson Laboratories. In addition, we perform a monthly audit of the mouse colony to ensure proper management.

2) Expression analysis of genes via publicly available databases and datasets prior to the start of any experiments will provide information about possible roles during development. Based on that information, experiments involving animals will be limited to meaningful hypothesis, i.e. if a specific protein is not expressed in progenitor cells, no experiments will be carried out to assess a role in neurogenesis.

3) Animal samples will be clearly labelled and properly stored to maximise its use through the course of the project. This is particularly relevant because analysis of developmental processes implies that experiments are required at multiple time points, including pre-natal stages. Because only whole litters can be harvested at embryonic stages, careful planning and consideration of future experiments will ensure that surplus samples are processed in ways that allow future use. This can also apply to animals that are used for behavioural experiments, which can then be perfused to generate a bank of tissue ready for further analysis.

4) Researchers will receive extensive training for the procedures where technical expertise significantly influences the success rate. The use of intrauterine manipulation techniques can in many cases eliminate the need to create knockout or knockin animals, thus reducing total animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of species and model:

To gain insight into the development of the mammalian isocortex, a species with a six-layered cortex needs to be used. For this project the chosen species is the mouse. Mice have an isocortex and are close enough to humans to reveal principles of brain development. Because mice have been extensively used as model animals in this field, there is a wide body of research to build upon and findings can be related to previous results. Most of the experiments will be carried out on wild type animals, but some genetically modified ones will be needed as well. They will primarily be already characterised reporter lines with sub-threshold to mild phenotypes. For knockout (KO) animals that might be imported into this licence, careful monitoring will be implemented to make sure that any adverse phenotypes do not exceed the severity limits.

Choice of methods:

The methods that will be used in this project include immunohistochemistry, in situ hybridisation, in utero manipulations, neuronal tracing and behavioural assessments. To maximise refinement, many of them are used ex vivo, on material obtained from animals that have been humanely killed. In vivo methodologies such as in utero manipulations will be used to address questions where the complex context of the developing cortex has to be preserved to obtain conclusive results. By affecting only a proportion of cells in the whole brain, in utero manipulations are more refined than conventional knockouts because the effect on the animal as a whole is reduced.

Surgery will be performed under general anaesthesia and under aseptic conditions to prevent any post- surgical infections. Analgesics will be administered as standard to minimise suffering, and animals will be monitored regularly to ensure their wellbeing.

Training of these procedures is done in a very gradual step by step way, due to the technical skills needed. No greater loss is expected during training of new licensees / members of the group. Training for intracranial injection into early post-natal animals will be obtained from other groups performing this technique at the home establishment, or from collaborators in other universities. No injections will be performed until the licensees are deemed competent by an experienced trainer.

Why can't you use animals that are less sentient?

The six-layered cortex (or isocortex) is present only in mammals, so invertebrates like the fruit fly or lower vertebrates like the zebra fish, although useful for some studies (genetic interactions, cascades), cannot be used in this project. Mice are the lowest vertebrate group in which the experiments required to complete the project can be performed. They have an isocortex and their patterns of cortical development are similar to those in primates. Despite a much smaller size and a lower complexity, much of what we know about cortical development in humans has been contributed by studies carried out in mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Whenever we receive or generate new strains of genetically altered animals, we will monitor them closely, in collaboration with the animal technicians. If any adverse effects become apparent, we will seek the help of the named veterinary surgeon to assess the severity of the phenotype and discuss how to adjust our analysis to avoid animal suffering. This might include restricting the analysis to earlier time points (before the appearance of symptoms, or before the symptoms worsen), using mutants in which the gene has been deleted only in specific tissues, or using techniques (such as in utero electroporation) to reduce the number of neurons affected and, therefore, any assocaited negative effects.

Intrauterine surgery will be performed under general anaesthesia in a form and dose suitable for the species and under aseptic conditions to prevent any post-surgical infections. Analgesics suitable for the species will be applied peri-operatively as standard to minimise suffering, and animals will be monitored regularly (at least twice on the day of surgery, then once daily until the end of experiment). A general pain-scoring chart will be used to record the well being of the animals, as well as any adverse effects specific to the operations performed on that animal. To reduce the stress levels of animals used in behavioural analysis, they will be handled prior to the experiment, so that they can get used to the researcher.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines published by the N3CRs and any other refinement measures that are published in the literature (particularly in methods papers). Our collaborators are also very experienced and have excellent track records in their respective areas, being able to provide further guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive the monthly newsletter from the N3CRs by email, allowing us to stay on top of advances in the 3Rs. We will also attend local and regional 3Rs symposia and keep our

communication with the animal technicians and NACWOs, who can be very helpful, especially with the implementation of refinement advances.

163. Neuronal and glial function and dysfunction across the life-course

Project duration

5 years 0 months

Project purpose

Basic research
Key words

brain, neurodevelopmental disorders, neurodegeneration, neuron, glia

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our overarching aim of our programme of research is to determine how cell to cell communication in the brain is altered in diseases or disorders which affect either its normal development or cause its degeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

An estimate from 2010 indicated that the financial burden in the UK of brain disorders (neurodegenerative and neurodevelopmental diseases, psychotic disorders, clinical

depression, anxiety and addiction) was around £70billion. Fundamental research into the mechanisms of brain disorders of the sort we conduct are the first step in understanding how they can be either prevented or treated. Given the ability to mimic the genetic bases in rodents of many of the disorders we study this gives us hugely valuable information about the origins of disorders, whether they show common traits in terms of the dysfunction they cause and whether interventions either genetic or pharmacological can ameliorate the dysfunction that is present. This Licence seeks authority to conduct experiments which are aimed at increasing fundamental knowledge about ‘normal’ neuronal and glial function and how such function is altered in genetically altered animals (GAAs) that we use to model neurodevelopmental and neurodegenerative (including excitotoxic-induced) diseases (NNDs) and complements work we also do using human pluripotent derived neurons and glia to understand these disorders.

What outputs do you think you will see at the end of this project?

The major form of output from this work will be publications in peer-reviewed scientific journals. Since 2016 the individuals named in this application have published 77 papers; together these outputs have already been cited more than 1000 times. Indeed the 10 publications that are co-authored by each of the named individuals account for more than 25% of all citations reinforcing the notion that our individual expertise when combined gives rise to impactful science. In addition to primary research papers, authoritative reviews will be published and we will continue to be (co)-authors on position statement/papers that influence the research field within which our work contributes.

Who or what will benefit from these outputs, and how?

The major beneficiaries of our research will be colleagues working in our and related-research areas. They will be informed of our findings primarily through our publications. Some of our research may offer the potential identification of novel therapeutic targets and thus would contribute to the first steps of the drug discovery process for the pharmaceutical industry. A longer term benefit will be the contribution of fundamental knowledge as to the mechanistic bases of the diseases and disorders we model. Arguably this offers hope to patients and their families that therapeutic interventions may be possible in the future given the huge clinical unmet need that currently exists.

How will you look to maximise the outputs of this work?

We publish our work in leading international scientific journals, ensuring that our local Press Office is aware of publications that are likely to have significant impact or are of interest to the general public, patients/patient families. In addition we highlight our work through Public Engagement activities at science festivals, patient support groups and other stakeholder events. Where possible we publish our papers to allow immediate Open Access (Gold) to allow anyone in the world to read about our findings. Complete datasets are available to researchers on reasonable request.

Species and numbers of animals expected to be used

- Mice: 14500
- Rats: 29000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Invertebrate model organisms have been used widely in the field of synaptic neurophysiology and while studies using such organisms inform our work the focus of our research requires mammalian central nervous system (CNS) tissue where the complement of neurotransmitters, their receptors and the overall architecture/structural units/function of the nervous system is closely related to that of humans. Rodents are the most appropriate species for our work not only because they are amenable to genetic manipulation but studies have identified that the key proteins that will be the subject of investigation are found in both rodents and humans. Our research programme spans disorders that affect the developing brain and the aged brain and as such we need to use animals of an appropriate age that reflects the disorder under investigation.

Typically, what will be done to an animal used in your project?

The vast majority of animals will be bred so that we are able to collect brain tissue from appropriately aged animals for subsequent ex vivo electrophysiological recording, biochemical or neuro-anatomical studies. In addition, some animals will be terminally anesthetized for prolonged periods to assess the impact of reduced brain activity on cellular communication as assessed subsequently by ex vivo electrophysiological recording, biochemical or neuro-anatomical investigations. A small proportion (25%) of animals will be allowed to recover for up to 72 hours prior to culling for subsequent ex vivo studies. Furthermore to assess the effects of increased brain activity some animals will be terminally anesthetized but prior to culling will subjected to non-invasive transcranial brain stimulation; to allow analysis of longer-term effects of electrical stimulation on CNS tissue, a small proportion (25%) will be allowed to recover from anaesthesia for subsequent culling up to 72 hours later. Related to decreased brain activity, some animals will be dark-reared so that they do not have visual experience in order that we can assess the impact of this loss of cellular communication in the neurodevelopmental

disorders we study. Seizures are a very common feature that humans with neurodevelopmental disorders experience and we will assess seizure susceptibility in our rodent models by exposing them to loud noises. Finally, the Licence will allow us to administer substances that would be expected to alter cellular communication or we will re-activate disease-causing genes whose activity has been previously 'silenced' to assess the potential for either reversal or amelioration of pathophysiologies caused by loss of specific gene function.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals may have the potential to develop a harmful phenotype, eg tumours, neurological signs, after a certain age but in the majority cases will be killed before reaching that age and if they do reach this stage they will be monitored daily to determine whether the defined humane end points have been reached. Some animals may occasionally exhibit absence-like seizures. These are not considered to be detrimental to the health of the animal. Animals with altered immune status will be maintained in a barrier environment thereby minimising the likelihood of compromising health. Daily monitoring and appropriate animal husbandry will identify any animal experiencing detrimental impact during housing. Protocols in this PPL are designed to minimise all adverse impacts.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals (both mice and rats) will experience only mild severity impacts - these will account for approximately 70-80% of all animals. The remaining animals (both mice and rats) will experience moderate severity impacts. No protocol on this Licence has a "severe" banding.

What will happen to animals at the end of this project?

Killed
Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Humans share >97% genetic identity with mice and rats and as such these rodents are models with which we can carry out experiments to understand how the brain works. Non-animal alternatives are extremely useful to getting us “part of the way” but ultimately we need to study the mammalian brain and mice and rats are the lowest order mammal in which this can be done reproducibly while having the ability to perform genetic manipulations that allow us to create structural validity of disease.

Which non-animal alternatives did you consider for use in this project?

Complementary research in our lab uses systems which allow us to express, in cell culture systems, proteins that may be affected in neurodevelopmental and neurodegenerative disorders. Such studies are extremely valuable in assessing the properties of these

proteins. Moreover, we make use of technologies that allow us to generate human neurons and glial cells from human skin cells - so-called induced pluripotent stem cell models. This research complements our work with rodent model systems.

Why were they not suitable?

Cell culture systems do not reproduce the exquisite cellular architecture nor all the different cell populations that exist in the brain. In addition, cell culture systems do not allow us to reproduce the circuit networks found in the brain that are so crucial for brain signalling.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

There are a large number of PIL holders (approximately 30) who work under the authority of my current PPL. The numbers estimated are based on my Annual Return over the past 5 years. For a given PIL holder using five animals per week, over an average of 40 experimental week in a year, this gives an average of 200 animals. Over five years, this equals 1000 animals and with 30 PIL holders then a total of approximately 30,000 animals. Our use of rats and mice depends on the nature of the experiment to be conducted but over the past five years we have used these in a ratio of 2:1 (rats to mice), hence giving the estimated number indicated above.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

It is essential that the number of animals we use allows us to collect data that are robust. We have many years' of experience in performing experiments using animal tissue and this allows us to make predictions, using statistical analysis based on previous data and the expectation of effect size, about the anticipated effect size we are likely to see and how variable that effect will be. Using this information we can estimate the numbers of experiments we need to carry out. Our experience indicates that for the effect sizes we anticipate we require between 8 – 10 animals to ensure statistical robustness. Good experimental design means that we assess drug effects alongside non-drug treatments or control tissue with that obtained from genetically modified animals. All PIL holders working under the authority of this PPL will be asked to take the local Research Optimisation Course that covers rigorous experimental design, research conduct, analysis and the reporting of animals research.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We encourage, where possible, that experimenters share tissue from the same animal which will reduce the overall number of animals required for experimentation. We seek advice from statisticians where appropriate when planning experimental designs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice, together with rats, represent the most commonly used mammal to study central nervous system function. While genetically-altered mice have been models of choice for more than two decades, recent advances in transgenic technologies, together with the larger brain size of the rat and the increased behavioural repertoire they display means that is it now possible to conduct studies of brain signalling and its dysfunction. Such studies allow for cross-species comparisons which is essential when one considers the potential for translating findings from 'basic' research to potential therapeutics. The majority of the GAAs we study display few visible signs in terms of alterations in their physical features, development, behaviour or their ability to thrive. Indeed it is only with sort of detailed experiments we propose to carry out that deficits in brain signalling are revealed. Some of the pre- clinical models we use are classified as have a "moderate" phenotype as the mutation has the potential to cause harm if the animal was to live for a long time. However, we closely monitor our GAAs and if they show signs of distress they are killed humanely. For our experiments we use animals before these phenotypes develop. The animals in these studies will be cared for by trained staff within a well-resourced and well-equipped modern animal facility that contains individually ventilated cages (IVCs) and barrier systems to maintain specific pathogen-free (SPF) status/health. The majority of work to be conducted under this PPL will involve humanely killing animals to obtain tissue for subsequent experiments that examining the electrical activity of neurons and glial, or the biochemical signalling and its control that occurs within cells. Such experiments are all performed ex vivo. Some protocols involve exposing them to loud noises to assess seizure susceptibility, anesthetizing animals for prolonged periods or rearing in a dark environment. In the case of the latter two methods these are not considered to cause lasting harm. In the case of exposure to loud noise we need to use this method as it attempts to mimic the increased sensitivity some people with

neurodevelopmental disorders have to sensory inputs. This is a non-invasive method of assessing susceptibility and all animals experiencing this are culled immediately after exposure.

Why can’t you use animals that are less sentient?

The brain disorders we study affect humans and as such we need to model these in a mammalian system. Rodents such as mice and rats are the lowest order of species that are sufficiently genetically related (97%) to human to allow us to obtain data where we can begin to understand what goes wrong with cellular communication in people that suffer from these disorders. The majority of our work involves the collection of brain tissue from terminally anesthetized animals and which we use ex vivo to understand the mechanism by which dysfunction is manifested.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As required our rodent colonies are monitored daily for their welfare. As noted in the application most of the animal models we study display mild cognitive and behavioural deficits. Where a mutation/deletion has the potential to cause a harmful phenotype, animals are culled before these manifest. For animals where we administer substances, they are monitored frequently to check for any adverse reactions and if these are observed we take appropriate action or seek veterinary advice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult and refer to publications and resources produced by NC3Rs (www.nc3rs.org.uk). These include advice on Experimental Design and 3Rs Self-assessment tools to maintain oversight of our use of the most refined protocols. Where appropriate we will consult PREPARE guidelines and ensure that we follow best-practice, veterinary advice to ensure most appropriate routes for substance administration and induction/maintenance of general anesthesia

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are informed of the latest findings and proposals from organisations such as National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and Understanding Animal Research (UAR). We discuss these within our research group and consult with veterinary staff to ensure that, where appropriate for our research programme these are implemented.

164. Understanding the mechanisms of the carotid body hyperactivity caused by chronic hypoxia

Project duration

3 years 0 months

Project purpose

- (a) Basic research

Key words

breathing problems, low blood oxygen, carotid body, high blood pressure, irregular heart beat

Animal types	Life stages
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify how a persistent fall in blood oxygen (called hypoxia) causes hyperactivity of the carotid body- the organ in the body which constantly senses and responds to changes in the blood oxygen. The project will also look at how this change in carotid body function leads to alterations in breathing, heart function and blood pressure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The carotid body is an important organ located in the neck that constantly monitors the blood supplying the brain. When the blood oxygen level drops (called hypoxia), the carotid

body immediately triggers an alarm in the form of thousands of nerve impulses sent to the brain. This activates important reflexes including an increase in breathing and heart rate, and narrowing of most blood vessels, so that enough blood and oxygen can instead be delivered to the brain. However, in patients with irreversible lung disease (such as chronic obstructive pulmonary disease) the blood oxygen level is always too low. The carotid body is constantly stimulated and over time becomes hyperactive. The hyperactive carotid body causes persistent over-stimulation of the cardiovascular/respiratory reflexes leading to a sustained rise in the nerve activity going to the blood vessels and heart. These patients therefore develop a high blood pressure and an irregular heartbeat. However, the mechanism of carotid body hyperactivity caused by lung disease and sustained hypoxia is poorly understood and currently there are no treatments used clinically that directly target the carotid body. A better understanding of the mechanisms underpinning carotid body hyperactivity and the rise in cardiovascular/breathing reflexes in response to chronic hypoxia would be an important first step towards developing new treatments for carotid body mediated cardiovascular disease.

What outputs do you think you will see at the end of this project?

This project will provide new information about the underlying processes that lead to carotid body hyperactivity in response to a persistent fall in blood oxygen (hypoxia). In addition, the project will reveal how this change in carotid body function can lead to alterations in heart function, breathing and blood pressure. This information is likely to be published as scientific articles in high impact cardiovascular and respiratory journals.

Who or what will benefit from these outputs, and how?

During and by the end of the PPL, the findings will greatly advance the biological understanding of how prolonged exposure to low blood oxygen causes the carotid body to become hyperactive. The project will show how the overactivity of the carotid body leads to important downstream changes in breathing, heart function and blood pressure. This new knowledge will be of benefit to scientists and clinicians who work on understanding the disease processes in the carotid body, heart, lungs and blood vessels. These findings will also benefit scientists and clinicians who work more broadly on understanding how exposure to low oxygen leads to disease. The new information should be an important first step in moving towards developing future treatments for carotid body mediated disease. The new information provided by the end of this project will therefore be beneficial to biotechnology companies that are aiming to develop new treatments associated with lung disease in which patients have a persistently low blood oxygen.

How will you look to maximise the outputs of this work?

We will disseminate important research findings at the most prestigious cardiovascular and respiratory conferences across the world. Furthermore, we will publish the findings in the form of research articles in internationally recognised cardiovascular and respiratory journals. We will aim to publish articles based on work in this PPL as Open Access to

extend reach, influence, and impact. Negative findings, unsuccessful approaches and null data will still be published in journals which encourage reporting of all data. I will also disseminate our research to the general public by hosting lab tours and seminars organised by our funders. Whilst talking about animal experimentation can be a contentious subject, I do believe that this provides an excellent opportunity to discuss the 3R principle and scientific studies involving animals in the UK to broaden perspective and challenge preconceptions.

Species and numbers of animals expected to be used

- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

High blood pressure and irregular heartbeats caused by exposure to low blood oxygen develop as a consequence of alterations in whole body reflexes pathways. This includes a persistent rise in nerve activity to the heart and blood vessels triggered by carotid body hyperactivity. This experimental programme is therefore centred on integrative whole-body reflex responses and requires in vivo research.

Juvenile and young adult rats will be used for this project once carotid body function is fully developed. Importantly, rat carotid body, cardiovascular and breathing function is sufficiently close to that of humans to allow transfer of findings to humans. For example, rats exhibit carotid body hyperactivity, high blood pressure and a high heart rate in response to persistent falls in their blood oxygen. These are the same changes seen in human patients with lung disease such as chronic obstructive pulmonary disease. We will use rat rather than mouse, as the reflex responses to low blood oxygen in the rat are more similar to humans and take place at more comparable oxygen levels. The reflex responses to low blood oxygen in the rat are also better maintained than in the mouse, again showing more similarity to humans. Thus, the rat offers a better model of disease relevant to humans for the specific aims of this project. Using the rat will therefore provide more valuable data in terms of promoting future translation to human disease. Searches for alternatives to in vivo (e.g. NC3Rs, NORINA) integrative experiments in this field do not provide replacements for the animal experiments proposed in this project.

Carotid body function is not fully developed in the womb or immediately after birth. Therefore, we will use animals at a minimum of 5 weeks or older once the carotid body has fully developed and is fully functional.

Typically, what will be done to an animal used in your project?

Some animals will be housed in normal ambient oxygen (approximately 21% $O2$,) throughout and then have carotid bodies isolated under non-recovery terminal general anaesthesia with killing completed by a schedule 1 method.

Some animals will breathe a lower environmental oxygen (by introducing a lower environmental oxygen mixture into a environmental chamber, 10-12% $O2$), for up to 10 days. This level (10-12% $O2$) and duration (up to 10 days) of lower environmental oxygen is chosen based on published evidence shown to cause long-term changes in carotid body function in rats. These animals will then have carotid bodies isolated under non-recovery terminal general anaesthesia with killing completed by a schedule 1 method.

Some animals will be housed in either normal ambient oxygen (approximately 21% $O2$) or a lower environmental oxygen (10-12% $O2$) for up to 10 days (approximately equal numbers per group). Acute breathing measurements will be measured up to two times per animal using non-invasive, whole body plethysmography. During this procedure, animals will be placed in the plethysmography chamber with a reduced floor space for a maximum of 3 hours. A rise in breathing is measured in response to short durations (maximum of 5 minutes) of low environmental oxygen (minimum 8% $O2$) and higher carbon dioxide (6% $CO2$). After these breathing reflexes have been made, animals will be returned to their home cage. A single injection of a substance aiming to lower carotid body activity (or control substance) may be administered before the second set of breathing measurements are made. Any single injection will be given based on known routes, doses and volumes published in the literature and will not exceed the maximum volume defined by the LASA guidelines. Animals will then be killed by a schedule 1 method or in vivo measurements of blood pressure and heart function will be made under non-recovery terminal general anaesthesia with killing completing by a schedule 1 method or carotid bodies will be isolated under non-recovery terminal general anaesthesia with killing completed by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

When the animals are placed in a lower environmental oxygen (10-12% $O2$) environment they are expected to demonstrate an increase in breathing rate and at times there will be noticeable larger breaths (sighs). The animals may also appear lethargic and it is expected that the activity of the animals will decrease especially on the first day. It is also likely that the animals will not have the same appetite and are expected to eat slightly less than usual especially during the first day. However, it is expected that the animals will adapt well and whilst the increase in breathing will continue throughout the duration of exposure to the lower oxygen environment, the animals will resume normal exploratory and feeding behaviour within 1-3 days.

When making acute measurements of breathing reflexes using non-invasive, whole animal plethysmography, animals will be placed in a plethysmography chamber with a reduced floor space of approximately 280 cm2. This will be temporary (up to 3 hours). The animals

are expected to explore around the plethysmography chamber as they get used to the new environment. When undergoing the short (up to 5 minute) exposure to environmental low oxygen, the animals will demonstrate an elevated breathing rate, some instances of larger breaths (sighs) and a reduction in activity. When undergoing the short (up to 5 minute) exposure to higher environmental CO2, the animals will demonstrate an elevated breathing rate, some instances of larger breaths (sighs) and an increase in exploratory and grooming behaviour. The administration of substances before the second measurement of breathing will be undertaken using a combination of doses, volumes and routes that of themselves will result in no more than transient discomfort and no lasting harm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately a third of animals will undergo induction of anaesthesia only one one occasion; those that are housed in normal ambient oxygen and and then have carotid bodies isolated under non-recovery terminal general anaesthesia with killing completing by a schedule 1 method.

Approximately two thirds of animals will experience procedures which fall under the moderate severity including either exposure to environmental chronic hypoxia using an adjustable environmental chamber and/or measuring acute breathing reflexes using whole body plethysmography.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The carotid body (CB) is the key oxygen sensor in the body that communicates with the brain to alter nerve activity to the heart, blood vessels and breathing muscles. However, in response to a long term fall in blood oxygen, the carotid body becomes hyperactive which causes a persistent rise in the reflex pathways and the nerve activity to the heart, blood vessels and breathing muscles. This research programme is centred on whole body reflex responses involving communication between multiple organs and therefore requires in vivo research. It is not possible to answer the key questions without using animals. Searches for alternatives to in vivo (e.g. NC3Rs, NORINA) integrative experiments in this field do not provide replacements for the animal experiments proposed in this project.

Which non-animal alternatives did you consider for use in this project?

Searches for alternatives (eg NC3Rs, NORINA) to integrative experiments in this field do not provide replacements for the animal research proposed in this licence. If we find that technology advances during the lifetime of this project, we will not hesitate in using non-animal systems if they are suitable to address our scientific question.

We have considered using culture based neuronal cell lines e.g. PC12 cells to identify the local effects of hypoxia. However, this does not allow us to investigate changes in reflex pathways in the whole organism.

Why were they not suitable?

There are significant limitations of basic culture conditions using cells gown in isolation and this is not an accurate representation of what occurs within a whole organism. A reason why many new drugs fail between cell culture and in vivo studies is in the inability to fully recapitulate the in vivo environment.

This experimental programme is centred on integrative whole body cardiovascular/respiratory reflex responses arising from carotid body stimulation, leading to downstream changes in breathing, heart and blood vessel function. Using cell lines would not allow us to investigate the pathological changes in carotid body function on the cardiovascular/respiratory reflex pathways in the whole organism. As such, it is not possible to answer the key questions using just cell lines and without using animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers have been estimated by calculations that are based on our own pilot data, previous in- house data and published studies by ourselves and others. Experimental design has been discussed with, and approved by, our statistical advisor and further approved by both internal and external peer review by our funders. These estimates will be updated and recalculated throughout the project as we generate new data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken a number of steps to ensure animal numbers are reduced and that experimental data is reliable and reproducible:

Several procedures will be performed using a single animal where this does not unduly increase the burden on the individual animal (e.g. non-invasive breathing measurements, followed by measuring cardiovascular reflexes and heart function under non-recovery terminal general anaesthesia).

Animals will be randomly assigned into experimental groups.

Rats in the control and experimental groups will be of a similar age and the same strain to reduce variability in age and genetics.

Control and experimental groups will have the same diet and access to water ad libitum. This will reduce variability due to diet.

Non-invasive in vivo breathing measurements will be made on control and experimental

rats at the same time of day to reduce variability due to changes in circadian (daily) rhythms.

All in vivo and ex vivo data will be presented as mean per animal data, to avoid technical replicates.

Where possible, experiments and data analysis will be performed blind to to whether or not animals have been exposed to a low environmental oxygen, to minimise investigator bias.

We will use well established experimental methods to reduce variability

We will use appropriate n numbers based on power calculations performed before the experiment has begun, this will ensure that we do not use too many animals.

We will optimise certain ex vivo techniques e.g. antibody concentrations, on cell lines prior to use of tissue/cells isolated from animals

All experiments have been designed in accordance with the NC3Rs Experimental design assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Both carotid bodies will be removed from each rat to allow for use in multiple ex vivo assays. E.g.1 carotid body could be used for analysis of carotid body nerve activity and the other used for analysis of gene expression.

If we are unable to estimate an effect size from our in vitro data, the literature, or our collaborators, we will conduct small pilot experiments.

Where possible, tissue surplus to requirement will be shared post-mortem for other ex vivo experimentation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

<u>Exposure to low environmental oxygen using an adjustable environmental chamber.</u>

This procedure is based on peer review and is a well-established method. The model is non-invasive and is achieved by reducing the O2 delivered to the adjustable environmental chamber to achieve an environmental O2 of 10-12%, for up to 10 days. To aid with animal adaptation, on the first day, the O2 will be gradually lowered over a period of hours before reaching the final value of 10-12% O2. The animals will be closely monitored during this adaptation period and for the first hour at 10-12% O2. This level (10-12% O2) and duration (up to 10 days) of low environmental oxygen is chosen based on published evidence shown to cause long-term changes in carotid body function and long-term increases in cardiovascular/breathing reflexes in rats. Breathing this level of oxygen (10-12% O2) also leads to a blood oxygen level similar to that seen in patients with lung diseases such as COPD. On the first day of low environmental oxygen exposure, the animals will demonstrate an increase in breathing, a slight decrease in activity and a slight reduction in feeding. However, it is expected that the vast majority of animals (>99%) will adapt well and, whilst the increase in breathing rate will continue, the animals will resume normal exploratory and feeding behaviour within 1-3 days. This method has been used successfully for many years by our collaborators at other institutions and is based on published work. The animals are transferred to a cage that has bedding and enrichment objects from the animal’s home cage to reduce stress. Animals are unrestrained and food and water is available ad libitum. To monitor animal welfare, animals will be briefly removed from the environmental chamber for measurement of body condition score and weight loss. This will be done a minimum of once per week with routine visual checks performed daily or more often as needed.

This is the least invasive method of causing a persistent fall in blood oxygen in animals. There are other models based around severe irreversible lung damage that we have ruled out. These include the injection of a enzymes into the lung to evoke significant long term damage and the use of virus-induced lung injury. These models that we have ruled out are significantly more severe and cause the animals increased amounts of long term stress,

suffering and can potentially be lethal. Furthermore, these methods both lead to strong immune responses making it difficult to pinpoint the specific effects of the low oxygen on the carotid body. Another method that causes a long term fall in blood oxygen is a complex recovery surgery to induce chronic heart failure. Whilst this procedure is shorter in duration, it requires exposure to general anaesthesia and a period of mechanical ventilation. Thus, it is more invasive, will cause more stress to the animal and more long-lasting harm. Also, in this instance any heartbeat irregularities might be a consequence of direct damage to the heart rather than the impact of the increased nerve activity to the heart. Thus, our proposed model is the least invasive but still causes relevant changes in carotid body function and cardiovascular/respiratory reflexes that are required to achieve the aims of the project.

Non-invasive unrestrained whole body plethysmography (WBP)

Measurements of breathing will be performed on awake animals using non-invasive unrestrained whole body plethysmography. This is the least invasive method to record breathing in awake animals. The maximum time animals have reduced floor space (approximately 280 cm2), is 3 hours, but are not restrained. Animal bedding from the home cage will be added to reduce animal stress. The technique allows for breathing to be measured without the potentially confounding effects of anaesthesia or the stress of restraint. The levels of acute lower oxygen (minimum of 8% O2) and higher carbon dioxide (maximum of 6% CO2) used to activate the carotid body and increase the breathing have been chosen based on published literature and are known to cause moderate carotid body stimulation without initiating defence responses, vocalisation or escape behaviours. The duration of individual episodes of lower oxygen or higher carbon dioxide or both is short but is long enough to measure the steady state rise in breathing. When undergoing exposure to lower oxygen or higher carbon dioxide or both, the animals are likely to demonstrate an increase in breathing and some instances of larger breaths (sighs). Animals may also demonstrate either a reduction in activity (during low oxygen) or an increase in activity and exploratory behaviour (during higher carbon dioxide). These effects are short lasting and are quickly reversed after switching back to normal oxygen and carbon dioxide. Measuring breathing in this way is expected to cause no lasting harm.

Measurements of cardiovascular reflexes and cardiac arrhythmia induction under non-recovery terminal general anaesthesia

Cardiovascular reflexes (blood pressure, blood flow) and heart electrical activity (ECG, heart rhythm, heart rate) will be measured in animals under non-recovery terminal general anaesthesia. The procedure requires surgical tracheal and blood vessel cannulation as well as pacing the heart with an electrode. The procedure will assess the electrical integrity of the heart by pacing the heart at high rates. Measuring these parameters in the whole animal allows for the nerve communication between the different organs to be maintained (e.g nerve activity to the blood vessels and heart that is controlled by the carotid body and the brain). Whilst there will be effects of the anaesthetic, we will minimise this by selecting agents that achieve surgical anaesthesia but have minimal direct effects on the carotid

body, cardiovascular and respiratory systems, as previously published by ourselves and others.

Sufficient surgical anaesthesia will be assessed by absence of a pedal withdrawal reflex and monitoring of breathing rate. The maximum time under general anaesthesia will be 4 hours and following experimentation animals will be euthanised by a Schedule 1 method.

Carotid body isolation under terminal non-recovery general anaesthesia

The carotid body is excised under deep non-recovery terminal general anaesthesia. The carotid body is removed from the animal whilst still being perfused in order to limit the extent of metabolic insult, to ensure the most valid and reproducible ex vivo measurements of carotid body function are generated.

Sufficient surgical anaesthesia will be assessed by absence of a pedal withdrawal reflex and monitoring of breathing rate. The maximum time under general anaesthesia is 45 minutes. Following carotid body removal, animals will be euthanised by a Schedule 1 method.

Why can’t you use animals that are less sentient?

The carotid bodies and reflex responses to low blood oxygen are not fully developed in rats until at least 2-4 weeks of age. We cannot use embryonic forms as the carotid body is not yet fully formed/functional. We will therefore study carotid body hyperactivity and cardiovascular parameters in rats when animals are of an age where the carotid bodies and cardiovascular reflexes are fully developed. We have chosen to use rats over other less sentient species such as Danio Rerio (zebra fish) and drosophila melanogaster (the fruitfly) as these animals do not have similarly developed carotid bodies and whole body cardiovascular and breathing reflexes in response to low oxygen and highercarbon dioxide. Importantly, rat cardiovascular and breathing reflexes are sufficiently close to that of humans to allow transfer of findings to humans. We will use rat rather than mouse, as the reflex responses to low oxygen in the rat are more similar to humans and take place at more comparable oxygen levels. The reflex responses to low oxygen in rats are also better maintained than in mice, again showing more similarity to humans. Thus, the rat offers a better model of disease relevant to humans for the specific aims of this project. Where possible we will obtain data under terminal non- recovery general anaesthesia. For example measurements of acute cardiovascular reflexes and heart function will be performed under terminal non-recovery general anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At the end of each experiment, we will continue to undertake a critical review to see how it can be refined going forward.

Over the years we have already implemented a number of refinements in regards to the use of the adjustable environmental chambers. For instance, to aid with animal adaptation, on the first day, the oxygen will be gradually lowered over a period of hours before reaching the final value of 10-12% O2. During this time the animals are closely monitored. After reaching the 10-12% level of oxygen, the animals will be closely monitored for the first hour and in the first 1-3 days of exposure, when animals are most likely to demonstrate reduced activity and increased breathing frequency, will we perform more frequent visual monitoring. After the first 3 days, routine visual checks will be performed daily or more often as needed. We will perform specific welfare checks including body-condition scoring and measurements of weight loss on a minimum of one occasion per week. Whilst in the environmental chamber, animals are housed in same-sex pairs rather than individually to minimise social stress. We also add in bedding and enrichment objects from the animal's home cage to reduce stress. All of these refinements will be implemented in this PPL. Furthermore, we will continue to review the technique to see how it can be further refined in the future.

For the non-invasive breathing measurements we have also already implemented changes to refine the technique and reduce animal harm. For instance, animals have at least 2 short visits to the recording chamber to get used to the new environment before the actual experimental procedure. Furthermore, we add in bedding into the plethysmography recording chamber to help adapt to the different environment and reduce stress. These refinements will be implemented in this PPL. We will also continue to review the techniques to see how they can be further refined in the future.

We will introduce a programme of acclimatisation where the user will increase the frequency of handling before entering onto the protocol. This will include rat tickling. This helps improve the rat- handler relationship and decreases animal stress. We will also monitor best practice guidelines for rat handling and implement any suggested changes that emerge in the future.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will use NC3Rs website for information and follow LASA guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will aim attend workshops hosted by the NC3Rs. In addition, my lab will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs- developed checklist of the essential information that should be included in publications reporting animal research. This will include reporting of the essential 10:

1) type of study design and how controls were defined

2) total number of animals used, sample size and what was classed as a single experimental subject for each experiment

3) inclusion and exclusion criteria

4) if and how animals were randomly assigned into each control and experimental group

5) whether the investigator was blinded during the acquisition and analysis of data

6) outcome measures and if (and why) any have not been included in the article

7) full descriptions of data analysis and statistical methods used

8) species, strain, substrain, sex, weight, and age of animals

9) essential information relating to the experimental procedures performed

10) summary of descriptive statistics for each experiment including some measure of variability (e.g. SE, SD, interquartile range), and where appropriate the effect size and if we consider this to be of biological relevance

Myself and team members will also sign up to receive the NC3Rs newsletter.

I will also review literature regarding the specific procedures that we perform to see if they can be refined further.

Any new advancements will be made clear to members of my team through our weekly lab

165. Regulation of immune responses in cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immune responses, Lymphocytes, Immunotherapy, Metabolism

Animal types	Life stages
Mice	pregnant, adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will study immune responses to tumours with an overall aim of identifying new approaches for the treatment of cancer. We are particularly interested in understanding how responses of populations of white blood cells called T lymphocytes are turned on or switched off in response to tumours sited in distinct areas of the body and the role of metabolism in these processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite advances in the treatment of cancer, the World Health Organisation reports that cancer remains the second leading cause of death worldwide. In recent years, novel

approaches that harness the body's own immune defences against tumours, collectively termed immunotherapies, have proven highly effective in the treatment of otherwise incurable cancers such as malignant melanoma, a form of skin cancer. Nonetheless, for several cancer types these approaches have yet to bring benefit to patients, whilst even with "immunotherapy-sensitive" cancers, a proportion of patients do not respond. Therefore, there remains an urgent need to understand better how immune cells respond to tumours and the mechanisms that tumours exert to prevent effective immune responses. This work will aid our understanding of immune responses to tumours and assess novel targets with the aim of improving cancer immunotherapies.

What outputs do you think you will see at the end of this project?

Through studying the response of T lymphocytes and other white blood cell (immune cell) populations to cancer, our studies will enable us to:

1. Define the impact of cancers cells and their products on white blood cell function and metabolism

2. Determine how the availability of nutrients within the body affects the outcome of anti-tumour immune responses and tumour growth

3. Screen and target molecules that regulate immune activation in cancer

4. Test combinations of therapies to enhance clearance of tumours by the immune system

An immune response is frequently provoked during the early stages of cancer, yet one of the hallmarks of advanced cancer is the ability of tumours cells to evade these responses. Current immunotherapies seek to overcome the failure of immune responses and can broadly be placed in two main categories:

1) Drugs that enhance the responses and / or relieve suppression of immune cells already present within cancer patients.

2) Tumour-targeting immune cell populations that may be genetically modified to enhance their anti- cancer function, before injection into patients

Both pre-existing and transferred immune cell populations must overcome a characteristically hostile environment that is created within tumour masses. Our project will seek to gain an understanding of the responses of immune cells within these challenging environments, with a view to developing new approaches to improve immune function in cancer. Importantly, we suggest that this work will have implications for the development and future success of novel immunotherapies.

Tlymphocytes and other immune cells need to maintain a supply of nutrients such as glucose and amino acids to provide energy to sustain their responses in cancer. Evidence suggests that fast- growing tumour cells can out-compete immune cells for these vital

nutrient resources within tumours. Furthermore, inhibitory products present within tumours impact upon immune cell metabolism. How these conditions vary between different types of cancer / different locations within the body, and the role of individual nutrients in determining immune responses is not fully understood. Through our previous published work, we identified one particular nutrient as being important for T lymphocyte responses. In this project, we will define the role of nutrient availability in anti-cancer immune responses and test how manipulating T lymphocytes might improve their capacity to thrive in nutrient- deprived conditions. Furthermore, Identification of factors within tumours that impede immune cell metabolism may enable the development of ways to improve immunotherapies.

The ability of T lymphocytes to respond to cancer cells depends upon triggering through a cell-surface molecule termed the T cell receptor (TCR). Several current immunotherapies seek to improve the ability of T cells to respond to TCR triggering, whilst our previous published work has defined key mechanisms that regulate these processes. In the current project, we will seek to build on this previous work and determine the impact of deleting inhibitory factors within T lymphocytes with a view to improving anti-cancer immune responses. If successful, these approaches could be incorporated into the design of novel immunotherapies in the future.

The overall benefit of this work will be to increase our understanding of the regulation of immunity, identifying how and why immune responses fail and testing new approaches to revive anti-cancer responses. Therefore, this work has the potential for publication in cross-disciplinary scientific and medical journals. We envisage that this will also lead to new productive collaborations with clinical colleagues and industrial partners to enable us to translate our findings into real-world benefits.

Who or what will benefit from these outputs, and how?

A major benefit of this work will be to increase our knowledge of the mechanisms that regulate the induction and suppression of immune responses to cancer. Importantly, this knowledge will inform our future scientific aims and, through the refinement of our experimental protocols, will enable us to maintain the highest welfare standards for our experimental animal colonies.

Cancer represents a considerable health burden in society. A major goal of the proposed program of work is to test the role of pathways, nutrients and genes that are implicated in protective immunity to tumours. For example, using GA mice, we can test whether modification of target genes alters the ability of immune cells to respond to cancer and provide proof-of-principle for future studies to improve immunotherapies.

Important and immediate outputs for the work will include scientific publications and talks at national and international scientific meetings. The work will be of value and of great interest to fellow researchers in the fields of immunology, immunometabolism and cancer immunotherapy. The project will also help identify novel approaches to manipulate immune

cell responses in disease. Thus, it is expected that the knowledge gained from our animal experiments will be translated to pre-clinical human studies with our colleagues within our establishment's hospital campus, that could generate intellectual property rights and inform the generation of new human therapeutics in the future.

How will you look to maximise the outputs of this work?

Our research involves collaboration with groups within our institute as well as national and international colleagues and the current project will seek to maximise the benefit to all partners through:

- transfer of knowledge and expertise. For example, international collaborators will provide access to protocols and reagents for investigating metabolic processes whilst our group will provide in vivo samples

- provision of training and new skillsets to postgraduate student and postdoctoral researchers, thereby facilitating and enhancing their career development

- enhanced quality of scientific publications through complementary experimental approaches and technologies. In this regard, our in vivo approaches will complement studies using clinical samples and / or lab-based molecular techniques.

We will publish the results of our studies in leading scientific journals and present the work at relevant national and international conferences. We have previously accelerated the dissemination of our research by posting our results as "pre-print" publications to the bioRxiv server (bioRxiv.org). This enables us to share our findings months before acceptance in peer-reviewed journals as well as to receive feedback from the scientific community. We will continue to use social-media platforms (e.g. Twitter) as well as traditional media outlets to inform and engage with both the scientific community and non-specialist public on our own and related scientific research.

Species and numbers of animals expected to be used

- Mice: We anticipate using up to 4750 over the 5 years that this project will run. Note that that up to 500 mice will be transferred from protocol 1, under continuous use, to protocols 2 and 3.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The species of choice is the mouse as it can be genetically modified in a manner that is not currently possible with other mammalian species. Furthermore, the use of well-characterized inbred mouse strains maximises the reproducibility of in vivo research.

Importantly, a wealth of commercial reagents are available for the study of the mouse immune system and for intervention in and treatment of mouse models of cancer. We will investigate immune responses of young adult mice to ensure the reproducibility and cost-effectiveness of our studies.

Typically, what will be done to an animal used in your project?

The purpose of this project is to study immune responses to cancer. Therefore, in typical experiments mice will be injected with cancer cells either into the skin, a vein or the peritoneal cavity with or without substances or immune cells that we hypothesize will modulate the immune response and growth of tumours. We will study the growth of tumours in mice using advanced imaging techniques and may take blood samples to monitor circulating immune cells or nutrient levels. Experiments will vary in duration depending on the growth rate of tumours. This can vary substantially in different models from 7-70days. Wherever possible we will use techniques that have the least possible impact on animal welfare and undertake experiments of the shortest possible duration.

What are the expected impacts and/or adverse effects for the animals during your project?

Injection of cells or substances with a needle causes mild and transient pain at the injection site. In some circumstances we may use temporary anaesthesia for a few minutes to minimise discomfort for animals resulting from injections or for imaging procedures. Injection of cancer cells leads to the formation of tumours that in a minority of cases (<20% in protocols 2 and 3) may cause moderate suffering such as difficulty with breathing (lung tumours resulting from intravenous injection) or the accumulation of fluid in the peritoneal cavity. Such suffering will be short in duration as we undertake regular monitoring of mice and humanely cull any animals to prevent unnecessary suffering. Through the experiments, we hope to define fundamental aspects of the processes underpinning immune responses in cancer and assist in developing novel medicines to improve the treatment of these diseases.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice will experience mild or subthreshold suffering. For example, much of the analysis of experimental mice is initially carried out in the laboratory using fresh cells and organs from the mice generated by breeding. Therefore, ~80% of our mouse colonies will be humanely culled with no regulated procedures performed beyond being bred. For mice that receive tumour cell injections, <20% of mice will experience moderate suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our aim is to understand complex biological processes in immune cells, as this information will be most relevant to the design of future therapeutic approaches. Whilst some basic questions can be addressed using immortalized cell lines, such approaches have numerous limitations, most importantly that these cells are by definition quite distinct from primary cells. Immortalized cell lines frequently have mutations in key signalling and metabolic proteins which enable their survival and growth out with the body. As such, these genetic alterations render the analysis of signalling and metabolism in cell lines as quite distinct.

Wherever possible, we study immune cell function in the laboratory; e.g. tissue co-culture of lymphocyte populations with tumour cells. However, to understand the complex interplay between immune cells, cancer cells and environmental factors such as nutrients, requires the use of in vivo animal models. This is particularly prescient when the aim of the programme is to study the role that individual cell types and molecules play in these highly complex immune responses, as proposed here. These diseases involve the interplay of multiple tissues and factors that cannot be modelled using currently available tissue culture systems.

Which non-animal alternatives did you consider for use in this project?

We will study immune cells from healthy blood donor and cancer patient samples to complement our animal studies.

Why were they not suitable?

Study of human cells in the laboratory will enable us to begin to assess the translational implications of our animal work. Nonetheless, if we are to define mechanisms of immune regulation and metabolism in cancer and assess whether molecules can be targeted therapeutically, the use of some animal experiments is essential.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Depending on the consistency of the results obtained in an experiment, more or fewer animals are required to support or reject our hypotheses. We can use online mathematical tools or get advice from statisticians in order to perform statistical tests to assess the robustness and reproducibility of our experimental findings. We have used the results of our previous projects and data from similar experimental systems to predict how variable our experimental data are likely to be and therefore estimate how many animals will be required. In all cases, we use the minimum number required to generate meaningful data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have substantial experience in using and setting up the experimental protocols detailed in this application. In this regard, in many cases estimates of animal numbers have already been established either through analysis of previous experiments or small-scale pilot studies to establish variability.

We also take advantage of online experimental design tools, particularly the Experimental Design Assistant from the NC3Rs. This tool enables researchers to input the key components from each stage of an experiment; from numbers of animals and numbers of experimental groups through to data measurement protocols and statistical analysis. This provides assistance in the design of robust and reproducible experiments that minimise the possibility for subjective bias in the measurement and analysis of data and reduce animal numbers to the minimum required to achieve the scientific objectives.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In all cases, we ensure that mice are bred in the most efficient manner. Where practical, established genetically-altered mouse breeding colonies are bred in a manner that all offspring will have the required genetic modifications and can be used for experimental purposes. The size, frequency, numbers and health of litters from breeding mice are closely monitored by animal facility staff and researchers so as to maintain efficient colonies of adequate but not excessive animal numbers.

In many cases, we can minimise animal numbers by using multiple tissues from one animal to assess several experimental parameters; e.g. tumour tissues, blood and lymphoid organs such as the spleen can all be harvested and assessed in the laboratory.

When setting up new experimental protocols, pilot studies using small numbers of animals will be performed to enable us to determine the optimal strategy required to answer the experimental objectives.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For protocol 1, the majority of mouse lines have no defects beyond alterations in or loss of immune cell populations and suffer no ill effects when they are maintained in filtered cages in our specific-pathogen free animal facility. In addition, we will use mouse models of cancer to model immune responses and therapeutic approaches to the treatment of cancer (protocols 2 and 3). In these experiments, cancer cells grown in the laboratory are injected into animals with a needle and a tumour will form at the injection site or in the case of intravenous injection, in the lungs. It is therefore unavoidable that some animals will experience suffering. The severity of these approaches will be kept to a minimum with

~80% of mice in protocols 2 and 3 experiencing a mild form of suffering. For some mice, growth of tumours may result in moderate levels of suffering. However, regular monitoring of animal symptoms as well as measurement of tumour growth by imaging techniques and/or visual inspection ensures that mice do not experience unnecessary suffering and are humanely culled. Through this work, we will be able to address fundamental questions about the immune response to cancer and help in the development of improved medicines to treat these diseases.

Why can't you use animals that are less sentient?

We wish to model cancer and immune responses in adults. Importantly, studies of adult mice are widely recognised to be relevant for the study of immune processes and cancer whilst many therapeutic breakthroughs have been made following initial mouse studies e.g. the use of several immunotherapies for the treatment of cancer. Furthermore, the ability to genetically manipulate mice is essential to test our specific hypotheses whilst the availability of key reagents and therapies to assess mouse immune function is central to our experimental design. With this in mind and to best of our knowledge, there are currently no non-sentient or lower sentient alternatives to the use of adult mice for our work.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals undergoing experimental protocols are monitored routinely by researchers and animal facility staff using specific checklists to assess wellbeing, discomfort and suffering. The frequency of monitoring is increased upon the development of specific symptoms. Anaesthetic is used whenever appropriate to minimise pain/discomfort and advice from

veterinary surgeons sought whenever unexpected or unexplained signs of distress, discomfort or pain develop.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All animal suffering will be limited to unavoidable procedures required for the performance of our experimental protocols. For general guidance on the conduct and refinement of animal experiments, the NC3Rs provide a wealth of resources and information online (https://nc3rs.org.uk/refinement- refining-animal-experiments-minimise-pain-suffering-and-distress). Relevant academic literature on the care and use of mice in research will be referred to, including NC3Rs published guidelines (1).

Furthermore, specific guidelines on the conduct of cancer research in experimental animals will be adhered to at all times (2).

1. Prescott MJ, Lidster K (2017). Improving quality of science through better animal welfare: the NC3Rs strategy. Laboratory Animal 46:152-156.

2. Workman P et al (2010). Guidelines for the welfare and use of animals in cancer research. British Journal of Cancer 102:1555-1577.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to subscribe to regular e-mails from NC3Rs, that contains updates on best practice in animal husbandry and experimental design. All researchers undertaking experimental protocols under this project will review relevant scientific literature, particularly in specialized peer-reviewed journals such as Laboratory Animal, that pertain to the conduct and refinement of mouse cancer models and will implement any advances in the design of subsequent experiments.

166. In vivo pharmacokinetic and pharmacodynamic properties of potential new treatments for cns and other disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Drug discovery, Pharmacokinetics, Pharmacodynamics, CNS penetration

Animal types	Life stages
Mice	neonate, juvenile, adult
Rats	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To evaluate the properties of compounds that are being developed as potential drugs for the treatment of central nervous system (CNS) and other disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There remains a large, unmet medical need for the treatment of a variety of central nervous system (CNS) and other disorders. This is exemplified by age-related diseases, such as Alzheimer's disease, that are increasing in prevalence as the population ages. However, there is an increasing awareness of the devasting personal and societal impact of psychiatric disorders and mental ill-health. The collective impact of all these disorders is a testament to the inadequacy of existing therapies and the need for new and innovative treatments.

As our understanding of the mechanisms underlying a variety of diseases increases, then so our ability to identify novel potential strategies for treating those diseases also improves. More specifically, we can identify particular proteins involved in the disease process and as part of the drug discovery process we can identify synthetic molecules that alter the function of those proteins in the test-tube and in in vitro cellular models. However, despite the technological advances in computer (in silico) and in vitro (test-tube and cellular assay) methodologies, there nevertheless remains a critically important need to evaluate what effect a drug has on the intact, live animal (pharmacodynamics) as well as what effect the animal has on the drug (pharmacokinetics). It is the pharmacodynamics and pharmacokinetics of novel compounds that are the focus of this Project Licence.

What outputs do you think you will see at the end of this project?

Over the five-year period of the project, the primary outcomes will be the identification of novel drugs for the treatment of CNS and other (e.g., cancer, immunological) disorders. As regards CNS disorders, the host institution is currently working on early-stage drug targets for Alzheimer’s disease, Huntington’s disease, anxiety disorders, schizophrenia, bipolar disorder and treatment-resistant depression and therefore patients suffering from any of these disorders could be potential beneficiaries from the studies covered by this licence. In addition, drug discovery projects in non-neuroscience-related therapeutic areas will be established as and when the scientific opportunity arises.

The primary outputs of the work conducted under this licence will be novel small molecules, the most advanced of which will become drugs for human use. Compounds that do not meet all the criteria required for a drug suitable for human use, will be made available to the wider scientific community to enable mechanistic studies into the protein and/or disease of interest.

Who or what will benefit from these outputs, and how?

The primary outputs from the work conducted under this licence will be new drugs for the treatment of CNS and/or other disorders. Within the 5-year period covered by this Project Licence we would anticipate that drugs for certain of our projects will progress into early-stage (Phase 1) clinical studies and in the longer term (5-10 years following commencement of this licence) we would hope that at least one drug will have achieved Regulatory Approval and is being marketed for either a CNS or other disease.

How will you look to maximise the outputs of this work?

The work conducted under this licence will contribute to the Intellectual Property that describes the compounds/potential drugs of interest. This Intellectual Property will be protected by Patent Filings which are critical to the licensing of our drugs to the pharmaceutical companies that have the required clinical trial expertise needed to achieve the Regulatory Approval (by the FDA, EMA or MRHA) needed to licence the drugs and make them available to the patient population.

During the drug discovery process, we will identify pharmacological tools compounds that are suitable for further preclinical characterisation but, for whatever reason, cannot be progressed into clinical studies. These will be made available to the wider scientific community and will be "advertised" by means of standard academic procedures (meeting attendance, poster presentations etc).

Species and numbers of animals expected to be used

- Mice: 5250
- Rats: 9500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will typically use young adult mice or rats since these are standard species for examining the effects of drugs on animals (pharmacodynamics) and the effects of the animal on the drug (pharmacokinetics). Previous studies have highlighted the value of these animal studies in predicting the behaviour of drugs in man.

Typically, what will be done to an animal used in your project?

A typical experiment will involve the injection of compound into the animal followed by the measurement of some parameter related to the effect of the drug (pharmacodynamics) or how long the drug lasts in the animal (pharmacokinetics). Such parameters might include the measurement of drug concentrations in the blood plasma and/or brain or the effects on brain function (e.g., protein expression or behavioural pharmacology). The majority of experiments (>90%) will involve the administration of a single dose of test compound followed by termination and sample collection (e.g., the brain) within a day of dosing the compound.

What are the expected impacts and/or adverse effects for the animals during your project?

The anticipated adverse effects include mild/moderate effects either as a result of the dosing procedure itself (e.g., transient immobility) or, in <1% of animals, drug-related adverse pharmacological effects.

More specifically, we are generally identifying and developing drugs that affect the balance of nerve cell excitability and nerve cell inhibition. This “Ying and Yang” of brain function requires that we subtlety modulate nerve cell function (i.e., increase or decrease nerve cell excitability or inhibition) without producing side-effects that characterise the extremes of nerve cell excitability (i.e., seizures) or inhibition (i.e., sedation or unconsciousness). These risks are considerably mitigated by our characterisation of the in vitro pharmacology of compounds, but there nevertheless remains a small risk that some of these side-effects may manifest themselves during in vivo testing. Compounds which produce significant Adverse Events will not be of interest for additional in vivo profiling since such liabilities will clearly prevent further preclinical development of such compounds. Hence, any observed Adverse Events will be sufficient to make a No-Go decision for the further in vivo characterization of such a compound.

It is important to emphasise that novel compounds due to be tested in live animals will be been characterised in a variety of laboratory tests. These laboratory tests are critical in order to prioritise compounds for live animal tests and to exclude compounds that will be of only limited interest and value to the overall drug discovery project.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

For both mice and rats, the overall severity of effects experienced by animals is anticipated to be minimal with the vast majority (>95%) showing no drug-related adverse effects. Of the remainder, most are anticipated to show mild/moderate effects either as a result of the dosing procedure itself (e.g., transient immobility) or possibly a longer term, drug-related immobility (e.g. sedation).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The drug discovery process involves the synthesis of multiple (several hundred) novel compounds in which iterative changes are made to a molecule in order to improve its

properties. Each compound needs to be tested in order to ensure that it retains the desired properties and while most of these tests are conducted in test tubes or in cell cultures (in vitro) at some point, a few, more advanced compounds need to be tested in live animals (in vivo). Importantly, novel compounds will not be directly tested live animals without prior in vitro characterisation.

Depending upon the specific project and the scientific question, partial replacement may be possible in so far as cells or tissues may be used from animals that have not undergone any procedures other than killing by a humane method.

There are other key aspects of the drug discovery process that based upon our current understanding of the intact, living organism cannot be replaced by other methods in vitro or computer prediction (in silico) methods. Such aspects include, for example, how rapidly an animal will metabolise a novel compound, to what extent a compound can cross the blood-brain barrier and penetrate into the CNS and engage with the target of interest (e.g., receptor occupancy, enzyme inhibition), and what the functional consequences are of a drug modulating the function of its target protein.

Which non-animal alternatives did you consider for use in this project?

There are currently no non-animal alternatives for certain aspects of the drug discovery process. However, wherever possible we will use in vitro surrogate assays to deprioritise compounds prior to the in vivo stage. Such assays can include in vitro assays of drug metabolism (liver microsome and/or hepatocyte assays), blood-brain barrier permeability and efflux (drug transport across Caco-2 cell monolayers). Moreover, in silico predictions of metabolic "soft-spots" on compounds of interest will also be used to predict - and therefore deprioritise - compounds that are likely to be inherently unstable in vivo.

Why were they not suitable?

The complexities of the systems involved, for instance the brain, mean it is not possible to predict, either in silico or via in vitro cellular or other assays, what the response of the live animal will be. This is particularly the case for the brain where the intricacies of the nerve cell connections and their circuitry mean it is not possible to predict, for example, what the functional consequences of a compound penetrating across the blood brain barrier and engaging the target protein of interest will be.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based upon the usage under the previous 2016-21 Project Licence (5250 mice and 9500 rats) which supports 3 projects. That project supported three main projects, supported by four members of staff and this current project proposal will support those existing projects plus an additional three new projects. However, not only are these new projects at an earlier stage that requires less animal usage, but the existing projects are maturing such that their animal usage will also be reduced as they move closer to or into the clinical testing phase. Collectively, these projects are funded by roughly £10m of research funding.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The data from the in vivo experiments described in this Project Licence form part of a collective data set that is used to prioritise compounds for further progression (e.g., from target engagement studies to functional - behavioural pharmacology - studies). Since compound prioritisation is a combination of the combined in vitro, in vivo and other "druggability" data sets, it is often sufficient to generate qualitative data to differentiate compounds that, for instance, give penetration into the CNS that is good, bad or in-between. Such qualitative data can be generated using smaller group sizes (e.g., n=3-5) compared to quantitatively demonstrating that Compound X gives significantly greater CNS penetration than Compound Y.

For studies in which quantitative comparisons of the functional effects of compounds are required (e.g., the effect in drug- versus vehicle-treated animals), experiments will be designed in accordance with the NC3R's Experimental Design Assistant (https://eda.nc3rs.org.uk/) and follow guidance from the MRC (https://mrc.ukri.org/funding/guidance-for-applicants/4-proposals-involving-animal-use/).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our in vivo studies will be guided by the principles of the ARRIVE guidelines (https://arriveguidelines.org/) and where necessary, pilot studies will be conducted according to NC3R guidelines (https://nc3rs.org.uk/conducting-pilot-study).

For studies in which samples need to be collected for assay development work, we will endeavour to use tissues obtained from animals no longer required for their primary purpose. For in vivo assay development, relatively small pilot studies will be conducted to: a) assess feasibility; and b) conduct power analyses should they be required for quantitative analyses (e.g., does Compound X significantly alter parameter Y in relation to vehicle-treated animals?).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This Licence will generally use young adult mice or rats. The basic experimental design is to dose animals with test compound and measure the pharmacodynamic effects that compound has on the animal (for instance effects on a biomarker of target engagement or a functional response, such as behaviour) and the pharmacokinetic effects the animal has on the test compound in terms of absorption, distribution, metabolism and excretion (e.g., penetration in the CNS across the blood-brain barrier).

Animals will normally receive a single dose of test compound and will be killed a short time (<24 h) later, thereby minimising any potential lasting harm.

Assays will generally be selected on the basis of pharmaceutical industry standards. For example, we will use behavioural assays that are well recognised to provide the best construct and/or face and/or predictive validity in relation to the phenotype they are modelling.

Why can’t you use animals that are less sentient?

Generally, young adults will be used rather than more immature animals since they normally more accurately model the physiological aspects we are trying to assess. For example, younger animals do not possess a mature blood-brain barrier and therefore cannot be used to measure the ability of a compound to cross the blood-brain barrier. On occasion, it may be necessary to use non-adult (e.g., new born or juvenile) animals if, for instance, the protein of interest is developmentally regulated such that expression is much higher in new-born or juvenile animals compared to adults.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our species of choice will be the rat since any data that are generated as part of this project are then consistent with subsequent safety and toxicity studies that are required by the regulatory bodies to be conducted in rat. However, where necessary, we will use mice to generate data that are consistent with other studies showing the effects (efficacy) or side-effects of drugs in mice (e.g., efficacy studies in particular strains of transgenic mice to be covered outside of this Project Licence).

As regards animal welfare, where necessary, pre-meetings between researchers and animal care staff will take place to evaluate and put in place monitoring systems to identify potential welfare issues arising from specific protocols. Environmental enriched housing is provided to all of the animals throughout these procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our general approach to our choice of the most appropriate animal model will be informed by resources such as 'Systematic reviews of animal studies' webinar (https://vimeo.com/421550517/65395c0b20) and the NC3Rs Systematic Review Facility (SyRF; https://www.nc3rs.org.uk/camaradesnc3rs- systematic-review-facility-syrf). Moreover, we will seek input from our colleagues within the pharmaceutical industry to get their advice on the relative decision-making values of the various alternatives for in vivo assays.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Subscription to NC3Rs newsletter.

167. Brain networks in epilepsy and neurodevelopmental disorders

Project duration

5 years 0 months

Project purpose

Basic research
Translational or applied research with one of the following aims:
- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Epilepsy, Anatomical Networks in the Brain, Genetic Models, Neurodevelopmental Disorders, New Therapies for Epilepsy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, aged
Rats	neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to better understand the anatomical pathways that allow seizures to spread in the brain. This will allow us to better identify the causes of epilepsy and develop improved ways to treat the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Anti-epileptic drugs and surgery to remove epileptic tissue are ineffective in controlling seizures in one third of patients with epilepsy. A major obstacle that prevents us from developing better therapies is that our knowledge of how seizures in epilepsy spread through the brain is limited. Seizures that spread throughout the brain are also particularly dangerous and can lead to people dying from a seizure, if critical areas of the nervous system that control the heart or respiration stop functioning are affected. Furthermore, there are new technologies being tested to treat different diseases including drugs with less adverse effects, electrical stimulation of specific brain areas and, genetic therapies to change the activity of individual populations of brain cells. However, in order to target these effectively to reduce seizures spreading dangerously through the brain, it is necessary to understand how seizures do so. Once we know this, we can change the activity of a specific area and stop seizures.

This is similar to a network of pipes in a house, if there is a leak that allows damage to occur then we need to figure out where that leak is. Once we do, we can direct therapies to block this leak and prevent the damage associated with the disease.

What outputs do you think you will see at the end of this project?

New treatments are urgently needed for epilepsy. The ultimate goal of this project licence is to understand how seizures spread through the brain and stop those seizures from spreading by modulating the activity of a specific groups of cells. The outputs of this work will be scientific articles that highlight this and motivate clinicians to undertake interventions in patients developed in animal models.

We will also identify biomarkers of the disease that can be tested in clinical patients and can be used to diagnose patients and quantify improvement in therapies.

Who or what will benefit from these outputs, and how?

The outputs will eventually benefit patients and their families. Epilepsy can affect people of any age but children under 5 and adults over 60 have a higher likelihood of developing chronic seizures. 1 in 103 people in the UK suffer from epilepsy and a third of those patients is not able to attain control of their seizures with anti-epileptic drugs and must undergo surgery to remove epileptic tissue. In the UK 1150 people died of epilepsy related causes in 2009. The cost of epilepsy is £244 million per year. A prominent clinician has noted that “…epilepsy has an impact on the education of children and young people". One third of children with epilepsy have continuing seizures, which are likely to affect their concentration, behaviour and/or attendance levels at school. Even for the two thirds of children whose seizures are controlled, the anti-epileptic drugs they are taking can impact upon their concentration and learning. Unemployment rates are doubled for people with

epilepsy compared to those without a disability. From 2005 to 2011 the number of people suffering from epilepsy has risen by 32%. Thus, epilepsy has a major impact on the UK's economy and the prosperity of its population.

The outputs will also help other epilepsy researchers as well as clinicians in better understanding the disease.

How will you look to maximise the outputs of this work?

The results from this work will be shared at international conferences for basic scientists and neurologists. We will also engage in public engagement through donor groups, patients, charities and social media.

Species and numbers of animals expected to be used

- Mice: 8000
- Rats: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are studying complex brain anatomy that leads to seizures spreading through the brain. This type of research requires nervous systems that are similar in structure to that in humans to increase our understanding of the disease and develop new therapies. Mice and rats have brains that are similar in structure to humans. We study them from early life to late adulthood as different types of epilepsy occur at different points in life. In human genetic epilepsies and neurodevelopmental disorders, such as severe autism or intellectual disabilities, seizures can block or delay normal brain development.

Therefore, we study young animals to mimic the human paediatric cases. While other types of epilepsy occur in adulthood or in later life.

Typically, what will be done to an animal used in your project?

Animals will be made epileptic, where seizures emerge, either by genetic manipulation or through stimulation of the brain. Animals will be implanted with electrodes in different locations in the brain that we know are interconnected with each other. We will study how seizures move through these different areas by recording from these animals. Animals will be recorded for multiple weeks 24 hours per day. This is done through wireless transmitters that prevent animals from being connected and allows them to move freely in their enclosures. We will also perform interventions to block seizures by stimulating specific brain cells in order to develop new potential therapies.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will develop epilepsy therefore animals will have seizures. These are usually of the kind where animals will lose consciousness, as human patients that have these type of seizures do not remember the seizure event.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

95% of animals will be of moderate severity, with 5% being mild (both in mice and rats).

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed as we do not know enough of how seizures move through complex brains that share a high level of similarity with humans. This is only possible in animals.

Which non-animal alternatives did you consider for use in this project?

I have considered computer models, human patients and in vitro models of epilepsy.

Why were they not suitable?

Our knowledge of brain networks during seizures is still not sufficient to be able to make these models informative. I hope to be able to gain knowledge in this field through these experiments that may be used to generate these models in the future. These experiments cannot be tested in humans as we are looking to understand how epilepsy comes about in the brain and to develop treatments, however this will take time. It is also not possible to use brain extracts in our experiments as these do not mimic the human version of seizures accurately.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have utilized statistical analyses to come up with estimates of how many animals are needed per experiment. These analyses are based on previous experience with this type of experiment and expectations of an expanding number of researchers and projects over the next five years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will utilize pilot studies to ensure that there is a high likelihood of an experiment that is capable of testing a proposed hypothesis. Furthermore, different data types will be collected from each animal including electrical, video and anatomy, which will generate information about different aspects of the disease.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most animals will generate hundreds of hours of brain activity. These large data sets will be analysed in great detail utilizing advanced analyses such as machine learning to develop seizure prediction, biomarkers for disease to allow for better diagnosis and new potential avenues of research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use animal models of induced epilepsy through chemical or electrical stimulation as well as genetic models where specific mutations that predispose patients to epilepsy and neurodevelopmental disorders have been generated in mice and rats.

Why can’t you use animals that are less sentient?

In order to study how seizures propagate through complex brain networks that are clinically relevant it is necessary to use brains that highly approximate human brain.

Rodents have the overall same structure as human brain with a cortical mantel and underlying structures. This cannot be done in less sentient animals that do not have brain structures that allow for higher cognition. Furthermore, epilepsy often affects elements of cognition and it is important to understand how cognition is affected in our models and how these comorbidities are affected by how seizures spread through the brain.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are primarily using wireless technologies to perform long-term recordings in these animals. This allows us to study epilepsy more accurately as seizures in patients occur spontaneously, so we need 24 hour long term recordings. However, since the recordings are wireless animals are free to move in their cage and often can be housed in groups, which lowers stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

"Opportunities for improving animal welfare in rodent models of epilepsy and seizures" J. Neurosci. Methods

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will consult scientific literature on 3Rs, take heed of local announcements of the 3Rs in my institution and follow 3R accounts on social media.

168. Towards mechanistic understanding and improved treatment of nervous disorders

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

neurological disorders, psychiatric disorders, genes, brain, behaviour

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To enhance understanding of how genetic alterations pertaining to human nervous disorders affect brain structure/function and behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A wide variety of conditions come under the umbrella term 'nervous disorders' because they impair the normal functioning of the brain and affect behaviour. Neurodevelopmental disorders, such as autism and learning disability, affect the development and structure of

the brain. Epilepsy is characterised by unpredictable epileptic fits or seizures. Psychiatric disorders, such as schizophrenia, alter behaviour, perceptions and mood. Neurodegenerative disorders, such as Alzheimer's disease, are characterised by the death of nerve cells in the brain. Although these disorders have different characteristics, the first sign that something is wrong is often a change in behaviour. For example, an infant with learning disability may not begin saying simple words at the expected age, or an elderly person with the first signs of Alzheimer's disease may get lost walking to the shops.

Nervous disorders can be difficult to treat effectively with currently available medications, which at best provide only symptomatic relief - not tackling the underlying cause of the disorder. For some patients, symptoms may be alleviated by the prescribed treatment, but the disease may still gradually get worse (known as disease progression). Treatments often have unwanted side effects (e.g. tiredness, tremors), which themselves may affect patient well-being, causing some patients to stop taking their medication - which could lead to symptoms returning. For other patients, symptoms cannot be alleviated at all with current treatments. There is thus an unmet need for improved treatments for nervous disorders.

It is important to undertake work to achieve the aim of this project because patients with nervous disorders often have changes in their genes compared with healthy individuals. Through the use of DNA sequencing, scientists are able to identify genetic changes that are likely to contribute to the patient's condition. In this way, we are beginning to gain an understanding of what is causing the brain to function abnormally. For example, my research group recently identified an altered gene as the likely cause of a form of learning disability. Better knowledge of what causes the onset of each nervous disorder, and the possible worsening of symptoms, will help scientists to develop better treatments.

Given the strict limitations upon invasive approaches in clinical studies, it is difficult to do the necessary experiments in human patients. Unlike taking a blood sample or a skin biopsy, it is hazardous to a patient's health to take a biopsy from their brain. Therefore, we need to consider alternative ways to study how disease-associated genetic changes cause the brain to function abnormally. One way is to introduce the same genetic change found in human patients into cells grown in the lab. This cell culture approach may tell us how the genetic change affects aspects of the health of cells grown in a Petri dish, but it cannot tell us how the genetic change affects a whole brain made up of millions of cells, nor how it affects behaviour. A more informative approach is to introduce the same genetic change into mice, and study its effects on their brain and behaviour. This is a valid approach because mice and humans share all but ~1% of each other’s genes, the brains of all mammals have the same basic components and

structure, and mice exhibit a range of behaviours that can be measured and are similar to those exhibited by human beings (e.g. learning and memory, anxiety, social interactions).

What outputs do you think you will see at the end of this project?

Outputs in the form of published scientific articles and presentations to scientific conferences and patients' groups at the end of this project are expected to emerge from new information gained on how genetic alterations pertaining to human nervous disorders affect brain structure/function and behaviour.

Who or what will benefit from these outputs, and how?

In the short-term, these outputs would benefit affected families through genetic counselling and carrier screening, and facilitate the genetic diagnosis of other patients. The latter would allow affected families with the same genetic diagnosis to contact each other and provide mutual support, and allow doctors to prescribe (and patients to receive) existing treatments known to be beneficial in other patients with the same genetic diagnosis. Other beneficiaries in the short-term would be scientists trying to understand the molecular mechanisms of nervous disorders, and those trying to develop better treatments. It may also benefit scientists studying the normal biological functions and development of the brain, because a useful way of understanding how something works is to find out what happens when it goes wrong. In the longer term, patients and their carers would be obvious beneficiaries of the development and availability of better treatments.

How will you look to maximise the outputs of this work?

I would look to maximise the outputs of this work in multiple ways.

1. By collecting and archiving tissue from the brain and other organs of genetically altered mice and wild-type littermates, so that collaborators and ourselves can continue to study the effects of genetic changes after the mice have died.

2. By collaborating with other scientists who use techniques (under separate authority) in which my research group has little expertise.

3. By video recording mouse behavioural tests so that they can be analysed offline to look for subtle effects not detected initially.

4. By using non-animal approaches, such as differentiated neurones, to corroborate research findings.

5. By publishing successful approaches in high-impact journals, but also attempting to publish less successful approaches.

6. By disseminating research findings to patients' group and clinicians.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For several reasons, the project will use mice.

(i) There is extensive knowledge of their neuroanatomy, physiology, and genome.

(ii) They have a similar genetic make up to humans, sharing all but ~1% of each other's genes.

(iii) The ability to manipulate the mouse genome permits the introduction of genetic alterations pertaining to human nervous disorders.

(iv) The techniques we intend to use have been designed for mice and shown to be successful, including a variety of behavioural tests that allow us to assess nervous disorder-related behaviours.

Given the strict limitations on studies with human patients to find out how genetic changes affect their brain structure/function and behaviour, we will use genetically altered mice that harbour genetic changes shared with nervous disorder patients. There is growing recognition that manifestations of many human disorders most likely emerge from an underlying developmental and cellular biology shared in large part with other species.

When we are using genetically altered mice to study neurodevelopmental disorders that begin early in life, such as autism, we will observe juveniles and conduct experiments on young adults. When we are using genetically altered mice to study neurodegenerative disorders that begin later in life, such as Alzheimer's disease, we will observe young adults and conduct experiments on mature adults and aged mice to determine how the disease progresses with age.

Typically, what will be done to an animal used in your project?

If only one copy of a genetic change is required to cause the human nervous disorder under study, we will breed mice harbouring one copy of the genetic change (known as heterozygous) with mice harbouring two copies of a normal gene (known as wild-type); we would expect 50% of the offspring to be heterozygous and 50% to be wild-type. If two copies of a genetic change are required to cause the human nervous disorder, we will breed heterozygous males to heterozygous females, and would expect 50% of the offspring to be heterozygous, 25% to be wild-type, and 25% to have two copies of the genetic change (known as homozygous). Typically just after weaning at 3-4 weeks of age, each pup will have a notch of tissue clipped from its ear to identify it and for DNA analysis to determine its genotype, i.e. whether it is heterozygous, homozygous or wild-type.

Typically, adult mice will be habituated to handling for 7 days prior to behavioural testing comprising a battery of up to 8 tests, including no more than one test involving electric

shock, one test involving food restriction, and one test involving water restriction. The duration of an individual behavioural test can vary from 5 minutes to 2-3 weeks, if a test requires extensive training of the mice. The behavioural testing would usually be completed within 3 months. Occasionally, to assess disease progression, 4 of the 8 tests may be repeated no more than twice, after a period of at least 3 months, such that any one animal will be subject to a maximum of 16 behavioural tests in their lifetime.

Occasionally, a substance (e.g. an experimental drug treatment for the nervous disorder) may be injected into the mice prior to the commencement of behavioural testing. At the end of behavioural testing, the mice may be humanely killed (Schedule 1), and have their brain and organs collected, or may be retained for conventional breeding (Protocol 1 or 2) or 14C-2- deoxyglucose functional brain imaging (Protocol 7) if they have not been subject to administration of substances or surgery.

Occasionally, mice may be subject to a surgical procedure for a variety of reasons, including implantation of electrodes into the brain (to record electrophysiological signals during sleep and seizures); to facilitate collection of fluids from discrete parts of the brain; or to implant a mini-osmotic pump (for continuous infusion of drugs).

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the genetically altered mouse lines bred for use in this project do not show any adverse effects (a mild rating). However, three of the genetically altered mouse lines show reduced weight gain compared with wild-type littermates (a moderate rating). In one of these lines, homozgous mice also exhibit unusual repetitive hindlimb jumping in the home cage. Heterozgous mice in another of these lines exhibit stress-induced seizures in the home cage (a moderate rating), which are occasionally fatal (a severe rating). When an adverse effect is caused by the genetic change that the animal harbours, it would typically be lifelong.

Most of behavioural tests used in the project do not have adverse effects (a moderate rating). However, one of the protocols includes administration of a convulsant substance to evaluate seizure susceptibility. At the lowest dose, the convulsant is not expected to induce seizures in wild-type mice, but it may induce seizures lasting a few minutes in mice with increased susceptibility to seizures (a moderate rating). At a 1.75 times higher dose, the convulsant is expected to induce seizures in wild- type mice (a moderate rating).

Three of the protocols include use of surgical procedures (a moderate rating). The following adverse effects are expected during surgery: corneal drying (occurs regularly under anaesthesia), respiratory depression (occurs routinely), decreased body temperature (occurs routinely), and pain (occurs routinely). However, these adverse effects will be ameliorated and controlled using appropriate measures (e.g. use of appropriate analgesia).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mice
- Mild: 50%
- Moderate: 47%
- Severe: 3%

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Biochemical, anatomical, physiological, pathological and behavioural assays all contribute to understanding the functional consequences of a genetic change. Behavioural abnormalities, such as memory loss or convulsions, are the primary symptoms and diagnostic indicators of nervous disorders. Behaviour is an emergent property of brain function, involving coordinated activity both within and external to the CNS. Changes to genes and their expression may affect brain functioning, and hence behaviour, at multiple levels.

Unlike taking a blood sample or a skin biopsy, it is hazardous to a patient's health to take a biopsy of their brain. Given the strict limitations upon invasive approaches in clinical studies with human patients, we need to consider alternative ways to study how disease-associated genetic changes cause the brain to function abnormally.

Whilst in vitro model systems, such as cultured cells, have enhanced our knowledge of the cellular mechanisms through which genetic changes act, they have very limited utility for determining how genetic changes confer risk for nervous disorders, primarily because cells do not exhibit behaviours. As behaviour can only be studied in intact living animals, it is necessary to use animals to achieve the aim of this project.

Our approach is to introduce the disease-associated genetic change into the mouse genome, and find out how it affects the mouse's brain and behaviour. This approach is valid because humans and mice share all but ~1% of each other’s genes, the brains of all

mammals have the same basic components and structure, and mice exhibit a wide range of behaviours that can be measured and are similar to those exhibited by human beings (e.g. learning and memory, anxiety, social interactions).

Which non-animal alternatives did you consider for use in this project?

We recently began collaborating with a colleague to develop non-animal alternatives for the study of nervous disorders, namely 3-dimensional cultures called organoids. Genetic changes identified in patients with nervous disorders are introduced into human stem cells grown in the lab, which can then be turned into nerve cells and ultimately cultured into brain organoids (lab-grown 'mini-brains'). As human brain organoids are reported to recapitulate some features of the human brain, they could be used as alternatives to mice for studying the effects of genetic changes on brain development and structure.

Why were they not suitable?

Human brain organoid models are not currently suitable for use in this project because the technology is still at an early stage and too limited for organoids to replace animals. In future, in vitro investigations using organoids may provide some information on how genetic alterations pertaining to human nervous disorders affect brain structure/function, but not behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of mice used in the project is based on the following considerations.

- The number of genetically altered mouse lines to be used.
- The length of the project.
- The number of mice per experimental group (i.e. sample size) required to detect the effects of genotype (homozygous/heterozygous vs. wild-type) and sex.
- The number of mouse lines bred from heterozygous males and heterozygous females (i.e. intercrossing).
- The number of mouse lines bred from heterozygous males and wild-type females.

- The typical number of tests to which each mouse will be subject.
- Previous experience of running similar projects under two previous project licences.
- The likelihood of obtaining further grant funding.

These considerations have determined our overall plans for mouse breeding, maintenance and experimentation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

General strategies that reduce the number of animals in each experimental group necessary to obtain statistically significant results will be adopted whenever appropriate. We will ensure reduction by writing a protocol for each experiment, which will include statistically designed sample sizes (by power calculations) and by searching the literature to ensure experiments are not unnecessarily duplicated.

Typically, sample sizes are estimated using statistical methods which result in group sizes of 12 being necessary to achieve satisfactory results. Such calculations have determined our overall plans for mouse breeding, maintenance and experimentation.

To avoid the necessity of breeding new cohorts for each behavioural test, each cohort will be subject to a battery of tests, rather than a single test. Battery testing has the advantage of reducing the number of animals required. Although this approach may lead to different results compared to naïve cohorts, large differences are unlikely. Hence, although this approach has limitations, the benefits outweigh the costs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding protocols will be designed to ensure that only the required number of animals are bred, to minimise wastage. The number of new mice born within each genetically altered line will be monitored on a monthly basis to ensure that the supply of mice for experiments or line maintenance is appropriate. If the supply of mice is excessive, the number of breeding animals will be reduced by Schedule 1 killing.

When studying a homozygous genetic change, mouse numbers could be reduced further by breeding independent cohorts of wild-type and homozygous mice for comparison. However, to minimise variation, we will instead intercross heterozygotes to generate sex-matched littermate controls for our experiments, which is standard practice for behavioural studies.

To avoid the necessity of maintaining animals solely for conventional breeding, animals that have been subject only to non-invasive behavioural tests, without administration of substances or surgery, may be maintained for conventional breeding.

To avoid an excess of post-weaning mice of unknown genotype on the shelf, we will strive to ear notch mice and identify genotypes as soon as possible after weaning. In this way, mice of a particular genotype and sex that are not required for experiments or breeding can be killed (Schedule 1) before reaching sexual maturity.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Medical conditions that come under the umbrella term 'nervous disorders' typically impair the normal functioning of the brain and affect behaviour. Behavioural abnormalities, such as memory loss or convulsions, are often the primary symptoms and diagnostic indicators of nervous disorders. Patients with nervous disorders often have changes in their genes compared with healthy individuals. Through the use of DNA sequencing, scientists are able to identify genetic changes that are likely to contribute to the patient's condition.

The ability to manipulate the mouse genome permits the generation of mice with the same genetic change as in human patients. The genetically altered mice are studied to determine how the genetic change affects their brain and behaviour. This is a valid approach to understanding more about human nervous disorders because mice and humans share all but ~1% of each other’s genes, the brains of all mammals have the same basic components and structure, and mice exhibit a wide range of behaviours that can be measured and are similar to those exhibited by human beings.

To measure nervous disorder-related behaviours in mice, they will be subject to a series of behavioural tests that are not expected to cause any lasting pain or distress. The techniques we intend to use have been designed for mice and shown to be successful. During the last project licence, it was realised that the active avoidance test, which includes administration of electric shocks over a 5-day period, could be adequately replaced by the less-stressful passive avoidance test, which we were already using.

Similarly, it was realised that the forced swim test, which is classified as severe, could be adequately replaced by a 'water exposure' test in which the mouse is placed in a container of water that is sufficiently shallow to permit the mouse to touch the floor with its hind paws, such that the mouse is not forced to swim.

If a genetically altered mouse line exhibits behaviours that replicate abnormalities exhibited by human patients, we may subsequently use it to test prophylactic or therapeutic strategies. Dosing with drugs by injection will cause only transient pain.

To quantify the degree to which genetic changes found in epilepsy and related nervous disorders affect susceptibility to seizures, mouse lines harbouring these genetic changes will be subject to procedures that may induce seizures. However, the seizure-inducing procedures that we have selected are designed to induce seizures only in mice with an increased susceptibility to seizures, not in wild-type control animals.

Why can’t you use animals that are less sentient?

Behaviour can only be studied in awake, living organisms, so animals that have been terminally anaesthetised would be unsuitable. Although epilepsy, fragile X syndrome and other nervous disorders can be studied in lower model organisms, most notably Drosophila fruit flies, their nervous system is quite different from that of mammals, with less similarity to humans. Moreover, relative to lower model organisms, the wide range of behaviours exhibited by mice (e.g. learning and memory, anxiety, social interactions) has a greater degree of similarity to human behaviours.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Before behavioural testing, mice will be handled to reduce the stress of human interactions. Behavioural tests in general do not cause pain and suffering, but there will be a limit on the total number of tests and the number of aversive stimuli given to any one animal. Tests involving electric shock will only be used at the end of the test battery if milder tests of learning and memory are either inappropriate or do not achieve the desired outcome. Moreover, mouse lines with visible neurological defects due to the genetic variant they harbour will not be subject to behavioural tests involving electric shock.

Good handling and injection technique will minimise any minor/brief distress associated with the systemic administration of test substances. Where multiple daily injections are given, the injection site will be changed to minimise pain and potential inflammation.

For surgical procedures, suitable anaesthesia and analgesia will be administered in consultation with the Named Veterinary Surgeon; any sign of suffering will be discussed with the NVS for immediate advice.

There are multiple established tests to assess seizure susceptibility in rodents. However, the methods that we have selected are the least invasive and most refined because each procedure (including an observation period) can be completed within 1 hour and is designed to induce seizures only in mice with an increased susceptibility to seizures, not in wild-type control animals. For example, in the water exposure test, the mouse is placed in a container of water that is sufficiently shallow to permit it to touch the floor with its hind

paws; consequently, unlike in the forced swim test (which is classified as severe), the mouse is not forced to swim.

Planned future work includes the use of home cage video-monitoring to assess the behaviour (including incidence of spontaneous seizures) of genetically altered mice, which may eventually lead to fewer behavioural tests being conducted in this project.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure experiments are conducted in the most refined way, best practice guidance in the following publications will be followed:

Handbook of Laboratory Animal Management and Welfare, Third Edition. September 2003. S. Wolfensohn & M. Lloyd. Blackwell Publishing Ltd. https://onlinelibrary.wiley.com/doi/book/10.1002/9780470751077

Guiding Principles for Behavioural Laboratory Animal Science. Edition One: November 2013. LASA. https://www.lasa.co.uk/wp-content/uploads/2018/05/LASA_BAP_BNA_ESSWAP_GP_Behavioural_LAS_Nov13.pdf

The Design and Statistical Analysis of Animal Experiments. March 2014. S.T. Bate & R.A. Clark. Cambridge University Press. https://doi.org/10.1017/CBO9781139344319

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The licence holder has a track-record in the application of 3Rs in their programme of work, including NC3Rs funding for a replacement strategy and sitting on an NC3Rs grant panel. To stay informed about new advances in the 3Rs relevant to this project, we will utilise the PubMed and NC3Rs websites. If refinements to experimental procedures are published that will improve animal welfare, we will conduct pilot studies to determine whether they are suitable for adoption in this project

169. Lymphocyte development and ageing

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

lymphocyte development, ageing, antibodies, gene regulation, signalling mechanisms

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand gene expression and protein interactions that regulate development of B lymphocytes and antibody production, and how these change in ageing and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

B lymphocytes generated in the bone marrow produce the enormous antibody repertoire that we need to fight millions of different infections we may encounter. We do not fully understand many of the gene regulation and signalling mechanisms required to produce sufficient numbers of B cells with sufficient quality of antibodies throughout our normal lifespan. Undertaking this work will help to reveal how B cells progress through multiple stages of development, and how they convert a few hundred antibody genes into millions

of different antibodies. This will help us to understand why some people fight infections well, while others do not, and may identify new therapeutic strategies that could be used.

More specifically, older people are less able to fight infection and to benefit from vaccination. This is partly because older people make fewer B cells in the bone marrow, and these B cells make fewer different antibodies. If we can understand the major pathways that are defective in ageing, we can design strategies to reduce these defects and boost the ageing immune system. This will make a vital contribution to improving healthspan (how many years we stay healthy) in our increasingly long-lived population. Unfortunately healthspan is not currently keeping pace with lifespan, resulting in an ageing population that is living longer with multiple health conditions that reduce quality of life. Finally these studies will also contribute to our understanding of immunodeficiency diseases caused by poor antibody responses, and to our understanding of B cell leukaemias that initiate in bone marrow B cells.

What outputs do you think you will see at the end of this project?

Using state of the art genome-wide sequencing and computational mapping of the DNA and RNA data, we expect to generate many large databases of information on expression of genes and antibodies and how they change in ageing. We will publish several papers on the three objectives of the project. We may identify new products for the clinic, or provide new knowledge on therapeutic combination of existing products. We may generate new intellectual property, which we will protect with patents. We will also engage in active dialogue with the public to inform people about our research and its relevance to ageing and healthspan.

Who or what will benefit from these outputs, and how?

The earliest beneficiaries will be researchers working in related aspects of lymphocyte development, who will benefit from our databases to inform their studies. They will benefit from new understanding of key cellular signalling pathways and gene regulation mechanisms that enable B cell growth and development, and how they are altered in ageing B cells.

Researchers working on ageing in other systems will benefit from new knowledge on common ageing pathways, and ageing heterogeneity (how individuals age differently)

Researchers working on growth, metabolism and gene regulation in other tissues will benefit from our findings, which will be relevant for many tissues.

In the longer term, clinicians and immunologists working with ageing patients will have greater understanding of the characteristics of the antibody repertoire that change with ageing, and may have new tools to assess immune system health.

Vaccinologists may have new insights into ways to boost vaccine efficacy, in the general population and in older people.

Clinicians treating B cell and other leukaemias will benefit from new understanding of how genes are organised on different chromosomes in the nucleus, and how this positioning may predispose to leukaemias.

Once intellectual property is protected, commercial interests may have new therapeutic products to develop.

How will you look to maximise the outputs of this work?

We will maximise the utility of the large datasets we will generate, eg by sharing data early and seeking collaborations on important discoveries that we do not have the expertise or resources to follow up. We will publish our research as preprints on bioRxiv in advance of submission to journals. We will publicise any unsuccessful approaches to the scientific community to avoid others wasting resources on these (eg published mouse models in which we discover a fault). We will present our results at scientific conferences before publication. We will secure any potential intellectual property by patent to protect UK commercial interests. We will do this early in order to avoid delays in publication. We will actively engage with appropriate commercial and clinical interests to progress our results towards the clinic in a timely fashion.

Species and numbers of animals expected to be used

- Mice: 7160

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice because the mouse immune system, in particular lymphocyte development, is extraordinarily similar to the human system. Furthermore, gene regulation and cytoplasmic signalling, our main investigation areas, are also very similar between mouse and human. Additionally individual genes can be effectively deleted in mice in specific tissues without affecting the whole animal. We will use two types of mouse models. First, we will study mice in which specific genes that we have shown are important in ageing, have been deleted only in B cells, ensuring the mice remain healthy overall. These studies will be in mice aged 3 months (equivalent to a human young adult). Second, we will compare 3 month-old wild-type mice with wild-type mice that we will age up to 24 months (equivalent to a human of over 70 years). This will enable us to study defects in B cells that occur as a consequence of ageing.

In addition to the fact that the ability to delete individual genes in mice enables highly specific and detailed studies that are not possible in humans, we are also particularly

restricted to using mouse models specifically for these studies, because, unlike human blood samples, it is very difficult to obtain human bone marrow samples for research.

Typically, what will be done to an animal used in your project?

A small number of female mice (<100) will be injected with hormones to increase production of embryos (superovulation) and a similarly small number (<50) will receive embryos via surgical or non- surgical procedures to establish new mouse strains. A very small number of male mice (<10) will be vasectomised to help with this.

For the vast majority of our studies, including both gene-deleted and aged mice, we will remove bone marrow and spleen from mice post-mortem, and purify and/or grow B cells from these samples. We will occasionally re-inject some of these purified B cells back into mice to determine how efficient they are at restoring B cells in the mouse.

What are the expected impacts and/or adverse effects for the animals during your project?

Superovulation, receipt of embryos and vasectomy described above are surgical procedures that are considered moderate, due to pain post-surgery. This is controlled by analgesia before and after surgery.

For most of the mice, we do not expect any adverse effects in our extremely high quality animal care facility. Some mice will be immunodeficient, but we know from experience that this has no adverse impact on health in our specific pathogen-free (SPF) facility. We also know that the vast majority of our aged mice remain healthy throughout the duration of our experiments. A small minority get tumours, but regular checking by our experienced animal technicians ensures these are detected early, and the mouse euthanised immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for most of the mice will be mild. The expected severity for embryo recipients and vasectomy will be moderate. Together, the proportion of those in the moderate category will be 1% of the total mouse cohort.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals primarily because this is the only way that we can study the role of individual genes in detail, by investigating the effects of single gene deletion on all the stages of development they affect, in this case bone marrow B cell development. Furthermore, it is extremely difficult to study B cell development in the bone marrow in humans, because it is very difficult to obtain human bone marrow samples, in particular from healthy donors.

Nevertheless, as part of our current PPL and future plans, we have established a pilot human bone marrow culture system, which will replace some of our mouse studies and/or provide important cross species validation.

Which non-animal alternatives did you consider for use in this project?

We have considered using mouse bone-marrow derived B cell lines.

Why were they not suitable?

These lines only represent one stage of B cell development at a time, and thus we can't study how all the stages of development affect each other. Also the culture conditions they grow in do not allow all of the possible different antibodies to be made, and some cell lines only allow one type of antibody to be made, so we could not investigate the role of individual genes in generating the millions of different antibodies that our millions of B cells make.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals we will use from our previous studies using aged mice, and mice in which we have altered a gene. This has enabled us to predict the numbers of mice of the correct genotype that we will produce from breeding, and the numbers of aged mice that we will need.

Data from previous experiments has enabled us to estimate the numbers of cells we will need for each experiment, and consequently the numbers of mice of each genotype.

Important considerations have included adjusting for the reduced numbers of B cells produced by aged mice compared with young mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted in depth with our Biostatistician, and have built on our previous experience of working with these and similar mice. In particular, we have learned that individual aged mice have much more variation in the genes they express compared with young mice. Accordingly we have had to increase the number of aged mice compared with young mice within some experiments, but this will reduce numbers in the future, since individual experiments will be statistically significant.

We have increased the focus of our experiments towards the B cell culture system that we have developed, instead of using ex vivo purified B cells. While culture systems have some caveats, and are not suitable for all experiments, they have the advantage that cell numbers can be expanded to provide many more cells per individual mouse, which also has the synergistic advantage that parallel experiments can be conducted in the same mouse rather than in separate mice, increasing statistical robustness. One mouse can provide the equivalent number of B cells expanded in culture to the number of ex vivo purified B cells from 20 mice. We have used the NC3R's Experimental Design Assistant to ensure we are considering all relevant aspects of design.

We will avail of ongoing improvements in next generation sequencing methods that have reduced cell numbers required. For example one of our methods previously required 10 million cells, but improved methods now only require half a million cells.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our mouse facility has an extremely efficient pipeline of 10 day biopsies, and rapid genotyping by a commercial provider, that provides timely results to enable efficient breeding.

Selective deletion of individual genes in specific tissues will be achieved by the use of Cre-Lox recombination to delete the gene of interest in the desired type of cells. We will do pilot studies with cre recombinase expressing mouse lines crossed to mouse lines expressing conditional floxed genes of interest to ensure, first that the gene is efficiently deleted in the cells in which we want it to be deleted, and second that the approach does not delete the gene in other cells. For the latter we will make extensive use of genotyping for deleted genes, which has previously alerted us to off-target gene deletion events which necessitated re-design of our experiments. Pilot studies ensure minimum use of mice before decision points are reached in experimental design.

For our aged mouse studies, we have an established and highly successful programme of sharing of tissues with other investigators, which we will continue. This often includes up to 4 investigators using tissues from the same mouse.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use wild-type, transgenic, gene-targeted young mice up to 3 months, and aged mice up to 26 months.

Transgenic and gene-targeted mice usually only have a single gene, or at most, three genes, altered. Either by natural expression patterns, or by targeted deletion this only affects a small number of tissues. In this project these are primarily bone marrow and spleen B cells. Any potential pain or suffering would arise from infection, since these mice will have defective B cells and thus be more susceptible to infection. All mice are housed in very clean conditions, which prevent infections, and thus prevents any such pain or suffering.

Most experiments only take tissues post-mortem. A small number of experiments will involve injecting bone marrow cells into a recipient mouse to reconstitute the immune system. These experiments provide detailed in vivo knowledge on the ability of haematopoietic cells from a gene targeted mouse to contribute to B cell development, in ways that studying cells ex vivo can not do. Furthermore, relatively few cells from a single gene-targeted mouse can reconstitute several recipient mice, contributing to greater statistical power. In some cases these experiments will restore the immune system of immunodeficient mice, and will have no negative impact. In a small number of cases, wild-type mice will be irradiated to remove endogenous lymphocytes, to ensure donor bone marrow is providing reconstitution. This can occasionally lead to ill health, but these mice will be carefully monitored and any animal exhibiting pain or distress will be culled immediately.

Thus in most cases, there is no pain, suffering, distress, or lasting harm expected with the models or planned experiments. The exception to this is that a small number of animals that will be embryo recipients, or will be vasectomized, will experience transient pain due to surgery. This will be ameliorated by analgesia.

Why can’t you use animals that are less sentient?

We can't use animals that are less sentient, because they do not have an adaptive immune system that is comparable to the human system. This system first appears in evolution in the lamprey and zebrafish, but in a very rudimentary form, that is not suitable for in-depth studies. Species including C elegans and Drosophila melongaster, have rudimentary innate immune systems, but do not produce lymphocytes.

We also cannot use early stage mouse embryos because the adaptive immune system does not develop until late stages of embryogenesis.

Although some species including C elegans are established models of ageing, their lack of an adaptive immune system makes them unsuitable for our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are mindful of increased possibility of welfare costs as mice age, and we have implemented a programme of increased frequency of observation of these mice. We have developed a detailed checklist of possible age related changes, and procedures for monitoring and treatment, which informs our decisions. We will gather data from these studies to further refine best practice.

We will implement any refinements developed by our animal house staff, who have a long history of innovative practice, including environmental enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published best practice guidance from NC3Rs, LASA and the Home Office.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs during this project via the monthly NC3Rs e- newsletter, NC3R workshops and webinars, and our annual Institute 3Rs seminar. We will avail of Home office advice made available to us through our dedicated Home Office Liaison.

To implement advances effectively, we will follow advice from our local AWERB. Our animal facility also has a dedicated Strategy Committee and a User group, on which we are represented. Both groups discuss and make collective decisions about advances in the 3Rs and advise on how they can be implemented, both across the organisation, and by individual groups.

170. Gene and environment influences contributing to psychiatric disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

addiction, impulsivity, zebrafish, cognition, behaviour

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to advance understanding of genetic and environmental factors that influence an individual's vulnerability to psychiatric disease, and the biological processes by which they act.

A secondary aim is to identify small molecules that ameliorate psychiatric disease phenotypes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Psychiatric or behavioural disease including addictions, anxiety disorders and depression is a major concern for modern society with huge financial and social cost: The World Health Organisation estimates untreated mental health problems account for 13% of the total global burden of disease. It is projected that, by 2030, mental health problems will be the leading cause of mortality and morbidity globally. The UK 2013 Chief Medical Officer's report estimated that the wider costs of mental health problems to the UK economy are £70–100 billion per year – 4.5% of gross domestic product.

Identification of genes and gene products influencing psychiatric disease phenotypes gives insight into the etiology of the disease allowing the identification of vulnerable individuals, the development of therapeutic interventions and more personalised therapies. Human genome wide association studies (GWAS) have identified a number of alleles and copy number variants associated with psychiatric disorders e.g.[Horwitz et al 2019 for review] but causality has yet to be established and the mechanisms by which these factors act, and which component behaviour they regulate, is in large part unknown.

Further, it is clear that environmental factors throughout the life course interact with genetic pre- disposition to influence behavioural outcomes (see Dick 2011 for review). Understanding the nature of these interactions and the biological processes affected will lead to better preventative and treatment options.

Horwitz, T., Lam, K., Chen, Y. et al. A decade in psychiatric GWAS research. Mol Psychiatry 24, 378– 389 (2019). https://doi.org/10.1038/s41380-018-0055-z

Dick, D.M. Gene-Environment Interaction in Psychological Traits and Disorders (2011). Annual Review of Clinical Psychology 2011 7:1, 383-409

What outputs do you think you will see at the end of this project?

Expected outputs include:

1) Identification of up to 20 genes affecting behavioural phenotypes associated with psychiatric disease. Specific phenotypes examined are; reward responses to drugs of abuse, impulse control, social interaction, anxiety, sleep, circadian rhythm, memory and learning.

2) Establishment of the developmental and cell biological processes by which genetic variants associated with psychiatric disease act.

3) Greater understanding of the interaction between genetic variants, developmental and environmental factors contributing to psychiatric disease.

3) 5 or more publications.

Who or what will benefit from these outputs, and how?

Long term benefits:

Academics, clinicians and the wider population:

Output 1, 2) Identification of genes and gene products influencing psychiatric disease phenotypes and how they act gives insight into the aetiology of the disease allowing the identification of vulnerable individuals, the development of therapeutic interventions and more personalised therapies.

Output 3) It is well established that environmental factors such as developmental stress, exposure to environmental toxins and dietary factors interact with genetic predisposition to influence the occurrence of psychiatric disease. Increased understanding of these interactions (for example, which genetic variant influences responses to specific environmental conditions) and how environmental factors impact on the aetiology and cell biology underlying behavioural disease will further the development of preventative strategies, of therapeutic interventions and of more personalised medicines.

Short term benefit: We use fish (zebrafish) as our model species. Zebrafish are vertebrate fish that are widely used as a model for the study of human development and disease due to the ease with which one can identify genetic factors that modify disease processes in these species. By extending the use of fish to the study of behavioural disease we contribute to the refinement of animal usage by reducing the use of mammalian species.

How will you look to maximise the outputs of this work?

To maximise outputs we aim to publish in well renowned journals, publicise findings via social media, the university Public Engagement office and at national and international conferences. We will collaborate with other researchers in the field, including industry, to ensure realisation of potential therapeutic benefits. Data will be stored in Institutional repositories (e.g. Apocrita) and made publicly available on publication in accordinance with Open Access policies. Identified lines will be shared with researchers on request.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): Adult wild type or genetically modified fish: 10,000, wild-type or genetically modified larvae: 35,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is not possible to study complex behavioural processes such as those associated with psychiatric disease and addiction without the use of animals. Zebrafish are non-mammalian vertebrates that have been shown to have a translationally relevant behavioural repertoire as well as conserved drug reward response to addictive drugs.

Zebrafish have been extensively used as a genetic model for the study of development and thus a large number of resources including transgenic lines and mutants are available. Large scale screens are more feasible in these species than in rat or mouse. Thus, they are the vertebrates with the lowest neurophysiological sensitivity likely to yield results relevant to the human condition.

Invertebrates such as Drosophila and C. elegans are other popular model systems for forward genetic screens. However, despite being useful models for the analysis of the acute effects of drugs of abuse, assays for psychiatric disease phenotypes and drug preference have yet to be established in these species. Furthermore, invertebrate brains do not show the same level of complexity as vertebrates and it is not clear whether the neuronal networks established to be involved in addiction and human behavioural disease are present in invertebrates. Thus findings from Drosophila and C. elegans are less likely to be relevant to human biology than findings from studies on vertebrates such as zebrafish where the conservation of neuronal networks has been established.

We use both larval and adult forms in our studies. Wherever possible, behavioural assays are conducted at larval stages. However, more complex behaviours associated with psychiatric disease, such as poor impulse control, deficits in social interaction, aggression, cognitive phenotypes, are not evident until juvenile or adult stages. In addition, many of the environmental factors that impact behaviour operate over an extended period or at juvenile stages requiring the use of older forms.

Typically, what will be done to an animal used in your project?

Wild type or genetically modified animals (fish carrying non-harmful reporter constructs or genetic mutations showing no clinical signs of harm) will be assessed for performance in behavioural assays. In the majority of cases fish will only be assessed in one behaviour during their lifetime. The exception to this may be evaluation of behaviour as larvae and subsequent evaluation of a second behaviour as adult. Behavioural assays in adults involve performance of operant learning tasks, such as approaching a light for food reward, as well as evaluation of natural behaviours such as response to a novel environment, startle responses, sleep, circadian rhythm or social interactions, and reward responses to commonly abused drugs. Larval behavioural assays are restricted to assessment of natural behaviours such as sleep, circadian rhythm, response to a novel environment, light or dark preference, or startle response.

Depending on the assay, behaviour may be assessed over a period of 5 min (response to novelty, social interaction), 1 hr (response to startle, reward response to drugs of abuse) or an hour a day over several weeks (operant learning tasks).

We assess the interaction between genetic variants and the environmental factor of developmental drug exposure.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected from the behavioural assays themselves. The genetically modified lines used for our studies are not expected to cause harm; we predominantly assess behaviour in existing mutant lines that have no obvious morphological defects or clinical impairments. However, where a new line is generated injected constructs may cause developmental abnormality (25%). No animal showing abnormal development will be reared.

On occasion individual animals show increased anxiety, evident as rapid breathing and altered swimming behaviour, and fail to habituate to the behavioural assay equipment. Animals that exhibit such behaviour for more than 10 minutes on any one day are removed from study that day. If animals fail to habituate to the apparatus repeatedly over 3 days, they are not used further for behavioural studies but may be used for breeding or tissue-based studies.

Animals used in appetitive learning tasks for food reward may show weight loss over the course of the experiment (up to 10 weeks) if they fail to learn well. Where >10% weight loss is evident by visual comparison with non-experimental animals, fish are given additional food outside the training session.

Where the impact of drug exposure on behaviour is evaluated, exposure to drugs may cause an acute (<10min) avoidance response. On rare occasions, where genetic variants cause hypersensitivity, drugs may be toxic leading to abnormal swimming or haemorrhage. In this event animals will be immediately removed from the drug and killed.

Where fish are genotyped using finclip, fish may experience brief <24 hr post-operative pain. Swabbing (https://www.liebertpub.com/doi/10.1089/zeb.2016.1348) will be used as an alternative method for collection of DNA for genotyping wherever possible.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

> 95% of animals (larval or adult) are expected to be used in behavioural assays of mild severity. <5% of animals are expected to be used in assays of moderate severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to study complex behavioural processes such as those associated with psychiatric disease and addiction without the use of animals.

Invertebrates such as Drosophila and C.elegans are other popular model systems for forward genetic screens. However, despite being useful models for the analysis of the acute effects of drugs of abuse, assays for psychiatric disease phenotypes and drug preference have yet to be established in these species.

Futhermore, invertebrate brains do not show the same level of complexity as vertebrates and it is not clear whether the neuronal networks established to be involved in addiction and human behavioural disease are present in invertebrates. Thus findings from Drosophila and C. elegans are less likely to be relevant to human biology than findings from studies on vertebrates such as zebrafish where the conservation of neuronal networks has been established.

Which non-animal alternatives did you consider for use in this project?

We collaborate with human geneticists to examine the genetics of psychiatric disease based on analysis of human genetic datasets. Meta-analysis of pathways affected in human cohorts together with those identified from existing mutants and from pharmacological studies in fish (our lab as well as those of others) as well as other species is used to identify candidate genes and pathways underlying addiction and psychiatric disease.

Why were they not suitable?

Although human studies can identify genetic variants associated with disease phenotypes, the complex nature of human behaviour coupled with variance within human cohorts makes identification of significant associations difficult. Further, it is not possible to test causality using human subjects, nor to conduct cell biological studies to determine cellular processes affected. Previous animal studies have largely focused on candidates identified from human studies and cannot account for all the variance seen within human populations. In addition, most animal studies to date do not address the phenotypes outlined here.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on previous studies in our lab and the lab of others in the field and have been recalculated and checked using the NC3Rs Experimental Design Assistant tool.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use research experimental tools like the NC3Rs Experimental Design Assistant ensure appropriate study design and to help reduce the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise number of animals used we will optimise genotyping protocols so as to allow genotyping at early life stages to increase breeding efficiency. Pilot studies will also be undertaken for all new studies to help minimise animal usage. Wherever possible animals that are to be killed following behavioural analysis will be used to provide tissue for molecular studies and tissue will be shared. When conducting experiments to isolate phenotypic fish for genotyping to identify novel mutations affecting behaviour, computer modelling is used to predict the number of animals required.

To reduce the number of animals used we have established a collaboration with other large zebrafish institutes in the UK and the USA, whereby they provide adults or embryos from their mutagenesis screens and transgenesis programmes thus reducing the number of new mutagenized/ transgenic animals generated.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use zebrafish as our model species. Zebrafish are non-mammalian vertebrates that have been shown to have a translationally relevant behavioural repertoire and conserved drug reward response to addictive drugs. Thus they are the vertebrates with the lowest neurophysiological sensitivity likely to yield results relevant to the human condition.

Zebrafish have been extensively used as a genetic model for the study of development and thus a large number of resources including transgenic lines and mutants are available. Large scale screens are more feasible in these species than in rat or mouse.

Zebrafish ENU-mutagenised lines carry mutations at a greater density than mammalian mutagenised lines allowing more efficient screening of the genome (and therefore minimising the numbers of animals used). Zebrafish embryos and larvae are transparent allowing visualisation of morphological defects at early life stages minimising harm.

We primarily use observation of natural behaviours or appetitive learning paradigms as our means of assessing behavioural phenotypes. Behavioural assays of natural behaviours are not predicted to cause pain, suffering or lasting distress or harm. Appetitive paradigms can be considered less severe than those using aversive learning. Although on occasion we assess behaviour in response to aversive stimuli, in fish adverse stimuli are generally mild and short-lived, such as a single knock on the side of the tank, flash of light or sight of a predator.

Why can't you use animals that are less sentient?

Invertebrates such as Drosophila and C.elegans are other popular model systems for behavioural genetic studies. However, despite being useful models for the analysis of the acute effects of drugs of abuse, assays for psychiatric disease phenotypes and drug preference have yet to be established in these species.

Furthermore, invertebrate brains do not show the same level of complexity as vertebrates and it is not clear whether the neuronal networks established to be involved in addiction and human behavioural disease are present in invertebrates. Thus findings from Drosophila and C. elegans are less likely to be relevant to human biology than findings from studies on vertebrates such as zebrafish where the conservation of neuronal networks has been established.

We use both larval and adult forms in our studies. Wherever possible, behavioural assays are conducted at larval stages. However, more complex behaviours associated with psychiatric disease, such as poor impulse control, deficits in social interaction, aggression, cognitive decline, are not evident until juvenile or adult stages. In addition, many of the environmental factors that impact behaviour operate over an extended period or at juvenile stages requiring the use of older forms.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements to minimise suffering include increased monitoring for all experimental animals, particularly following any invasive procedure (skin swabbing/anaethesia/finclip) or drug exposure. We regularly review protocols and the use of analgesics, for example post finclip, with the NACWO and NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow FELASA and LASA best practice guidelines and the ARRIVE guidelines. In addition, I am a member of the EU zebrafish society (https://www.ezsociety.org/), a society dedicated to promoting and improving the use of zebrafish for biomedical research. Through active participation in this society I am party to EU wide best practice advice regarding the use of zebrafish for research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are kept up to date with advances in the 3RS through the NC3Rs newsletter direct to personal email addresses and via Institutional notification from the NACWO, compliance officer and licensed vet, and through the AWERB.

171. Studies on the neurobiology of sensation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

chronic pain, neuroscience, cancer, neuropathy, therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	neonate, juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The pivotal aim of this project is to determine the basic bodily processes that underlie the sensation of touch and pain, and how these processes are altered in persistent pain states. The ultimate objective is to translate pre-clinical observations to the clinical domain

in order that we can better treat chronic pain in patients through targeted pharmacotherapeutic application.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important because pain remains a clinical unmet need with considerable socio-economic burdens because of the limited number and efficacy of existing therapies. Nearly 20% - that is >100m Europeans - suffer moderate or severe pain of long duration. Importantly, much of this pain is not adequately controlled by currently available pain-relief medications, and those therapies available are additionally associated with many significant and often dose-limiting side effects. There is clearly a pressing need for novel analgesic agents or therapies, and the effort to generate these will be greatly strengthened by a better understanding of the underlying mechanisms that cause and drive persistent pain. Chronic pain presents an intellectual challenge because of the complexity and range of biological and neuronal processes that change the way in which we perceive pain. Our work will examine the circuitry controlling and contributing to chronic pain and thus will increase our understanding of pain neurobiology, such that targeted pharmacotherapeutic approaches may be translated to the clinic.

Some studies of sensory phenomena are possible in humans however, mechanistic questions require invasive techniques that are not possible or feasible at present in humans and as such we propose the work herein.

What outputs do you think you will see at the end of this project?

We anticipate the following outputs:

1. Identifying novel pain mediators and analgesic strategies for varied pain states. It is likely that the precise role and involvement of these targets will differ depending on the precise pain state. We therefore require a variety of different models to investigate their function. Beyond new targets we are also working on novel analgesic strategies as to how persistent pain could be best treated.

2. Uncovering the role of neuro-immune interactions. We will investigate how nociceptors interact with immune and other supporting cells as these are frequently the source of pain inducing mediators.

3. Defining pain circuitry in health and disease. We will study how neuronal circuits transmit injury messages that lead to the sensation of pain, and how these circuits change in disease states. Fundamental questions regarding the integration of peripheral inputs with spinal circuitry and the top down cortical modulation of spinal circuitry will be answered.

4. Refining the administration of peri-operative analgesics to animals undergoing surgery to induce a chronic pain state. The positive impact of surgical administration of centrally-acting analgesics on the acute pain state (in the period immediately following surgery) is expected with no impact on the desired neuropharmacological experimental outcomes where the aim is to investigate chronic pain mechanisms.

Who or what will benefit from these outputs, and how?

1. **Immediate use of data and products**

This work will provide further knowledge of the normal properties and regulation of primary sensory systems and how they are affected in persistent pain states. Experimental results will be analysed and used to determine the direction and design of appropriate and efficient follow-up experiments. Data will also be written up and presented at international meetings and published in peer-reviewed journals for dissemination to the research community at large.

2. **Opening of new avenues for research**

We believe that the data generated from this project will open up new avenues of research. Research into and improved understanding of normal, pathophysiological and psychological pain processing and spinal cord function will lead to the determining of cell signals, neurotransmitters, channels etc. implicated in the production of pain syndromes. Each novel target identified will open a new avenue of research including replication and validation of hypothesis by numerous means.

3. **Practical Applications**

We believe that the work done in this project will have a future important practical value in the development of strategies to combat illness associated with chronic pain (such as arthritis, bone cancer, neuropathic pain). Previous studies indicate that the discoveries underlying chronic or persistent pain states in animals are transferable to analogous conditions in humans. In short, our hope is that our work will be translated into treatments for patients.

In total the knowledge that could arise from the proposed research would benefit many people within the pain community as we will significantly advance our understanding of the underlying pathology of pain conditions, particularly the recognition that chronic pain states are associated with maladaptive forms of plasticity in the peripheral and central nervous system.

How will you look to maximise the outputs of this work?

We have a number of external collaborators already in place (including those nationally in the UK as well as those internationally in Denmark, the USA and Canada). Understanding the neurobiology of sensation is of relevance to many audiences including academic and industrial researchers, clinicians, patients and the general public. Different forms of communication must reflect the varied nature of the beneficiaries and project results will be disseminated accordingly such that the importance of this research is described to different audiences in the most meaningful manner.

Results from this work will be presented at national and international scientific meetings with a focus on basic science and translational research. Data will be published in basic

science (pre-clinical and clinical) journals including those with an interdisciplinary focus. We will be targeting pain discovery and management communities. Social media such as the KCL pain-laboratories twitter feed will detail project progress, conference attendance and journal publication ensuring that the outputs of this work will be maximised.

Species and numbers of animals expected to be used

- Mice: 15400
- Rats: 3848

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are principally interested in pain mechanisms. Some studies of sensory phenomena are possible in humans. However, the mechanistic questions that we wish to answer require more invasive techniques that are not possible or feasible at present in humans. In vitro techniques are also not sufficiently advanced (and are not likely to be so for some considerable time) that they can model the integrated actions of the nervous system. Thus, we will undertake some of our work in animals. The use of rats and mice throughout the project, which requires in some areas modelling of a pain state, is critically important. The neuroanatomy/neurophysiology of the rat and mouse is well understood and there is a comparable central nervous system complexity to the human. In rats and mice we can unequivocally establish which pathways underlie distinct pain processing mechanisms where a cell culture system would not model the necessary aspects of pain perception.

The questions we are asking usually relate to a specific human disease or pathology, which we need to model with suitable animal models: for instance TNF and NGF may interact in the context of interstitial cystitis, where there is an important inflammatory component, but not in the context of osteoarthritis.

Conversely, osteoclasts may play a role in sensitizing neurons in osteoarthritis, but obviously not in bladder pain. We therefore need to study a range of animal models of different human diseases.

Some of these animal models are short onset and short duration (hours) and can therefore be studied acutely in animals. For example, the injection of a chemical agent like capsaicin in the hind paw is associated with a nocifensive reflex and paw withdrawal from a noxious stimulus which are observed and recorded for up to 120 minutes. Other models, like their human counterparts, develop and change over time and so some of these experiments may last weeks or even months. For example, the injection of the chemical monoiodoacetate in the knee as a model of osteoarthritis is associated with nocifensive reflex and paw withdrawal from a noxious stimulus which are observed and recorded for

several weeks. The prolonged time course of some experiments and the fact that one of the most important outcome measures in our work is behavioural assessment of the animal, means that only some work can be done on animals under terminal anaesthesia - the remainder will require the use of recovery protocols.

Our scientific questions largely relate to the study of pain mechanisms in mature animals. However, in some cases an intervention is necessary at an earlier developmental stage. One example is the use of systemic capsaicin or resiniferotoxin, which if given in the early post-natal period (but not later in life) in rodents leads to a permanent depletion of nociceptors. This provides an important control experiment in mature animals. Another example relates to epigenetic studies. There is a belief that early life experiences may have a long-term regulatory role function of pain sensitivity, explaining why some patients appear to be very vulnerable to develop chronic pain. To study this phenomenon, it is necessary to give an intervention, such as an inflammatory stimulus or an inflammatory mediator to developing animals, even though the major aim is to understand the consequences for the mature animal.

Typically, what will be done to an animal used in your project?

Typically our experimental themes (in terms of what will be done to an animal used in this project) will rely on the following sequence steps following determination that animal work is necessary for the question at hand:

1. Genetically label or manipulate the cell population under study, e.g. inject AAV9-GCaMP6s virus into a rat to label DRG neurons or breed a transgenic mouse line which is knockout for a putative pain mediator

2. Induce a pain model

3. Apply a treatment (either in the form of a drug or toxin or using neuromodulation)

4. Test the functional outcomes of this treatment through the means below:

a) via behavioural studies: we have begun to innovate with assays that capture more natural, spontaneous animal behaviour – e.g. using home-cage monitoring. We will undertake a variety of behavioural tests of pain sensitivity. Most use threshold stimuli (eg heating the hindpaw) and the animal is free to withdraw from the stimulus at any time. Two, however, use surprathreshold stimuli (the formalin test and the capsaicin test).

b).by measuring neuronal activity in real time, using terminal electrophysiology, terminal calcium or optical imaging or – only when absolutely necessary for the scientific question: optical imaging or neurostimulation in awake animals (protocols 3-7).

5. Sacrifice the animal through schedule 1 or perfusion for subsequent anatomical studies or gene expression/protein assays.

What are the expected impacts and/or adverse effects for the animals during your project?

For all protocols: In the event of reaching the end-points described below, humane killing of the animal would be carried out by a schedule 1 method.

Weight: Weight loss of less than 10% in the absence of other clinical signs (see below) will result in increased monitoring and supportive measures such as wet mash diet. Weight loss of 15% in the presence of other clinical signs (see below) will result in humane killing. Weight loss of 20% in the absence of any other clinical signs will result in humane killing.

Posture: Hunched posture is indicative of discomfort, distress and pain. Continuous hunched posture or repeated phases of intermittent hunched posture over a period of 24h or prostration will result in humane killing.

Coat: Changes in animal's coat and condition is indicative of discomfort, distress and pain. Animals with a staring coat with marked piloerection will be humanely killed.

Behaviour: Rodents tend to be curious, exploratory and sociable in behaviour. Subdued behaviour and isolation are indicative of discomfort, pain and distress. An animal showing subdued behaviour, even when provoked, and little peer interaction, will be humanely killed. Similarly, animals which exhibit vocalisation to handling or gentle touch for more than a transient period will be humanly killed.

In addition the following expected impacts and/or adverse effects are noteworthy:

1. **Regarding new mouse lines:** It is not possible to fully predict the nature or severity of any potential defect and for all types of mice. As a result, with new lines, there will be careful monitoring for possible side effects. Animals exhibiting any unexpected harmful phenotypes will be killed, or in the case of individual animals of particular scientific interest, advice will be sought from the Home Office Inspector. Where the immune status of the animals might compromise health, they will be maintained in a barrier environment. Small samples of tissue will be taken for genotyping. No more than 0.3 cm of the tail will be removed. Other than in terminally anaesthetised animals, dosing and sampling procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm.

2. **Regarding dosing of agents:** Other than in terminally anaesthetised animals, dosing of agents will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. The dose of each agent will be chosen to avoid adverse systemic effects with veterinary consultation where appropriate, for novel agents or combinations thereof. As the majority of agents administered are produced to human clinical standards and their dosages have already been defined in animal models, adverse events are less likely to occur. In our experience, animals rarely die post i.v or i.p. injection (less than 1%) and generally recover well post anaesthesia. Dosing regimens for therapeutic agents is likely to be known in most cases. If dose escalation studies are required, they will be performed such that animal behaviour post administration can be observed for at least 15min before proceeding to the next higher dose (in a different animal). Thereby any acute adverse

effects can be detected. Control/vehicle substances will be administered first. If animals do not recover from acute adverse effects by the end of the working day OR show signs of pain exceeding a moderate severity they will be killed by a schedule 1 method. Some agents may cause adverse effects such as diarrhoea, skin and coat changes, feeding and behavioural abnormalities. We will regularly check the animals for limiting clinical. If any limiting clinical sign (see end points described above) is more than transient then the animal will first be closely monitored and then humanely killed by a schedule 1 method or anaesthetic overdose if there is no improvement within 48h.

3. Labelling of cell populations: In rare instances, surgeries to administer viruses/labelling agents may have complications associated with the procedure: i. Deaths resulting from anaesthetic or surgical complications are most uncommon (<1%) and will be minimised by ensuring correct dose/body weight and maintenance of body temperature (e.g. by use of warming pads). ii. Post-surgical infections are rare with the procedures described here. The risk of infection or delayed healing will be minimised by good surgical and aseptic techniques. Any signs of wound infection will be treated with antibiotics and wound powder, and if signs persist for more than 48 h the animal will be killed by a schedule 1 method. iii. Skin closure can produce local pain and/or necrosis and the risk will be minimised by removing any non- resorbable closure devices (e.g. stitches, clips) at approximately 7-10 days post-surgery. Reopening of wounds is a rare occurrence, but if it did occur, then it will be treated by re-closure under short-term anaesthesia on one occasion only. iv. Any animal showing signs of uncontrolled pain (described in 'Monitoring of animal characteristics and end-points' below) will be humanely killed. v. The injection of viruses into deeper brain regions, particularly into the parabrachial area may result in vestibular problems due to the proximity of the target to the vestibular nuclei. Vestibular problems, including some gait abnormality, turning upon picking up by the tail and escape upon touch always occurring in one direction, shall lead to termination of the experiment. In any such cases, tissue from these animals may be taken after perfusion with fixatives or under deep anaesthesia or after killing by a schedule 1 method.

4. Behavioural testing: Very few adverse events are anticipated with most of the behavioural tests we use. Most use threshold stimuli and a cut-off, preventing unintended adverse events. Some cold and heat suprathreshold tests induce a brief and transient painful episode, but no adverse effects are expected beyond that. In the very unlikely event that during a test an animal shows clear signs of distress (abnormal or extreme response to the test stimulus, aggression or unresponsiveness), it will be removed from that test and not entered into any others. In these tests animals will generally be habituated to the testing environment prior to the start of the experiment. The formalin test induces two phases of pain-related behaviour. We are evaluating a refined procedure using volatile anaesthetics to reduce or eliminate the first, and more intense, phase while leaving the second phase intact. If this proves fit for purpose it will be adopted in all experiments. If animals show unexpected severe reactions to capsaicin we will use local cooling of the treated paw (using cool water) to ameliorate the effects of capsaicin

5. Anaesthesia: A small number of animals may die from respiratory depression (1-2 %) and/or hypothermia, evidenced by depression in rate and rhythm of respiration and cold/pale extremities. To mitigate these effects depth of anaesthesia will be monitored regularly using the following checks: a) testing the pedal reflex, b) checking the rate and rhythm of respiration. Heating will be provided during anaesthesia where possible. For prolonged periods of anaesthesia, animals will be periodically rehydrated by subcutaneous injection of appropriate fluids (preferably glucose or dextrose/saline), as necessary. Animals receiving inhalation anaesthesia will, where possible, be allowed to recover in an induction box filled with 100% medical air or air, the colour of mucous membranes the depth and rate of breathing and pO2 would be monitored. The frequency of anaesthesia inductions will be kept to a minimum whilst still achieving the scientific objectives. Multiple procedures will be combined, where possible, to minimise frequency of induction. It is expected that at least 90% of the animals will receive no more than 3 general anaesthetics during the experiment. Between induction sessions, animals will be fully recovered, eating and drinking before being re-anaesthetised. Animals will not be re- anaesthetised if they have not resumed normal mobility and eating and drinking.

6. Terminal procedures: The terminal experiments measuring activity in sensory systems are not expected to have any adverse consequences. A surgical level of anaesthesia will be maintained throughout. Physiological functions such as deep body temperature, blood, pressure, end-expired CO2 will be monitored and maintained within normal limits. If a power failure occurs while an anaesthetised animal is being artificially respired, the animal will be killed by anaesthetic overdose.

7. Blood Sampling: Blood sampling will be undertaken under anaesthesia. Adverse effects are expected to result in no more than transient discomfort (after recovery from anaesthesia) and no lasting harm. Any bleeding after blood sampling (from superficial veins) will be controlled by local pressure and/or by application of a haemostat. If bleeding cannot be controlled the animal will be killed by a Schedule 1 method or by anaesthetic overdose.

8. Long term spinal stimulation studies: Certain complications may arise as a result of implantation surgery or the animals having connectors fixed to the skull and being physically connected to a stimulation device. Following epidural electrode implantation, animals will be monitored for 3-5 days for signs of hind limb dysfunction, spinal asymmetry, difficulties in movement, or signs of pain or major discomfort, before being considered for a study. Any animals showing these signs will be humanely killed. If post-implantation motor impairment is detected, such that the animal is unable to groom or move easily to reach food or water, it will be humanely killed. Partial evulsion of the stimulating lead near the point of connection to the skull-mounted pedestal may occur due to the animal's normal grooming. In this case, the animal will immediately be assessed to determine whether repair is possible. If this is deemed to be practical, the animal will immediately be re-anaesthetised and the lead replaced beneath the skin. Such a repair will be carried out only once. Should the problem recur, the animal will either be killed by a Schedule 1 method or anaesthetised and subjected to a terminal experiment. Partial

dislocation of the skull-mounted connector pedestal may occur due to failure of the cement-screw bond. In this case, the animal will immediately be assessed to determine whether repair is possible. If this is deemed to be practical, the animal will immediately be re-anaesthetised and bond repaired. Such a repair will be carried out only once. Should the problem recur, the animal will either be killed by a Schedule 1 method or anaesthetised and subjected to a terminal experiment. We will also observe on a daily basis the general behaviour and condition of animals during the periods of chronic sub-threshold stimulation and will we adopt the procedures and endpoints described. In the event that signs of distress are observed during the chronic stimulation period, we will pause the stimulation and reassess the current threshold. Regardless of whether or not this has changed, we will consider reducing the chronic stimulation current to alleviate the distress. We may cease stimulation completely for a period to see if distress signs are alleviated. If distress signs return when stimulation is restarted at the original (or lower) level, we may reduce the current further. In the unlikely event that minimal current intensity (0.1mA) still causes signs of distress, the experiment will be terminated and the animal either subject to a non-recovery electrophysiological experiment under general anaesthesia or killed by a Schedule 1 method. Tissue samples may be recovered from these animals. Any other adverse effects will be carefully documented and reported to BSU staff.

9. Neuropathy studies: Pain in the affected limb is the main intended adverse event. It usually manifests in a slight guarding of the paw. Up to one week following neuropathy, a mild motor impairment may also be observed (dragging of the hind limb). This will be permitted, but thereafter the animals should exhibit weight bearing on all four paws and a normal locomotor rhythm – albeit retain an eccentric paw placement (guarding). Rarely (<0.1%) an animal may show autotomy following nerve injury; if loss of more than two phalanges of two digits occurs the animal will be killed. Any animals exceeding a moderate level of pain will be culled as described in the section ‘Monitoring animal characteristics and end-points’, below. Following epidural electrode implantation, animals will be monitored during recovery until they are fully conscious. After recovery, animals will be monitored for 3- 5 days for signs of hind limb dysfunction, spinal asymmetry, difficulties in movement, or signs of pain or major discomfort, before being considered for a study. Any animals showing these signs will be humanely killed.

9. Drug induced neuropathy studies: Pain in the extremities is the main intended adverse event following induction of chemotherapy-induced neuropathy. However, when not specifically tested, the animals generally do not display any obvious outward signs of pain. Initial weight loss and general malaise may be observed while injections are ongoing and chemotherapeutic agents are taking their maximal effect. Animals will be carefully monitored and weighed every day while injections are ongoing, and regularly thereafter (min 3x a week), once pre-injection weights have been recovered. We will follow the guidelines and end-points set out in ‘monitoring animal characteristics and end-points’, below. Rarely (<0.1%) an animal may show autotomy following retraction of nerves as a result of the neuropathy; if loss of more than two phalanges of two digits occurs the animal will be killed.

10. Cancer pain studies: Subsequent to intraosseous injection of tumour cells, animals can show signs of lameness within hours. If animals do not recover normal mobility within the working day or within 24h (whichever is earliest), they will be culled by Schedule 1 method. Progression of bone tumours and model-specific endpoints: The prime method of tumour monitoring will be by looking for clinical signs including distress/pain, changes in mobility and abnormal characteristics (listed in section 'monitoring animal characteristics and endpoints' below). In some cases longitudinal imaging may be suitable to assess tumour progression. One endpoint will be the appearance of a visible surface tumour on the hind limb, the animal will be killed by a humane method. Impediment of locomotion due to tumour growth in bones/joints is likely, particularly after intratibial injection and at later progression stages. If an animal shows distress/pain reaching moderate severity limits OR exhibits non- weightbearing lameness, it will be killed by a humane method.

11. Induction of inflammation: Most of the experiments to be performed under this protocol will be performed on entirely on anaesthetised preparations and no animal welfare issues associated with the models is anticipated. The studies performed on conscious animals under this protocol will persist for relatively short time periods and few adverse effects beyond pain are not expected. All studies done on conscious animals should only induce pain at the affected site and not exceed moderate levels of pain as described in the section below 'monitoring animal characteristics and endpoints'. If these limits are exceeded the animals will be humanely killed. Systemic administration of LPS may cause hypothermia, hypotension, diarrhoea or lethargy. These may be expected to last for up to 4 hours and then subside; a saline injection will be given to these animals to ensure adequate hydration. UV irradiation: UV irradiation will produce inflammation of the paw which may include some sloughing of the irradiated epidermis. If this occurs and there are subsequent signs of infection, the animals will be humanely killed. Animals do not usually avoid weight bearing of the treated paw. However, all animals will be observed for signs of excessive discomfort such as sustained licking of the paw and other signs of distress. In those cases, they will be killed humanely.

12. Induction of chronic inflammation: For all types of chronic inflammation, pain in, and swelling of, the affected site is the main intended adverse event. However, pain should not extend beyond the affected limb or exceed a moderate level. To this end we will adopt the criteria and endpoints described in 'monitoring animal characteristics and endpoints' below. UV irradiation: UV irradiation produces an inflammatory response that typically grows over 48hours and then subsides over the following few days. If irradiated animals show signs of increasing inflammation beyond 72hours, they will be humanely killed. UV irradiation may induce some sloughing of the irradiated epidermis. If this occurs and there are subsequent signs of infection, the animals will be humanely killed. Animals do not usually avoid weight bearing of the treated paw. However, all animals will be observed for signs of excessive discomfort such as sustained licking of the paw and other signs of distress. In those cases, they will be killed humanely. Administration of inflammatory mediators into the CNS may result in systemic signs of an inflammatory

reaction such as changes in core temperature, sedation or lethargy, hypotension, and loss of body weight. All animals will be monitored for up to 6 hours on the day of injection, and daily thereafter for signs of ill-health. Any animal not recovering within 48h will be humanly killed. Injections of CFA or other irritants subcutaneously or into a joint are expected to cause local oedema and swelling and often some erythema. These signs typically increase in the hours following treatment and reach a stable plateau in the case of CFA with a few days. The local inflammation subsides, depending on CFA dose, after a week or two. Animals will therefore be monitored daily for 3 days and thereafter at least every other day, for signs of excessive local inflammation or the presence of widespread inflammation, and if detected, those animals will be humanely killed. If there are clear signs of irritation such as persistent scratching causing tissue damage the animal will be killed by a schedule 1 method. Some weight bearing of a treated limb is expected and if animals show absence of weight bearing persisting for more than 24 hours, they will be humanely killed. The inflammatory agents may in some animals induce diarrhoea. If symptoms persist for more than 24hours the advice of the NVS will be sort.

13. Induction of osteoarthritis: The surgical models of osteoarthritis typically develop slowly over many weeks. In contrast, the chemical methods of inducing the condition typically have a short lasting (days) inflammatory response which is sensitive to non-steroidal anti-inflammatory (NSAID) drugs, followed by a persistent phase of hypersensitivity relatively insensitive to NSAIDS. Signs of pain – increased sensitivity to local stimuli and reduced weight bearing of the treated limb - develop slowly in the surgical models and rapidly in the chemical models. Animals will therefore be monitored daily for the first 3 days and thereafter weekly for signs of excessive adverse effects. If weight bearing of a limb is lost for more than 24 hours, those animals will be humanely killed. Osteoarthritis may increase joint instability and in rare cases may lead to skeletal deformations. Any animals unable to normally reach food and water will be humanly killed.

14. Brainstem mechanisms underlying neuropathy/cancer pain: Animals undergoing surgical procedures where no peri-operative analgesia is given may have additional pain-like responses including prolonged vocalisation upon handling, a higher incidence of autotomy and more than 10% weight loss. All factors will be end points. Animals will be under daily surveillance in the acute post- operative 5 day period in order that, if these end points are reached, the animals may be culled to reduce suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Protocol 1: Mild severity (10000 mice)
- Protocol 2: Moderate severity (2000 mice 2000 rats)
- Protocol 3: Moderate severity (1000 mice 1000 rats)
- Protocol 4: Moderate severity (400 mice 300 rats)
- Protocol 5: Moderate severity (1000 mice 1000 rats)

- Protocol 6: Moderate severity (500 mice 500 rats)
- Protocol 7: Moderate severity (500 mice 500 rats)
- Protocol 8: Moderate severity (16 rats)
- Protocol 9: Moderate severity (32 rats)

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Some studies of sensory phenomena are possible in humans however, mechanistic questions require invasive techniques that are not possible or feasible at present in humans and as such we propose the work herein. We are principally interested in pain mechanisms. In vitro techniques are also not sufficiently advanced (and are not likely to be so for some considerable time) that they can model the integrated actions of the nervous system. Thus, we will undertake some of our work in animals. The use of rats and mice throughout the project, which requires in some areas modelling of a pain state, is critically important. The neuroanatomy/neurophysiology of the rat and mouse is well understood and there is a comparable central nervous system complexity to the human. In rats and mice we can unequivocally establish which pathways underlie distinct pain processing mechanisms where a cell culture system would not model the necessary aspects of pain perception.

Which non-animal alternatives did you consider for use in this project?

It was not an option to consider non animal alternatives for use in this project.

Why were they not suitable?

The functionality of the circuitries that we wish to investigate, which rely on peripheral and central nervous system processes as peripheral and central manifestations of pain impact one another, cannot be investigated in vitro and would be too complex to investigate other than in vivo .

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used will vary from procedure to procedure depending on the degree of variability in the experimental measures, but our extensive experience with these models has shown that group sizes of 6 – 8 (rats) and 8-10 (mice) are generally appropriate. For those procedures involving surgery it is scientifically more rigorous to include sham operated control animals in an experiment. However, for techniques which are well established and for which we know from experience that there is no sham effect we will not include such animals in every experiment, but refer to historical control data. The effect of sham surgery will be reviewed periodically and when a new experimenter is using the technique.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I am familiar with the NC3Rs Experimental Design Assistant having used it for my NC3Rs studentship application which regards refinement in the use of peri-operative analgesia in generating animal models of chronic pain and for all subsequent studies using animals. The use of this tool when planning experiments means that the numbers of animals being used in the project is at a minimum.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will seek to reduce the number of animals studied by careful experimental design, the adoption of sensitive outcome measures with small variation and the study of only the most relevant time points. Where possible each animal will be used as its own control. In all in vivo tests the number of animals in each group will be the minimum required to allow valid statistical analysis. It is possible in some instances to supplement the in vivo work outlined by using in vitro cell systems to analyse, for example, the effect of inflammatory mediators on receptor or ion channel expression and we plan to use such studies extensively. However, it is not yet possible to make stable cell lines of sensory neurones, our main cell type of interest, or to mimic the long-term effects of neuronal damage or inflammation that occur in vivo. In these instances, the use of animals is unavoidable. By cryopreserving sperm we will reduce the number of animals culled in breeding programmes.

Several of our protocols involve treating one hindpaw in some way, for instance delivering a neuronal labelling compound intraplantarly. Conventionally, a separate cohort of animals is used as controls.

However, where we know the control intervention is non-noxious, we will also use the contralateral hindpaw as a control.

To further reduce the numbers of animals used and to refine animal use wherever possible, animals may be tested within the same protocol with additional compounds. This may occur with protocols where extensive surgery is required to establish the baseline state (e.g. peripheral neuropathy) and the risk-benefit assessment is arguably in favour of reducing the number of animals submitted for surgery rather than reducing the number of compounds and behavioural tests that an individual animal is subjected to. All compounds will not be tested in all in vivo models but rather will be initially examined in the model most appropriate for that class of compound in which activity could be anticipated.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

During this project we will use animal models of neuropathy, cancer pain and inflammatory pain. The methods that we will apply include cell population labelling, behavioural assays and electrophysiology techniques. The extensive use of rodents in biological research has already provided considerable information on nociceptive and inflammatory processes. We will limit the severity of our models by limiting the time for which animals are kept following surgery or induction of inflammation as much as possible.

We will also be working on a specific example of refinement with our NC3Rs funding, where we aim to refine the common procedure of administering no or limited peri-operative analgesia to animals undergoing surgery to induce a chronic pain state.

None of our protocols fall under the severe category.

Why can’t you use animals that are less sentient?

Due to the nature of our studies, which aim to identify the mechanisms that underlie the progression of chronic pain states, using animals that are at a less sentient life stage is not possible since the diseases that we study are progressive. Pain can only be properly understood via the integration of knowledge spanning molecular, cellular, systems and psychological levels, hence less sentient species are not suitable. For a proportion of the animals that we use, following behavioural and/or electrophysiological experiments, the

study will proceed in the terminally anaesthetised animal as ex vivo tissue is harvested for subsequent immunohistochemical analysis for example.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For the majority of procedures (some exemptions sought within), animals will be provided with suitable post-operative analgesia. For establishment of models, suitable post-operative analgesia will be provided in a manner that does not affect disease progression. All will be performed under veterinary guidance. Animals will be regularly monitored for post-operative recovery. In addition animals may be trained to self-administer analgesics.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

No answer provided

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Since the NC3Rs are one of my funders, I participate in RSPCA and NC3Rs meetings. This allows me to keep informed about advances in the 3Rs, and implement any advances possible to my projects.

172. Production of genetically altered animals and provision of tissues (service provision)

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Transgenics, Cryopreservation, Genetic Alteration

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To supply genetically altered (GA) mice for scientific research, allowing researchers to advance our understanding of health and disease. This PPL allows us to freeze mouse lines for long term storage, to bring in mouse lines established elsewhere, and to generate novel lines in house.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The biological, physiological and genomic similarities between mouse and human have informed research into human disease for decades. The generation of complex genetically modified mouse lines not only affords better mechanistic understanding of natural biological processes and how these go wrong, but also enables the development of

therapeutic interventions (where appropriate). Exploitation of cutting-edge genome manipulation technologies allows the generation of models that better recapitulate normal and diseased states, thus generating more actionable knowledge 'per animal'.

Separately, having a centralised cryopreservation and rederivation program in our state-of-the-art facility ensures the minimum number of live animals at any one time and the provision of high-quality pathogen free (SPF) GA animals for research for the Institute and the wider scientific community.

What outputs do you think you will see at the end of this project?

Genetically Altered (GA) mice:

By ensuring the Transgenic Service remains a centralised core service we can ensure that each technique is only performed by specially-trained, highly-skilled staff, resulting in efficient animal production of high quality animals.

Centralisation of expertise allows new procedures and techniques to be adopted and benchmarked efficiently, ensuring mouse production approaches are state-of-the-art. Further, centralisation in transgenic production and also avoids the need for individual Project Licenses to require those procedures. Importantly, a centralised service can have a profound improvement on the efficiency of transgenic production, reduction of mouse usage and consistently improved welfare standards.

In addition, a rederivation program in our state-of-the-art facility, by our highly-skilled team will provide to the scientific community high quality SPF GA animals

New information/Publications:

New findings will be disseminated locally via the AWERB, User Groups, Animal Facility and seminars. Externally, these findings will be disseminated by peer reviewed publication and seminars.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries of this GA service provision will be the researchers, and the advancement of the biological questions answered by the generation of GA animals. In the longer term it is hoped that this will translate into advancement of understanding of health and disease, ultimately enabling novel therapies.

The Transgenic facility acts as a core facility for GA mouse production, breeding, rederivation and cryopreservation, for local academic community. The centralisation of transgenic production into a core facility allows standardisation of procedures, consistency of approach, adherence to regulation, balance of harms and benefits, rigorous quality control/assurance and reproducibility. Further, we have developed robust pre-experimental workflows that ensure suitability of the model, compliance (on destination PPL), genotyping protocols, funding structures and a clear delineation of roles and

responsibilities. The end result of these processes is high quality, efficient production of GAAs that are tailored to the researchers needs.

How will you look to maximise the outputs of this work?

We will ensure that all the new technologies discovered by transgenic team, that will lead to a more efficient and finer generation of GA animals will be exchanged within the scientific community by: being published in peer-reviewed journals, sharing our knowledge through scientific conferences and meetings, submitting posters in the conferences with our new discoveries in the transgenic field. In addition, as a member of the International Society for Transgenic Technologies (ISTT) I am always available to answer relative questions through their internal email ISTT list. This will include the sharing of both successes and failures, lending advice to colleagues, and receiving advice from peers.

Species and numbers of animals expected to be used

- Mice: 15000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are widely used to gain an understanding of the complex cellular interactions that underpin both health and disease. Mice are well adapted to the laboratory setting, their small size makes it permissible to house multiple animals in a space and cost-efficient manner, and they are generally easy to handle and dose. Much of its biology and biochemistry mirrors that of human, and the mouse genome has been well characterised.

The life stages of mouse that will be used in this license are: adult, neonate, juvenile and embryo. We need to use the life stages that best address the biological questions that are posed by researchers. In addition, some technologies of genomic manipulation require specific stages of mouse development.

Typically, what will be done to an animal used in your project?

In the generation of a GA animal the following procedure will be implemented:

All putative projects to generate a novel mouse line are subjected to a pre-experimental design meeting where the appropriateness of the model and the need to generate a new line are assessed. Also addressed are the legal, regulatory, funding, technical and logistical aspects of the project.

Following a successful design meeting, optimal experimental parameters will be assessed in vitro (ie without generating animals). The goal of the in vitro optimisation is to both

assess the fidelity of the experimental approach (eg is the approach technically sound) but also to give an indication of the efficiency of the approach to allow us to gain an understanding of the total number of animals we need to generate to ensure project success. Importantly, in the instance that we wish to explore a new approach or technique this will first be performed in vitro where possible. These experiments will typically be short term (2-4 days), using a minimal number of embryos to quantitatively assess the efficiency.

After we understand the efficiency of the given approach, we will use this information to ensure the minimum number of donor animals are used to provide an appropriate yield of embryos for manipulation (microinjection – electroporation – rederivation – cryopreservation) (see general constraints). The optimised conditions will be used to make the desired genetic alteration in the embryo's DNA, embryo health will be assessed, and then embryos will be surgically implanted (see general constraints) into foster mice. Note – some embryos may be kept in culture for further experimentation or may cryopreserved for future study/use.

For approaches in which genome alteration was performed in the embryo, the resultant pups will be mosaic (different edits in different cells of the animal). For approaches where genome manipulation was performed in embryonic stem (ES) cells, the resultant mice will be chimeric (consisting of both ES- derived and donor-derived cells). Both mosaicism and chimerism is then 'purified' through breeding to generate pure GA lines. The new lines will be monitored by a team of scientists and technicians to ensure Germ Line Transmission (GLT) is obtained in a time sensitive manner and eventually will be transferred to the end user for further studies. All the surrogate mothers will be culled after the weaning of pups. All the pups produced that have undesirable genome manipulation will be made available for training purposes or will be culled.

What are the expected impacts and/or adverse effects for the animals during your project?

From our experience through the past 15 years, the vast majority of animals will experience no or limited adverse effects (eg transient pain from injections of hormones). In protocols that involve surgical procedures, analgesia and anaesthesia will be used to limit pain to the animal that results from these procedures (surgical procedures/administration of pain relief, see general constraints). Any pain associated with surgery is not anticipated to last more than a few hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the animals used at this PPL, will be approximately 51% mild such as hormone dosing, 29% sub-threshold for transgenic breeding, and others approximately at

20%, that will be used as embryo recipients and vasectomized males will experience a moderate severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because the aim of this PPL is to create, import/export, breed and maintain genetically altered (GA) mice and supply them for scientific research. In order to understand the maintenance of health and the development of disease (for example cancer), it is necessary to use animal model systems that can authentically recapitulate the complex cellular interactions involved.

Which non-animal alternatives did you consider for use in this project?

- None.

Why were they not suitable?

The aim of this license is to create GA animals

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Over the last five-year period (excluding 2020, due to covid-19), both the average number of experiments per year performed in the genome editing core and the average number of animals per experiment were approximatively equal to 50. Assuming a 20% increase in demand due to the covid backlog, the predicted number of animals required during the 5-year time period covered by this PPL equals 5*(50^2)*1.2 = 15000 animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Unnecessary production of genetically altered animals will be avoided by searching cryobanks and databases. Examples of resources available include:

Mouse locator: https://bioinformatics.crick.ac.uk/mouse_locator/

NC3R's mouse database: http://www.nc3rs.org.uk/category.asp?catID=8 Jackson laboratory: http://www.jax.org/ http://jaxmice.jax.org/index.html Cre transgenic database: http://www.mshri.on.ca/nagy/Cre-pub.html

The strain used for generating a new colony will be carefully considered to avoid producing unwanted mice. Animals will only be bred if a user requirement has been established, and the breeding programme will be subject to regular review to optimally meet anticipated demand. Spare animals will be made available for use on other scientific projects.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We take an array of measures to optimise the number of animals per project/experiment:

- First and foremost, we have pre-experimental design meetings that address the regulatory, scientific merits, experimental and quantitative aspects of the project.

- We assess in vitro, through pilot experiments, the efficacy of the GA approach. This involves genetic modification of embryos and quantitative assessment of editing approaches. These experiments are typically performed in vitro, limiting the creation of animals with sub-optimal genotypes. Further, the efficiency/efficacy of the approach informs the total number of animals that should be created to ensure project success.

- The use of well-established methods and protocols aiming to the use of the minimum numbers of mice in production of genetically altered animals. For example: establishing the CRISPR methodology in contrast to ES-cell microinjection, choosing wild type strains for embryo generation and to use as foster mothers, using the most reliable method for superovulation, optimising the numbers of embryos transferred to surrogate mice avoiding the use of surplus female mice and at the same time having less animals undergoing surgical procedures

- Purchase of wild type strains from approved suppliers in order to avoid the generation of surplus animals from in house colonies

- Collaborating with peers to refine and reduce mouse numbers used in protocols, eg through the use of genetically sterile mice as opposed to surgical vasectomisation

- Literature studies, in order to assess any known phenotypes.

- Cryopreservation of gametes and embryos to archive lines will avoid wastage from the need to maintain colonies by continuous breeding .

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal model that will be used is the mouse. Mice are widely used to gain an understanding of the complex cellular interactions that underpin both health and disease. Mice are well adapted to the laboratory setting, their small size makes it permissible to house multiple animals in a space and cost- efficient manner, and they are generally easy to handle and dose. Much of its biology and biochemistry mirrors that of human, and the mouse genome has been well characterised

The transgenic team will use highly refined and widely accepted methods for the generation of GA mice and there is adequate literature to support the standardization of protocols, methods and reagents that will be used. For example, I am exploring the possibility of replacing surgical vasectomised mice with wild type hybrids (Replacement of surgical vasectomy through the use of wild-type sterile hybrids https://rdcu.be/cc2CF).

Why can’t you use animals that are less sentient?

Because mice are the least sentient animals for the purpose of this license. The mouse genome mirrors the human genome, is genetically sequenced, it is relatively easy to manipulate the mouse genome, for example, adding or removing a gene to better understand its role in the body. In addition, many GA strains are already available and well characterised. Furthermore, they are close to human physiology and there is a wealth of literature to support the studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- By adapting any new techniques discovered in the transgenic field, always in line with the 3Rs principles.

- By encouraging the end users to cryopreserve their mouse lines, in the case that they are not needed in the short term.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The transgenic team will use highly refined and widely accepted methods for this type of work and there is adequate literature to support the standardisation of protocols, methods and reagents that will be used. Published guidelines for best practice will be followed, including:

Refinement and reduction in the production of genetically modified mice; Laboratory Animals Vol 37, Supp 1 July 2011. (http://la.rsmjournals.com/content/vol37/suppl_1)Assessing welfare and severity of GA mice under Directive 2010/63/EU. https://www.rsb.org.uk/images/assessing-animal-welfare-.pdf Genetically altered mice. https://www.nc3rs.org.uk/GAmice

Guiding principles on good practice for Animal Welfare and Ethical Review Bodies. October 1998. 3rd Edition - September 2015.

http://www.lasa.co.uk/PDF/AWERB_Guiding_Principles_2015_final.pd

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By:

- Attending in all the relevant scientific meetings and conferences

- Reading papers

- Establishing a good communication with Named Persons.

- Being an ongoing member of International Society for Transgenic Technologies.

- Being an ongoing member of Hellenic Society of biomedical and laboratory Animal Science (HSBLAS member of FELASA).

- Being an ongoing member of European Federation on Animal Science (EAAP).

173. Preclinical validation of intraperitoneal delivery of chemotherapy for treatment of ovarian cancer

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Chemotherapy, Peritoneum

Animal types	Life stages
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Using a pre-clinical, translational animal (porcine) model, this project will test and validate therapies used to treat abdominal cancer, in particular ovarian, in situ.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ovarian cancer is the biggest gynaecological killer of women in the UK with around 7,500 women diagnosed each year. Current treatment includes extensive surgery and chemotherapy. However, only 46% of women diagnosed with ovarian cancer survive

beyond 5-years. Previous research has shown that administrating Hyperthermic Intraperitoneal Chemotherapy (HIPEC) directly into the peritoneal cavity in situ (e.g. immediately after removal of the cancerous ovaries) has a positive clinical benefit to the patient in terms of increased patient survival rate and reduced cancer recurrence. HIPEC is only currently used in the surgical theatre. A recent development in delivery of peritoneal chemotherapy has been Normothermic Intraperitoneal Chemotherapy (NIPEC), which can be used outside of the operating theatre. However, to date NIPEC has only been used sparingly, due to low patient compliance when conscious, an inability to tolerate the treatment, often due to catheter infection and toxicity, when left in situ for many weeks. Working with a UK company with experience of both HIPEC and NIPEC, a newer system has been developed that enables chemotherapy to be administered into various body cavities but with accurate flow rates, at minimal pressure and optimal temperatures. The newer system will enable patients to receive a clinically superior administration of intraperitoneal chemotherapy, by using a bespoke catheter, which is inserted into the patient during surgery and can remain in situ for up to 6 months, with limited toxicity. This project will test and validate the new catheter design in a relevant pre-clinical model, before first-in-man clinical testing in association with medical colleagues working in the NHS.

What outputs do you think you will see at the end of this project?

Technology: This project works with a UK company currently delivering world-class solutions for the multi-billion dollar and rapidly growing marketplace of hyperthermic (heated) cancer treatments. The company have developed a unique modular recirculating system enabling chemotherapy to be delivered to patients at tightly controlled temperature, pressure and flow-rate with accuracy and control significantly greater than current state-of-the-art. The platform can perfuse and optimally deliver drugs into different organs by varying the flow rate and pressures. After securing IP for the novel delivery platform and clinical procedure, then this new technology, once validated in pre-clinical models, will enable the company to push for National Institute for Clinical Excellence (NICE) approval to adopt into the NHS for the benefit of improved patient care and recovery post-surgery for abdominal cancers.

Researchers in the UK: the data generated as a result of the work in the porcine model will be published open-access in peer-reviewed journals. Therefore, the information will be disseminated amongst scientists, clinicians and technologists primarily within the surgical and oncology communities. There is considerable interest in HIPEC for treatment of abdominal, particularly late-stage ovarian, cancer. Potential new treatments with high efficacy and fewer side-effects, as we envisage this new technology to be, are always welcomed warmly by the oncology community.

International researchers: Ovarian cancer is the biggest gynaecological killer of women in the UK with around 7,500 women diagnosed each year. Globally, this equates to 239,000 women. The economic burden associated with ovarian cancer in the UK, differs considerably depending upon the stage at diagnosis; stage 1 treatment costs £5,328

compared to stage 4 costing £15,081 [IncisiveHealth Report, 2014]. With 7,500 women being diagnosed with ovarian cancer in UK alone, then the economic impact in the UK and Internationally are huge. Current treatment includes extensive surgery and chemotherapy. Despite this, only 46% of women diagnosed survive 5-years post diagnosis. Hence, success of the current project will be of interest to the many 00's of researchers around the globe with a vested interest in ovarian cancer, and also other cancers affecting the abdominal cavity or peritoneum.

Who or what will benefit from these outputs, and how?

Short-term: The platform used to deliver intraperitoneal chemotherapy, together with the new catheter that this project will test will provide the first clinical solution for late-stage ovarian cancer patients where cancer has metastasised to the peritoneum. The preclinical work described in this project is a part of a large, funded project which, after successful pre-clinical validation of a new intraperitoneal delivery system (rate of recirculation, temperature, pressure, dose of chemotherapy all to be validated) will, within 2 years, be tested directly in patients attending NHS surgical oncology units.

Longer-term: The successful output of the project will be a unique intraperitoneal chemotherapy delivery system with preliminary clinical data, as a stepping stone to a larger clinical, trial prior to full clinical adoption (within 3 years). The overall benefit being the reduction of cancer-recurrence and significantly enhancing the 5-year survival rate of ovarian cancer patients.

How will you look to maximise the outputs of this work?

The data generated as a result of this work will be published open-access in peer-reviewed journals. Therefore, the information will be disseminated amongst scientists, clinicians and technologists primarily within the surgical and oncology communities. There is considerable interest in HIPEC for treatment of abdominal, particularly late-stage ovarian, cancer. Potential new treatments with high efficacy and fewer side-effects, as we envisage this new technology to be, are always welcomed warmly by the oncology community. Internationally, ovarian cancer is the biggest gynaecological killer of women, approximately 239,000 women per year. The economic burden associated with ovarian cancer within the US alone, has been estimated to be $6.03billion in 2020. Current treatment includes extensive surgery and chemotherapy. Despite this, only 46% of women diagnosed survive 5-years post diagnosis. Hence, success of the current project will be of interest to the many 00's of researchers around the globe with a vested interest in ovarian cancer, and also other cancers affecting the abdominal cavity or peritoneum. All information will be shared through conferences, publication and technology/industry events.

Species and numbers of animals expected to be used

- Pigs: 30

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will focus entirely on using the pig as the preclinical animal model of choice. That is because the technologies we are testing and developing will be adopted by the NHS whom require that any medical device, such as a catheter, that is going to be placed into a human body cavity must first be tested on an animal model. For this project, the abdominal cavity of a young adult pig (e.g. 50-70kg, 6-8 months of age) is of similar size and volume to a human patient and therefore allows similar rates of peritoneal flow e.g. upto 2.5L/min (average being 2L/min) that will be used clinically. Initial pre-clinical testing of scaled down pilot devices has been developed using rats (in Spain). Now, with a final product ready for potential use in humans then a pig is the most translational, applicable animal model. For studies of short-duration, where the similarity between porcine and human physiology is key to achieving the primary outcome, then certain breeds of commercial pig e.g. Landrace or Tamworth are suitable due to their size when young adults.

Typically, what will be done to an animal used in your project?

In this project, typically, female pigs will be placed under general anaesthesia and a peritoneal catheter will be inserted using a minimally-invasive approach and attached to a machine set to deliver peritoneal lavage at 2L/min for 90mins (with or without dissolved chemotherapy drugs). After the final sample, pigs will be humanely killed whilst still under anaesthetic using barbiturate overdose. Blood samples may be taken before and during the procedure to test, for example, for uptake of differing chemotherapy drugs. The rate, volume and pressure of the delivered peritoneal solutions will be varied to test for the optimal strategy that can then be used clinically. The system will be tested in a staged design; initially, 1 pig on one day to check all procedures. A second pig the following day to validate procedures. Then, upon need, one or two pigs per day to achieve our objectives, “validate a catheter used to deliver intraperitoneal chemotherapy”, that is in terms of the pressure, flow-rates and temperature of the lavage fluid. It is not expected that more than n=3 pigs will be needed for this phase. A further study may then be conducted likely involving n=12 pigs with n=4/group where the conditions optimised in study 1 will be applied to determine the distribution and dissolution of chemotherapy drugs (e.g. three groups of four pigs), as measured via peritoneal lavage and blood sampling.

What are the expected impacts and/or adverse effects for the animals during your project?

The pigs in this study will not be recovered after surgery. Therefore, the process of sedation and general anaesthesia involves a moderate level of harm experienced by the

animals but all are mitigated by effective anaesthesia and non-recovery. Pigs are also prone to porcine stress syndrome when housed individually. Therefore, we will always make sure that any pig is within sight, smell and touch of another pig while conscious.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity level is non-recovery for the pigs in this study. All pigs 100% will experience this severity. Some mild (not moderate) distress may be experienced during initial sedation and induction of anaesthesia.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We cannot first test a new medical device (catheter) designed for clinical use in Man, without first testing using an appropriate pre-clinical model. Therefore pre-clinical testing must first use an appropriate animal model. We consider the commercial pig appropriate due to size, immune similarity to human and anatomical similarity. Previously, rodent models have been used to develop the normothermic technology. This study is to validate a larger, new catheter that would allow normothermic delivery of intraperitoneal chemotherapy in a larger cavity, as occurs in pigs and humans. Since the catheter is a new medical device with a newly engineered recirculation design, allowing for normothermic perfusion at different rates of perfusion, temperature and pressure (to hyperthermic perfusion). Therefore, rodents and other less sentient animals are inappropriate to achieve our primary end-points.

Which non-animal alternatives did you consider for use in this project?

Not applicable. The peritoneal lavage system has been extensively tested by the company prior to being used in an animal model. However, the primary outcome is clinical use and therefore pre-clinical testing must use an appropriate animal model. This particular treatment system cannot be used on non- animal alternatives.

Why were they not suitable?

Not applicable. The peritoneal lavage system has been extensively tested by the company prior to being used in an animal model. However, the primary outcome is clinical use and therefore pre-clinical testing must use an appropriate animal model. Worms, flies, fish and lower sentient animals such as mice are inappropriate for various physiological reasons. Some testing has involved rats but now due to scaling up the technology for final testing then pigs are the most translationally relevant species.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I use specific experimental design software to calculate sample size. For any pilot trial we start with n=1 for testing, and would consider n=3 pigs sufficient to demonstrate effectiveness of the catheter such as during optimisation of either 1) flow rate, 2) temperature and 3) pressure of the recirculating system. For final testing, the primary outcome will be uptake of chemotherapy via the peritoneal route and for this aspect we do not envisage needing more than n=4 pigs per study group (at three dose levels, n=12 in total). A study group may comprise different doses of drug, but using a factorial design n=4 will factor up if no effect of dose delivered in the peritoneal gavage solution. We will not be quantitatively determining chemotherapy uptake as a result of optimising pressure, temp and flow rate. Therefore, we are not powering the trial using mean, standard deviation and effect size. Rather, we are testing if the catheter works effectively over the time period used clinically (90 mins) and whether the ideal temp, pressure and flow rate do not cause catheter failure. Assuming a 1 in 20 chance of failure by chance (0.05), then with n=4 no fails there is only a 1 in 160,000 chance that the design was optimal by chance (0.5 x 0.5 x 0.5 x 0.5 = 0.00000625). This is an acceptable risk for the study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

At all stages, the minimum number of animals is considered. For the first phase of the project - pilot testing of a new peritoneal catheter - then n=3 animals is sufficient to demonstrate effectiveness of the catheter while we vary flow rate, temperature and pressure of the recirculating system. This takes a within-animal experimental approach to reduce between-animal variability and reduce sample number required. With the primary outcome being asked, "Does the new catheter work effectively?" i.e. deliver fluid at the required flow rate, temperature and pressure in a stable and repetitive fashion, then n=3

for pilot studies and n=4 for any treatment group using a factorial design is considered satisfactory. The investigators will use experimental design software to guide and refine experimental design and sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pigs will be sourced from an accredited breeder. All studies will be staged as pilot studies initially. For final design of testing different chemotherapy drugs then power calculations will be used using information from pre-clinical testing in rats. We will be collaborating with NHS abdominal cancer specialists e.g. those specialising in ovarian cancer, and thus any tissue required for pump-priming projects or novel testing will be provided. We do not expect to use more than n=8/pigs per study group, although for pilot testing this will be no more than n=3 pigs in a staged design. If uptake of chemotherapy drugs is highly reproducible between pigs, then we will limit pre-clinical testing of the effectiveness of the catheter to n=3-4 pigs, as the experimental outcomes are not dependent on showing statistical significance of chemotherapy drug uptake, rather effectiveness of the peritoneal catheter.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Pigs sourced from an accredited commercial supplier which are guaranteed to be of high health status and from a strain likely to be free of malignant hypothermia, will be sourced, acclimitised for 7 days and subsequently placed under general anaesthesia. They will be sedated beforehand, then intubated and maintained using inhalation anaesthesia. They will not be recovered from the procedure as no outcomes relate to post-surgical recovery. Therefore, no animal will experience any harm beyond an intramuscular injection, intubation whilst sedated. Therefore we do not envisage any animal experiencing any pain, suffering, distress or lasting harm.

Why can’t you use animals that are less sentient?

These animals will be terminally anaesthetised. Rodent models have been used to develop the technology and are largely proof-of-principle. The need for the use of pigs is because we need to establish the temperatures, pressures and flow-rates that would be used in human translational studies. For any novel medical device that is to be used

invasively in humans then it has to be tested in an animal model beforehand. The abdominal cavity of rats and/or other less sentient animals, are too small to allow for similar conditions for the use of HIPEC or NIPEC treatments abdominally.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Initial sedation via IM injection may involve mild/moderate, short-term distress for all animals. All pain management during surgical induction and maintenance will be undertaken after consultation with the NACWO, Named veterinary Surgeon and colleagues/peers whom are experts in large animal anaesthesia. Refinement in surgical technique is always a consideration such as maintaining aseptic technique, use of local anaesthesia at the site of cannulation or catheterisation of vessels for blood sampling. Anaesthetic monitoring and depth of anaesthetic to be used will be at a minimum to achieve deep anaesthesia and constantly monitored. In addition, during GA we will monitor the pedal reflex, corneal response and depth of breathing to ensure appropriate depth of anaesthesia during the procedure. All GA will involve a mechanical ventilator to control the depth of breathing and thus anaesthesia by a competent person. Peritoneal catheterisation and lavage will be conducted according to best practice as used clinically in the NHS (a clinical oncologist will be present initially to ensure appropriate catheterisation and lavage is done according to NICE guidelines).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are few published best practice guidance for pigs, but all pain management during surgical induction and maintenance will be undertaken after consultation with the NACWO, Named veterinary Surgeon and experts in large animal anaesthesia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of AWERB at our University and of the University's research ethical review panel. The PPL holder is therefore in regular contact with an NC3Rs representative on the committee, particularly AWERB. At all meetings we discuss how to best stay informed and implementing best practice in our research studies. In addition, the study researchers keep up-to-date with developments in the 3Rs via publications such as the ARRIVE guidelines, or journals such as laboratory animal research or the NC3Rs website. This way the PPL holder is kept informed of any advances that may benefit the project and the welfare of the animals

174. Understanding the neuronal network involved in the regulation of glucose metabolism, feeding behaviour and energy expenditure

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Obesity, Diabetes, Blood glucose levels, Energy Expenditure, Brain regulation of metabolism

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how the central nervous system senses hormones like Insulin to regulate blood sugar levels, food intake and energy expenditure (how we burn calories).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The study of the brain regulation of energy balance has the potential to improve current treatments of diabetes and obesity. Insulin is released by the pancreas and goes to the liver to decrease glucose production (sugar released by the liver) and to promote glucose storage as glycogen. However, when insulin reaches the brain, it can act at multiple levels and have important functions like regulating the nervous system that controls how much we eat, blood sugar levels, cognition and memory and can affect mood. Deficits in brain insulin signalling have been linked to several neurodegenerative diseases including Alzheimer’s and Parkinson’s disease. Indeed, with Type 2 Diabetes (T2D) older adults suffer from decreased verbal learning, abstract reasoning, and complex psychomotor tasks. Restoring insulin sensitivity in the brain could be a good strategy to counteract the negative outcomes of obesity and diabetes. In addition, it could be beneficial for people suffering from neurodegenerative disease. The aim of this study is to investigate how the brain regulates glucose metabolism, feeding behaviour and energy expenditure. We will identify which brain cells are sending signals to the liver in order to control glucose levels and to the brown fat in order to control energy expenditure. We will also study how alteration of these brain cells can have deleterious consequences for the metabolism in particular in obese and diabetic models.

What outputs do you think you will see at the end of this project?

The involvement of the brain in controlling metabolic functions is well known, however, the impact that obesity and diabetes have on brain functionalities is understudied. The long-term effect of brain insulin resistance (decreased ability to respond to insulin) can increase the chances of developing neurodegenerative diseases. Memory loss is a big problem in diabetic individuals and this is due to the brain not functioning properly. Understanding the molecular mechanism that triggers insulin resistance in the brain is the first step for developing a specific treatment that targets the brain to ameliorate metabolic functions and also to prevent long term deleterious effects. In addition, we plan to determine the specific brain cells that are involved in insulin sensing and are affected by insulin resistance, diabetes and obesity.

Our work looks at mechanisms, our major output will be in the form of peer-reviewed publications. We are also involved in public engagement activities where we make aware the public of the effects that obesity and diabetes can have on brain functions.

Who or what will benefit from these outputs, and how?

The study of the brain regulation of energy homeostasis has the potential to improve current treatments of diabetes and obesity. Insulin is released by the pancreas and goes to the liver to decrease glucose production and promote glucose storage as glycogen. However, when insulin reaches the brain, it can act at multiple levels and have important functions, for example, regulating neural circuits that control appetite, blood glucose levels, cognition and memory and can also affect mood. Deficits in brain insulin signalling have been linked to several neurodegenerative diseases including Alzheimer’s and Parkinson’s disease. Indeed, with T2D older adults suffer from decreased verbal learning, abstract

reasoning, and complex psychomotor tasks. Restoring insulin sensitivity in the brain could be a good strategy to counteract the negative outcomes of obesity and diabetes, in addition, it could be beneficial for people suffering from neurodegenerative disease.

How will you look to maximise the outputs of this work?

The major output for this research will be of interest to the scientific community, the outcomes will be published in peer-reviewed journals. We will also present our data at conferences. The focus of this research is of significant interest to the general public, most people know someone who has T2D. In order to bring this research to the attention of academics in other disciplines and to the general public, we will work with the University Communications Office to ensure timely Press Releases. In addition, I will also present the work at the local public events organized during the science week.

As obesity is increasing amongst the young population, this project could bring awareness regarding the dangerous effect that overnutrition has on the brain and the bad consequences that this could have during development. An activity focused on this topic and targeted to young generations will be extremely important. To engage with young people, I will develop an exhibition based on our work to be used at the Festivals of Science organized locally. These events are attended by many 9-19-year-old schoolchildren. Both events are run annually and draw in around 1200 people per day from the local community.

Species and numbers of animals expected to be used

- Rats: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The experimental procedures proposed require the use of 8 to 12 weeks-old Male Sprague Dawley (SD) rats. These are fully developed rats that are still growing. We measure changes in body weight, and we aim to look at body weight increase over time. This is the best system to perform metabolic studies since their glucose levels are very stable. All our previous data are based on 8 to 12 weeks old male SD rats and in addition, they have a higher than 95% rate of survival after brain surgery. The stereotactic surgery is very easy to perform in rats and, due to their anatomy, is very easy to get the right coordinates to insert the Intracranial (ICV) cannula in the dorsal vagal complex (DVC) of the brain. In addition, the rats have fast and complete recovery after surgery. We measure changes in blood glucose levels using a pancreatic euglycemic clamp, SD rats have a stable blood glucose that make our analysis reliable over time. We have vast experience on using this

model and we can make the best use of these rats with the confidence to achieve the highest level of care and rate of survival until the end of the experiment.

Typically, what will be done to an animal used in your project?

First, rats will be subjected to brain surgery in order to insert a cannula in a specific brain area. The surgery lasts 10 minutes and is done under balanced general anaesthesia. The cannula is held with a small implant made of dental cement. Once in place, the implant does not cause any distress or pain to the rats. Rats are expected to make a full recovery within 6-12 hours after surgery. We will use the brain cannula to inject inactivated viruses that will be used to express specific proteins in the brain area we are interested in. In addition, the cannula will be used to deliver specific treatments in the brain.

On the same day of brain surgery, a subgroup of rats will also receive a small incision either in the abdominal cavity or the scapular area in order to expose the liver and the brown fat respectively. This procedure is done in order to inject an inactivated virus that can be taken up by neuronal terminals in these peripheral organs and can be visualised in the brain. After the viral injection, the small incision will be sutured. The viral injection will not cause any harm, disease or pain to the rats and the cut will be small enough to not cause post-surgical discomfort. Pain-relieving drugs are also given routinely to all animals that are subjected to surgical procedures and pain score is recorded post-surgically.

Insertion of catheters in the jugular vein and artery will be done in a subgroup of rats a week after brain surgery. This is also a moderate procedure. We will use the catheters in order to infuse substances and withdraw blood for analysis at the end stage of our experiments, which involve the injection of substances and serial withdrawal of blood for glucose tolerance test (GTT). These catheters also allow us to withdrawn blood from fully conscious rats and without the need for manual handling and repeated punctures of the vein. After vascular surgery, the rats are expected to have a full recovery and the catheters do not cause discomfort.

In order to monitor the effect that our brain treatment has on vital parameters like heart rate and blood pressure, we will implant subcutaneously telemetric devices. The implant has no effect on the day-to- day life of the rats and allows continuous monitoring of important physiological parameters.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the procedures will require recovery from anaesthesia following surgical procedures. The surgical procedures will involve the insertion of cannulas in specific areas of the brain for the purpose of infusing substances and the insertion of catheters in the blood vessels in order to infuse substances and withdrawal of blood. Brain cannulas are inserted using specialized equipment. We have extensive experience in performing such surgical procedures and do not envisage adverse effects during the post-surgical period. Post-operative pain relief is routinely given to all animals and pain response is monitored

on a score sheet. After surgery, the rats will be housed individually to avoid the dislodging of the catheters. We will use transparent cages near each other so the rats do not feel isolated. At the end of the experiments, animals will be humanely killed to allow for tissue collection. The genetically modified rats will not have an adverse phenotype. The use of the Cre recombinase expression system under a specific promoter will allow us to target only specific cell populations. This will be very important to identify the neuronal network involved in insulin sensing and resistance in the DVC. We will use PET, MRI or CT scan to monitor fat deposition ad brown fat activity in high fat diet-fed obese rats. This will help us understand how changes in brain activity can affect whole-body metabolism. These are terminal procedures performed under full anaesthesia. Finally, during imaging sessions, we will use telemetric devices implanted subcutaneously to monitor the heart rate of the animals.

Rats will be also placed in a cold environment (cold challenge) to stimulate the release of heat by the brown fat (thermogenesis). This experiment will be performed in fully anaesthetized rats at the end stage of our experimental procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All the procedures we will perform are expected to be of moderate severity. We expect a full recovery after brain and vascular cannulation. We expect that both the brain implant and the vascular tubing will not cause discomfort to the rats.

Our procedures include glucose clamp and intravenous tolerance tests to measure how the rats control their blood glucose. In both cases, the rats will be fully awake and free to move in the cage. The use of vein cannulas and long tubing will allow us to infuse substances and withdraw blood without causing any distress or harm to the rats.

The brain infusion is also painless and done through a long tubing so that the rats can be kept unrestrained in their cages.

Cold challenge and bioimaging (PET, MRI and CT scans) will be done in fully anaesthetized rats so no discomfort will be caused.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Since this study focuses on understanding the neuronal network involved in the brain control of metabolic functions and the physiological impact that insulin resistance, obesity and diabetes have on brain metabolic regulation, it is not possible to substitute the use of animals with alternative systems. We will study how the brain controls sugar metabolism, food intake, body weight and energy expenditure. For these studies, there is no possibility to use an alternative system for animals.

The experiments will be performed in rats; a vast amount of background data in relation to metabolic parameters is available which make these the most appropriate species in which to perform our studies. In particular, rat glucose levels are very stable, in addition, stereotactic brain surgery is very easy to perform in rats and, due to their anatomy, it is very easy to get the right coordinates to insert the brain cannula. Our research team has extensive experience in this kind of surgery. In addition, the rodents have a fast and complete recovery after ICV surgery and also recover well after vascular surgery.

However, where in vitro work can be undertaken we will do so e.g. all the validation of the adenoviruses and lentiviruses will be performed in cells, and only viruses that show a clear effect in vitro will be then used in vivo. Whenever an analysis can be performed using cells, we will do so instead of using rodents. We have available a plethora of brain cell lines that we can use when is needed.

Which non-animal alternatives did you consider for use in this project?

No animal alternative can be used.

Why were they not suitable?

Since we need to do neuronal tracing to look at the connection between different organs and the brain. The changes in whole-body metabolism can be studied only in the whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals that will be used in this project is based on power calculations that are based on prior experiments. To determine the required number of animals we used the variance estimated from prior work as well as expected effect sizes. We will conduct our

experiments to be able to publish to the Arrive guidelines: https://www.nc3rs.org.uk/arrive-guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals will be minimized in several ways:

Tissue and plasma from the same animal will be used for different objectives where possible. This reduces the total number of animals that would otherwise be required if a single animal was used for each experiment.

Tissue for neuroanatomical procedures such as immunohistochemistry will be stored long-term for future use where possible.

The NC3RS experimental design assistant will be considered for planning: https://www.nc3rs.org.uk/experimental-design-assistant-eda

Rodents are subjected to seasonal changes; this could affect the results in terms of high variability. In order to minimise this event, we will make sure to conduct all the experiments with the appropriate controls and to minimise the environmental changes that could affect the analysis. We will randomise the animals starting from the brain surgery (the first procedure that we perform) and when possible, we will match the body weights of control and treated subjects

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At the end of each experiment, we will harvest as many tissues as we can even if they are not useful for the moment because they might be needed in future. In this way, we will not have to repeat the experiment again.

For example, in our recent study published in Molecular Metabolism, we performed feeding studies and harvested at the end of the experiment different organs including the brown fat (BAT). We then realized that there were changes in BAT and we performed a series of analyses that led us to a completely new project for which most of the data has come from animal tissues that we already have.

We also collaborate with other groups in the university. The hearts, muscles and spinal cord of our obese and diabetic rats will be taken by different groups in the university that are interested in the effect of obesity and diabetes on heart functions, muscle activity and the spinal cord's ependymal cells functions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The aim of this study is to look at the brain regulation of glucose metabolism and feeding behaviour. We will look at the effect that the insulin resistance in the CNS has on the whole-body metabolism. The experimental procedures we propose require the use of 8 to 12 weeks old male Sprague Dawley rats.

These animals provide the best system to perform metabolic studies. In particular, their glucose levels are very stable and this makes them the perfect model to perform pancreatic clamp studies. All our preliminary data and previous studies have been performed with rats.

We have been performing brain and vascular surgeries for years now and we have been able to optimise the procedure in order to minimise the suffering of the rats and to obtain close to 100% success and recovery after surgery. Here are some examples of how we proceeded to refine our procedure:

1) At first, we were using injectable anaesthetics that remain in the system longer, delay the recovery after surgery and sometimes can cause an overdose of the rats. We now mainly use isoflurane that is well accepted by the rats and allows the rats to wake up soon after surgery, in this way we have a faster recovery and no issues with overdosing.

2) After surgery, the rodents are housed in single transparent cages in order to avoid any potential fights that could affect the surgical areas. Initially, we tried to pair housed surgically prepared animals but noticed that animals were chewing at each other's surgical area and losing their cranial implants, rendering the animal unusable. For this reason, single housing after surgery is imperative in this study. Animals are kept in visual contact with each other and are only singly housed for a maximum of 18 days

3) After vascular surgery we prepare food mushed with water and leave it in a small dish on the cage floor. This makes it easier for the rat to eat and keep hydrated right after surgery. In addition, extra bedding and nesting materials are also provided to all surgically prepared animals for cage comfort. Heated pads are also available to aid thermoregulation during recovery after anaesthesia

4) We experienced that Adenoviral injection in the dorsal vagal complex (the area of the brain we are mainly interested in) if injected on the day of surgery, is sometimes not well tolerated by the rats. This area controls the breathing and if the rats are not fully awake after surgery, they might stop breathing. We now inject the virus via intra-cranial

cannula the day after surgery, this allows the virus to be well tolerated and no side effects have been seen.

Why can’t you use animals that are less sentient?

Since we are studying how the brain controls blood glucose levels, thermogenesis and feeding behaviour, we need a fully developed animal. We are looking at how the brain regulates peripheral organs so using organoids won't be suitable for us.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All surgical procedures are performed under balanced general anaesthesia. We use inhalation anaesthesia using isoflurane which causes rapid induction and uneventful rapid recovery. In addition, full aseptic conditions are maintained for all surgical procedures and we follow LASA Guidelines for Aseptic Surgery.

Brain surgery requires the insertion of an ICV cannula in a specific brain area. The surgery lasts less than 10 minutes and is done under full anaesthesia. After surgery, the rodents are expected to have a

full recovery within 1 day. The cannula implanted has a very mild impact on the day-to-day life of the rodents and will be kept for up to 18 days.

Vascular surgery requires the insertion of catheters into the jugular vein and artery of the rodent. The surgery lasts ~30 min and is done under full anaesthesia After surgery, the rodents are expected to have a full recovery within 2 days. The implanted catheter has a very mild impact on the day-to-day life of the rodents and will be kept for up to 4 days.

All the surgical procedures will be carried out under aseptic conditions. After surgery, we will constantly monitor until animals regain full consciousness and we will give analgesic to the rodents for 3 days until we can see a full recovery. To limit suffering, animal responses will be monitored.

Viral injection in the liver will require a laparotomy of the abdominal area to expose the liver and perform the viral injection. The injection of the virus will not cause any harm and we will do the smallest incision we can in order to avoid discomfort after surgery.

Similar attention will be observed when we will do the brown fat viral injection that occurs at the level of the scapulae in the back of the rat.

The feeding protocol is very mild, we just remove the food in the morning (the rodents eat less in the daytime). The brain infusion is carried out with a long catheter that allows the

rodents to move freely in the cage to cause them minimum stress. The infusions through the vein catheter and blood withdrawal through the arterial catheter are also carried out with long tubing that allows the rodents to freely move to minimize stress.

For MRI/PET/CT imaging, motion artefacts from breathing and heartbeats can degrade the quality of imaging – meaning that the imaging may take longer to get quality data. By implanting telemetric ECG monitors, we can get the imaging on the heartbeats and make sure that images are only taken at the correct time, resulting in better quality images and shorter overall scans.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the NC3R best practice guidance. We attend webinars from Nc3R like "the best practice in experimental design": https://www.nc3rs.org.uk/events/webinar-best-practice-experimental-design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive newsletters from the NC3R, we rely on the website to find important information regarding ways to reduce, refine and replace (https://www.nc3rs.org.uk/). We also have regular talks with NACWO and veterinarian in order to refine our procedures.

Over the years we have changed the way in which we anaesthetize the rats, the way in which we perform post-surgical care and the way in which we keep the rats after surgery in order to improve the success rate of our procedures and the wellbeing of our animals. This has also reduced the number of animals needed for our experiments.

175. Target investigation and characterization of potential medicines

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

therapy, cancer, aging, vaccine, immune-mediated

Animal types	Life stages
Mice	adult, aged
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project is to support the investigation of potential targets for treatment of diseases and perform an assessment of the possible effectiveness of potential treatments before animal safety tests and human clinical trials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are many areas of unmet clinical need that significantly impact both lifespan and quality of life.

Many chronic diseases, often associated with an aging population, have a significant impact on individuals' ability to live independently, resulting in significant human and societal costs. Examples include rheumatoid and osteoarthritis, Alzheimer's disease, cystic fibrosis, heart disease and stroke, liver fibrosis and inflammatory bowel disease.

Despite the recent advances made in its treatment, there are still many types of cancer that are not currently curable (for example pancreatic, some breast cancers).

New targets and approaches to treating these diseases will improve quality of life of both patients and their families, as well as potentially lessening the burden on society associated with caring for patients.

What outputs do you think you will see at the end of this project?

The studies performed under this licence will contribute to the understanding of the role of previously identified molecular targets for treatment. This may be by improving confidence that medicines and other methods of altering these targets will result in a significant benefit for patients, or alternatively that they are not involved in the disease of interest so different targets should be explored.

Where there is confidence that altering a target is likely to provide patient benefit, further studies will be performed using animal models to examine the efficacy of specific potential medicines, with a view to identifying those treatments with sufficient promise to take forward into safety assessment and ultimately human clinical trials.

Where significant results are not subject to confidentiality agreements they will be communicated more widely at scientific meetings or published in peer reviewed journals.

Who or what will benefit from these outputs, and how?

In the short term clients, project teams and funding bodies will be able to make progression decisions to be able to better target their limited financial resources on to the potential treatments with the highest likelihood of clinical success.

In the medium term stopping the progression of projects with little chance of success (either due to lack of relevance of the target or the inability to develop a potential medicine that has a clear beneficial effect in animal models) will also mean that animals will not be used in safety assessment and human volunteers will not be put at risk in clinical trials.

In the long term the successful identification of validated disease-modifying targets and treatments will result in improvements in lifespan and quality of life for patients and carers.

How will you look to maximise the outputs of this work?

Where there may be broader interest in an animal modelling approach, and if the studies are not subject to confidentiality agreements, these will be published or shared at relevant conferences.

Clients and collaborating partners will be encouraged to publish all results in journals or share at relevant conferences.

Species and numbers of animals expected to be used

- Mice: 15000
- Rats: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice and rats (including genetically altered animals) will be used as these have been demonstrated to provide information that enables decisions to be made on the progression of projects. Using genetically altered animals allows the investigation of human-specific targets and treatments for these targets.

These animal studies serve as a bridge between computer or cell-based experiments and human clinical trials. These studies will, in many cases, be the final studies investigating the likelihood of a potential medicine having a benefit before clinical trials are started.

Aged animals may occasionally be used when studies investigating diseases strongly associated with older patient groups a specific age group are undertaken. Such conditions include rheumatoid arthritis, anaemia and immune senescence.

Typically, what will be done to an animal used in your project?

Typically animals will be purchased from a commercial supplier (including genetically altered lines) and will then:

- be used in procedures where blood and tissues samples are taken under general anaesthesia from which the animal does not recover. This would be a small number of animals, usually genetically altered, and the tissues would be used for cell-based tests.

- be dosed with potential medicines usually by oral, subcutaneous or intravenous injection on one or more occasions to investigate the action on the target system of interest. This would usually be no more than 4 times daily for up to 7 days but in approximately 5% of studies

may be up to 3 months (for example when investigating treatments for chronic diseases).

- To understand how a potential medicine affects a disease pathway (for example inflammation), a challenge may be administered prior to dosing. This would usually be in the form of a single dose (<5% of studies may require more than one dose) of a chemical or drug known to affect the pathway of interest.

These studies may include using genetically altered animals with relevant targets systems deleted or human-specific target systems inserted.

Occasionally (<5% of studies) surgical cannulation of blood vessels may be required to make administration and/or sampling less stressful for the animal than using a non-surgical approach

The effects of the target or potential medicine will generally be assessed by looking for markers in the blood meaning samples will be taken at intervals relevant to the disease. Blood samples taken may also have the levels of potential medicine assessed to allow the amount of effect on the tissue or target to be understood.

Typically this will be no more than 4 samples a day over 7 days. For longer studies, fewer samples will be required.

Non-invasive imaging (<10% of studies) may be performed to follow the effect of the target or potential medicine. Typically this may be up to 4 times in one day, or daily over 7 days.

- be administered an experimental vaccine no more than once weekly on up to 3 occasions during 24 week period, usually subcutaneous injection. Blood samples would be taken approximately weekly to assess the degree of immune response.

What are the expected impacts and/or adverse effects for the animals during your project?

Administration of substances causes stress and pain due to handling and needle insertion. These are controlled by skilled handling and minimising the numbers of administration and sampling events.

Some genetic alterations can cause adverse effects which are very dependent on the gene. We plan to only use genetically altered animals that have Mild adverse effects.

Challenge models are expected to stimulate the immune system and/or inflammatory pathways which can produce "flu-like" effects. These effects are expected to be Mild and short lived in most cases.

Where severity is greater and treatment is possible without negatively impacting the scientific purpose of the study these effects will be reduced by use of drugs such as paracetamol.

Anaesthesia for imaging can result in heat loss and unpleasant experiences when recovering. Animals will be closely monitored, have heat supplied throughout the imaging session and only undergo the minimum number of anaesthetics required to give a satisfactory scientific output.

Surgical cannulation of blood vessels will cause pain that is controlled by the use of pain-relieving drugs: generally this lasts for 48 hours, but the animals are closely monitored in case further doses are required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats and mice 80% Mild, 20% Moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Many of the biology studies performed to help in the validation of targets and assessment of potential medicines now take place in computer, genomic, receptor and cell-based experiments (as well as definitively in clinical trials in the patient population). Integrated cell-based systems (the "organ on a chip" or even "human on a chip") are improving year on year and replacing animal usage.

However, even with these advances, computer and cell-based approaches still do not allow the response of the target or potential medicine to be assessed in a way that reflects the full complexity of an integrated biological organism. This project aims to provide the data from a complex, integrated organism to allow decisions to be made on whether to progress targets or potential medicines to the next stage of development.

The use of non-mammalian species is also seen as a potential replacement approach, and useful information can be obtained from these approaches: however due to the degree of differences at a genetic and molecular level these models are more suited to very early scientific investigations rather than drug discovery and development.

Which non-animal alternatives did you consider for use in this project?

Some or all of computer modelling, genomic, cell-based and non-protected animal approaches will be used prior to undertaking studies on protected animals to minimise the number of studies and impact on the animals.

Clients will be asked to provide information on the work undertaken with approaches not using protected animals and an outline of literature reviewed searching for alternative approaches prior to performing in vivo studies. It would be expected that in vitro binding, cell-based biomarker assays and where possible human tissue studies will have been undertaken.

These studies will usually include ability to affect the target, assessing the properties of potential medicines for biological availability and likelihood of reaching tissues of interest and looking for early indications of toxicity liabilities. These test with reduce the numbers of experiments performed and increase the likelihood of those completed to deliver meaningful results.

Why were they not suitable?

There are no non-animal alternatives that can currently replicate the full complexity of the mammalian body. Now and for the foreseeable future there will need to be animal experiments performed to investigate target validity and the efficacy of potential medicines as part of the process of bridging from non-animals studies to clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based these estimates on the number of projects we anticipate supporting, with typical studies comparing genetically altered and/or treated animals with control animals. The estimate is that we will be supporting the in vivo work for in the region of 5 client drug discovery programmes plus occasional fee for service stand alone studies at any time under the authority of this licence.

Currently these models are predominantly available in mice but a significant number of models for disease are still performed in rats. Based on published studies a typical study may use 6 animals per group and up to 8 groups, including positive and untreated control groups, and multiple compounds at different dose levels. Running fewer, larger studies will reduce the number of positive and negative control animals used, whilst providing greater confidence in the results.

We additionally anticipate providing tissues from genetically altered animals for cell-based research where these are not available from other commercial sources at a suitable quality. The estimate is for approximately 6 animals per week to be used for this purpose.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use pre-existing data (published and internal pilot data) to perform power calculations that ensure group size is likely to provide a robust experimental output without using excess animals. This will usually be with the support of a biostatistician, but if this is not possible power calculations will normally be performed e.g. using the NC3R's Experimental Design Assistant.

In rare cases where there is no initial data to guide power calculations the Mead resource Equation will be used to estimate sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible pilot studies will be performed to help design the decision-making studies. If studies have been performed on how the potential medicine is absorbed and removed from the body, modelling will be used to predict the doses required for these studies. Using these pilot studies to understand how the experimental measures vary will also help design the decision making studies.

In some studies (especially those with a higher risk of toxic side effects) tissue samples will be taken after the study is completed and may help prevent further studies being performed should unexpected results be found.

When providing tissues and blood an email distribution list will be used to allow sharing of tissue throughout the company for use in cell-based studies, minimising the overall number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered animals that demonstrate no or only Mild signs will be used.

Models where a pathway of disease interest is stimulated (e.g. by bacterial cell wall fragments, other biologically active materials or compounds that stimulate a specific inflammatory response) will be chosen to investigate whether a target is significantly involved in or a potential medicine affects that pathway. These are chosen as they have fewer adverse effects than traditional animal models such as arthritis or inflammatory bowel disease. Whenever possible the models will be managed to a Mild severity.

Vaccination models will be managed with pain-relief medications to reduce any adverse effects that may occur.

Why can't you use animals that are less sentient?

Animal models will only be used at a stage in the research programme when it is essential to study the target or potential medicine in a fully-integrated organism allowing the complex interaction of many body systems to be assessed.

Prior to this some or all of computer simulation, simple receptor or cell-based studies, complex cell- based systems (e.g. organ on a chip) or simple animals (fruit flies, nematode worms) will have been performed to focus on potential medicines that have the highest chance of success.

Most studies will be investigating responses that develop over many hours or days so the use of terminal anaesthesia is not appropriate. In addition, anaesthetic agents are likely to interfere with many of the targets of interest.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

On site, working proactively with the AWERB, NVS and NACWO, there is a culture of constant improvement to animal care, control of adverse effects, performance of procedures and study design.

Scoring systems are used to identify early intervention and end points in studies, pain-relieving drugs are used when there is concern an animal is suffering, and monitoring is performed as often as required, including throughout the night.

Further refinement to technical procedures and housing are implemented when they are shown to be beneficial for the animals and will not interfere greatly with performing the studies.

When an established model is identified from the scientific literature and proposed for use under this licence, a small number of pilot studies will be performed to ensure the model delivers the expected changes in the pathway or tissue of interest. These pilot studies will also be used to determine the controls that may be able to be used to reduce the severity experienced by the animals and the study duration.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to Home Office and EU guidance documents, relevant best practice guidance will be sourced from the NC3Rs (e.g. ARRIVE Guidelines, blood sampling, experimental design), NORECOPA (e.g. PREPARE guidelines), LASA (e.g. blood sampling, drug administration, aseptic surgery) and model-specific publications.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

On a monthly basis the PPL Holder receives and reviews automated literature alerts on animal models and journals relevant to the project licence.

When a new disease area is proposed, a thorough literature review is performed to review the potential animal models to determine the most scientifically relevant whilst causing the least harm, and a new automated alert generated.

In addition to conference attendance, webinars and discussion groups are participated in by the PPL Holder and scientific staff.

176. In vivo assessment of novel injectable hydrogel biomaterials for spinal disc repair

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Intervertebral disc, sheep, biomaterial

Animal types	Life stages
Sheep	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to examine whether a novel injectable self assembling peptide gel in combination with glycosaminoglycan (PEP-GAG), delivered by a customised small bore needle system can effectively repair intervertebral disc damage in a naturally occurring sheep model.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lower back pain is the main cause of disability worldwide and affects many people. Lower back disease causes soreness and stiffness in the lower back and there is no specific cure, with many people suffering from lifelong discomfort and loss of function. There are a number of causes of lower back pain but one of the commonest is damage to the intervertebral discs of the spine. These discs act as shock absorbers between the bones of the spine. When the discs become damaged they lose their shape and shrink, which leads to pain and discomfort in the back.

At the moment, treatment of lower back pain relies primarily on physiotherapy and pain killers and there is an unmet clinical need for a direct treatment of disc damage. One strategy for treating disc damage is to inject the shrunken discs with a substance to increase the size of the disc and restore its function.

However, currently, products that are suitable for disc enlargement are very thick and need to be injected into the disc through large needles, which themselves cause further damage.

What outputs do you think you will see at the end of this project?

The intended output of this study is to test a new type of biomaterial, PEP-GAG, to treat disc degeneration, a significant cause of lower back pain and to develop a novel small bore needle system for delivery of the biomaterials. This output will be communicated to the scientific and lay audience by publications in peer-reviewed journals and presentations at conferences.

Who or what will benefit from these outputs, and how?

The data derived from this project will be used by scientific researchers, clinicians and veterinarians. Regardless of the success, or otherwise, of this biomaterial, researchers in the field of biomaterials and tissue engineering, especially those in the area of disc augmentation will benefit from the outputs as these studies will inform their research by identifying whether the biomaterial used is optimised for disc augmentation and, if it proves not to be, what information can be derived from this. This project has developed a system for injection into the disc by a small bore needle which will have applications in treating disc disease and other clinical situations. If this project does identify a successful product for disc augmentation, clinicians who are treating patients with disc degeneration and the patients themselves will benefit, as we will have developed a new product to treat disc degeneration and lower back pain. However the products would require clinical trial approval before use in patients.

Short-term benefits

In the short term the results of our experiments will benefit researchers working in the area of biomaterials development, tissue engineering and inter-vertebral disc disease. Our experiments will provide information on the compatibility of PEP-GAG hydrogels in the the intervertebral disc, the safety and efficacy of these preparations. In addition, the

development of a small bore dual injection needle, that allows the delivery of low viscous solutions, will provide equipment that can be used for variety of clinical uses in addition to disc injection. Both the design of the needles and the full delivery system have been completed. A device that can be used in both the sheep study and subsequent clinical trials has been designed.

Medium- and long-term benefits

Will be to clinicians and their patients as we are developing new therapies and a new delivery system for administering these therapies to treat intervertebral disc degeneration and lower back pain. If successful, these biomaterials and their delivery device, will be taken forward to Phase 0/1 clinical trials in human patients before being licensed to treat human patients. As stated above, lower back pain is the leading cause of disability worldwide. In this application we aim to show efficacy of new biomaterials, delivered via a novel small bore injection needle. If successful, this therapy could be used worldwide in a large number of patients as it is will not damage the disc on injection, as other disc augmentation materials are known to do and will provide physical expansion of the disc. This will reduce disc size loss in clinical patients and reduce back pain, leading to reduced disability, less days off work and a reduction in burden to the NHS and other healthcare providers.

How will you look to maximise the outputs of this work?

We will be collaborating with different research groups to develop our technology further. We will publish the results of this study and present at conferences regardless of the outcome, because the results will benefit groups working on other disc treatments who have an interest in the model as well as the therapy itself.

Species and numbers of animals expected to be used

- Sheep: 18

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is not possible to achieve the aim of this project without using animals as the only authentic test of a product designed to treat intervertebral disc degeneration is to place it into damaged discs and quantify its effect.

Sheep have been used to test implant devices and in the preclinical investigation of cellular therapies to support spinal fusion and disc reconstitution. Ovine discs, like human discs, undergo chondroid metaplasia with skeletal maturation because of the loss if their notochordal cell remnants. Additionally, the ovine disc is closer in size and cellular

phenotype to the human intervertebral disc than small animal models, important characteristics given the nutritional limitations associated with the central regions of the disc. Furthermore, despite its quadrupedal conformation the sheep spine has been shown to exhibit significant biomechanical similarities to the human spine.

Typically, what will be done to an animal used in your project?

Following non regulated behavioural monitoring to establish baseline behaviour and activity, the sheep receiving either the product or sham injection will then be anaesthetised and have an MRI or CT scan to identify and quantify the reduction in disc height and width and the presence of signifiers of degeneration such as osteophytes around the disc margins. Within a set period of time after the scan, for example 4 weeks, these same animals will be anaesthetised and have up to three lumbar discs injected under X-Ray guidance (maximum injection volume 0.5ml per disc).

We are working with naturally occurring disc degeneration and so there will be individual variation between animals and discs. To mitigate against the effects of this variation we will be imaging discs before and after treatment and comparing results of each disc to itself (size and appearance), so that each disc acts as its own control.

The animals will be housed indoors in small pens in groups of between three and six sheep for a week post-surgery and monitored clinically for any signs of pain following injection and then allowed to roam free in a field/barn for the remainder of the study during which further Fitbit and clinical monitoring will be undertaken.

At the end of this time, the animals will be euthanised and when dead will be imaged under MRI or CT before the spinal sections are extracted. From each animal, pairs of treated and untreated control discs will be evaluated using histology, immunohistochemistry and biomechanical testing.

What are the expected impacts and/or adverse effects for the animals during your project?

The overall severity of this procedure is moderate, which all animals receiving injections will reach transiently due to injections into their intervertebral discs.

We are not expecting animals to show clinical signs of increased pain or distress following injections. The injections are performed under general anaesthesia and so will not be experienced consciously by the animal. The animal may show mild signs associated with recovery from general anaesthetic, such as appearing slightly ataxic and sedated, but this is transitory and our experience is that sheep are usually standing within 15 minutes of the end of the general anaesthetic. Analgesia will be given for 72 hours post-operatively, unless an animal is assessed to require additional pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The overall severity of this procedure is moderate, which all animals in the experimental group or sham injection group will reach transiently as they will all have injections into their intervertebral discs.

Control sheep will not experience a spinal injection, but may have standing x-rays carried out.

What will happen to animals at the end of this project?

- Killed
- Rehomed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to achieve the aim of this project without using animals, as the only authentic test of a product designed to treat intervertebral disc degeneration is to place it into damaged discs and quantify its effect.

All products will have been thoroughly tested in vitro for biocompatibility and cytotoxicity before delivery into the sheep. In addition sub-cut testing was carried out in mice, and no adverse inflammatory response was detected.

Which non-animal alternatives did you consider for use in this project?

In vitro work was carried out to ensure the cytotoxicity and biocompatibility of the materials, but there is no in vitro model of spinal disc degeneration.

Why were they not suitable?

It is not possible to achieve the aim of this project without using animals as the only authentic test of a product designed to treat intervertebral disc degeneration is to place it into damaged discs and quantify its effect. In addition, testing the material in a large animal model is a regulatory requirement, so we therefore are a stage closer in translation to clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will always seek to use the minimum number of animals necessary to achieve the objectives of the project whilst maintaining statistical validity of results. We have based the numbers of sheep required on similar studies in sheep and goats that have been published in the literature and are using 6 animals per experimental group. The experimental design is a simple one - we will compare the efficacy of treating disc degeneration with a novel biomaterial compared to a sham injection of phosphate buffered saline (PBS). In our research we will randomise our experiments to avoid bias, for example we randomise which animals get which treatment i.e. biomaterial or sham and in what order they undergo procedures. We will analyse our data in a blinded fashion and use coding systems to anonymise data, thereby reducing unconscious bias. In some instances we may ask our collaborators to randomly allocate animals to experimental groups and to retain the information as to which group and animal belongs until the final results are collected. We believe that these methods contribute to the robustness of our data interpretation. We are committed to working to the PREPARE guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3R Experimental Design Assistant was used to create a study plan. This allowed us to critique the plan and run a power calculation. Values from published literature (change in disc height) was used in the EDA as this model has not yet been carried out by our group. Setting the power of the experiment at 80%, $p<0.05$ and a standard deviation of 2.5 we require a minimum of 6 animals per group.

We will also maximise the data obtained from each sheep e.g. activity data, post-mortem biomechanical, histological and immunohistochemistry data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Initially cadavers (collected at the end of another experiment) will be used to ensure that the injection techniques are of a high standard and in the correct location. A pilot study of three animals will then be used to ensure that the 3 disc injections do not compromise animal welfare but also to ensure that the material does not cause inflammation within the spine and that the sheep have a smooth recovery. The pilot sheep will remain within the study for the full 12 weeks, and their data will be included in the study.

At the end of the study any unwanted tissue may be harvested by other groups for further research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen the sheep as our model for a number of reasons. Firstly, the sheep exhibits naturally occurring disc degeneration and, by using these naturally affected animals, we avoid the need for painful interventions to induce disc degeneration. Secondly the sheep has an intervertebral disc of similar structure and anatomy to human intervertebral discs, making the translation of results from sheep to human more direct and, thirdly, the sheep has a sufficiently large intervertebral disc to allow injection of the hydrogel through a needle of similar size to that which would be used in man. The only other alternative, suitable species with naturally occurring disc degeneration is the goat, however, our group has considerable expertise in anaesthesia, surgery and management of sheep and considered that using sheep was within our sphere of knowledge when goats would not be. Thirdly, by using sheep exhibiting disc degeneration, we also avoid the uncertainty involved in artificial induction, which can produce variable levels of degeneration and may not mimic the naturally occurring pathophysiology.

We will be conducting a small stepwise pilot study of three sheep to ensure that the 3 disc injections/sheep proposed do not compromise animal welfare and that this injection regime is suitable to take forward to the main study. We will minimise animal suffering by ensuring that animals receive anti-inflammatory medication during and after spinal injections. We will monitor animal suffering by assessing their activity and behaviour via video and remote telemetry (using ‘Fitbits’).

The ‘Fitbits’ allow us to continuously record the ‘play’, ‘rest’ and ‘activity’ of the sheep before and during the experiment. This allows us to identify early indicators of reduced welfare in the animals and to intervene accordingly. If reduced activity or play and increased rest is noted, the NVS will be asked to examine the animals to identify the cause of the reduced mobility.

Why can’t you use animals that are less sentient?

It is not possible to achieve the aim of this project without using animals as the only authentic test of a product designed to treat intervertebral disc degeneration is to place it into damaged discs and quantify its effect.

The sheep are aged animals and will be assessed before spinal injection to confirm that there have naturally occurring degenerative changes in their lumbar spine.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will be conducting a small stepwise pilot study to ensure that the 3 disc injections/sheep proposed do not compromise animal welfare and that this injection regime is suitable to take forward to the main study. We will minimise animal suffering by ensuring that animals receive anti-inflammatory medication during and after spinal injections. We will monitor animal suffering by assessing their activity and behaviour via video and remote telemetry (using ‘Fitbits’). The ‘Fitbits’ allow us to continuously record the ‘play’, ‘rest’ and ‘activity’ of the sheep before and during the experiment. This allows us to identify early indicators of reduced welfare in the animals and to intervene accordingly. If reduced activity or play and increased rest is noted, the NVS will be asked to examine the animals to identify the cause of the reduced mobility.

All surgery will be carried out aseptically in dedicated facilities, according to the LASA guiding principles for preparing for and undertaking aseptic surgery.

The sheep will receive analgesia (e.g. fentanyl patches), as advised by the NVS, pre-operatively and post-operatively to allow for a continuous supply of analgesia for an appropriate period. In addition the sheep will receive local anaesthetic in the injection/incision site. To reduce the risk of infection the sheep will receive antibiotics pre-surgery and post-surgery. Non-steroidal anti-inflammatories will be used for up to 72 hours after injection, unless already being administered to ameliorate the effects of aging.

We will grade the spinal pain and in addition there are three clinical score sheets to guide us when monitoring the animals, one covers the mobility, food intake and water consumption, fever, demeanour and respiratory rate and is routinely used for all animals for a minimum of 3 days post-operatively.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgery will be carried out aseptically in dedicated facilities, according to the LASA guiding principles for preparing for and undertaking aseptic surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

During the study we will be in contact with the NACWO and the NVS in addition to monitoring any updates from the NC3Rs website.

177. Vascular calcification in kidney dysfunction

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

vascular calcification, chronic kidney disease, calcium

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the mechanisms that lead to the hardening of blood vessels in patients with chronic kidney disease (CKD).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Patients with CKD, diabetes and atherosclerosis have an increased risk of bone-like calcium deposits forming in their blood vessels. This process, known as vascular calcification, causes the blood vessels to become stiffer. Consequently they cannot stretch as easily as normal blood vessels, resulting in an increase in blood pressure which in turn places more stress on the heart. As a result, patients are more likely to die prematurely.

Currently there is no effective treatment for this condition. Therefore there is a clinical need to understand the underlying disease process in more detail so that potential drug targets can be identified.

What outputs do you think you will see at the end of this project?

The project has two arms, approaching the theme of vascular calcification from two different angles.

In the first part of the study we will use a genetically altered mouse strain that we have shown is more prone to developing vascular calcification than normal mice. One aim of the current study is to establish whether a drug that blocks the pathway activated as a result of the genetic modification is effective in inhibiting vascular calcification. As patients with CKD are known to show similarly increased activity in this pathway, by demonstrating the effectiveness of the drug our study would provide strong evidence for a new therapy.

In the second part of the study we will use a different genetically altered mouse strain to explore the relationship between calcium and phosphate in the development of vascular calcification. We have shown that the molecular sensor which detects the amount of calcium in the blood, and regulates the secretion of the hormone that controls the release of calcium from bones, can also detect phosphate. We have altered the phosphate sensing part of the molecule and predict that this will protect mice with CKD from developing vascular calcification. If that is the case this would point to towards a highly specific drug target that could not only reduce vascular calcification but may also be useful in the treatment of the bone and mineral disorder commonly found in patients with CKD.

Who or what will benefit from these outputs, and how?

In the short term, the project will help us to better understand the processes that lead to the formation of mineral deposits in blood vessels. This knowledge will help other researchers who are working in this field and more widely those who are seeking to understand blood vessel function and the control of calcium balance in the body.

In the longer term, the project may lead to the development of new treatments for patients suffering from vascular calcification. Both arms of the project could lead to the development of new drugs or the repurposing of existing drugs for the treatment of vascular calcification.

How will you look to maximise the outputs of this work?

The genetically altered mice strains that we have generated are likely to be of interest to other researchers, so we would be open to collaboration and the sharing of materials to maximise the impact of our work.

We already collaborate with other research groups, both at our own institution and elsewhere, so we envisage that the outputs of the current work will feed into further

refinement of techniques and research partnerships. For example, we have collaborated with colleagues with expertise in imaging to develop a method which allows us to make two separate sets of measurements in the same sample. Previously, two tissue samples from two separate mice would have been necessary to achieve the same outcome.

We will make data sets, including those with negative outcomes, available to other researchers via the institution's data repository.

Species and numbers of animals expected to be used

- Mice: 1400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice that have been genetically modified in one of two ways. One strain lacks the ability to make a target molecule of interest, making them more prone to developing vascular calcification than normal mice. In this way we can study the impact of the loss of this molecule on the calcification process and its related impacts on other parts of the body, such as the kidneys. The other strain of mouse has received a modification to the molecular sensor which detects calcium in the blood. We predict that a certain part of this sensor will also detect phosphate, and as such that it plays a role in the bone and mineral disorder that accompanies CKD in patients. We have changed the structure of this molecular sensor so that it no longer responds to phosphate, and in doing so we anticipate that these mice will be less prone to developing vascular calcification than normal mice.

We are using these mice because they have highly specific changes in the function of the molecules of interest. This means that we can study the impact of this altered function in the whole animal, thereby allowing us to model the complex disease process that occurs in patients with CKD and vascular calcification.

In order to generate mice for use in experiments, we will have to maintain breeding colonies of both strains of genetically modified mice. We will only use adult mice in the subsequent experiments, in order to model the form of vascular calcification that occurs in adult humans.

Typically, what will be done to an animal used in your project?

Mice will undergo a two-step surgical procedure to remove 5/6th of their kidney mass in order to induce CKD.

In the first part of this process, 2/3rd of one kidney are removed under anaesthesia. This involves making a small incision into the abdomen just below the ribs to access one of the

kidneys. It does not matter which kidney is chosen, as they are identical in structure and function; however we typically start with the left kidney as it is easier to access. The upper and lower parts of the kidney are removed, tissue glue is applied to stop any bleeding and then the wound is closed and the mouse is allowed to recover. Analgesics are administered to prevent the mouse from experiencing pain.

7-14 days later a similar procedure is undertaken, again under anaesthesia. This time the whole of the second kidney is removed. The wound is closed and analgesics are administered to prevent the mouse from experiencing pain.

At least 7 days after the second surgical procedure has been completed, the mouse's diet is switched from normal chow to one that contains a higher level of phosphate. This is done to speed up the development of vascular calcification. The mouse will be maintained on this high phosphate diet for up to 16 weeks, but typically 8 weeks, before being killed and tissues collected for further analysis.

In some experiments, a small device will be implanted under the skin on the animal's back, between its shoulder blades, in order to deliver a drug. These tiny pumps are able to deliver a drug at a constant rate for up to 4 weeks: where a longer period of drug delivery is required the pump may have to be removed under anaesthesia and a replacement implanted. This would only happen on one occasion extending the total period of drug delivery to 8 weeks.

In other experiments a drug may be administered orally by inserting a tube briefly down the mouse's throat and into its stomach: this is called gavage. This approach will be used rather than dissolving the drug in drinking water and allowing the animal to self-dose as it is important to ensure that each mouse receives the correct dose. It is also helpful when drugs are not soluble in water, or are unstable in aqueous solutions over several hours, or are very expensive which prohibits making up large volumes. This method of drug delivery would be used once daily for up to 4 weeks.

Small blood samples will be taken every 7-14 days for up to 8 weeks by pricking the mouse's tail with a sharp needle. A small drop of blood will be collected in order to assess markers of kidney function.

What are the expected impacts and/or adverse effects for the animals during your project?

The genetic modifications do not cause any overt effects, so neither strain of genetically altered mouse is expected to suffer from any adverse effects prior to entering an experimental procedure.

Surgical removal of 5/6 of the kidney may cause acute kidney injury, a condition in which the animal's remaining kidney mass is not able to function adequately to remove waste products from the blood. The risk of acute kidney injury is minimised by performing the

surgical procedure to remove the kidney tissue in two stages with at least 7 days recovery in between each step.

After the first surgical procedure the animal is unlikely to suffer any adverse effects and post-operative pain can be prevented by administering analgesics.

If acute kidney injury does occur, it is likely to do so in the period 10-24 hours after the second surgical step. The signs of acute kidney injury include lethargy and a lack of interest in food or water, fur standing on end and a pinched facial expression. Administration of fluids and analgesics by injection may help to alleviate these symptoms; however if there is no improvement the mouse will be killed to prevent further suffering.

The surgical procedure is designed to induce CKD in the mouse; however the animal will not experience the clinical consequences of this condition as the experiment will end before this stage is reached.

Once the mouse has recovered from surgery it will be fed a diet containing elevated levels of phosphate: this is designed to speed up the formation of calcium deposits in the blood vessels. The diet itself is palatable to mice, so they will eat it readily; however some animals can lose weight rapidly over 24-48 hours. Placing the animals temporarily in a warming cabinet can minimise this loss of weight, which will be detected by regular weighing.

Feeding a high phosphate diet in combination with removal of 5/6th of the kidney tissue will result in vascular calcification. Although this has adverse consequences for patients, which is the rationale for studying the condition in this project, the mice will be killed and tissue collected for further analysis long before they experience the clinical consequences of this condition.

The drugs that we plan to administer are not reported to cause any adverse effects at the intended doses and duration of treatment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity level associated with the breeding and maintenance of the genetically altered mice is mild.

Some of those mice will then undergo the surgical procedure to induce CKD and subsequent feeding of a high phosphate diet, which has an expected severity limit of moderate.

Therefore approximately 70% of mice will experience mild levels of suffering and 30% experience moderate levels of suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

CKD leads to complex changes in physiological function, both within the diseased kidney and in the body as a whole. Many of these changes are not understood fully and so cannot be reproduced using isolated cells or computer modelling. However it is precisely these systemic changes that result in vascular calcification. Consequently, it is necessary to study the changes that occur in blood vessels in the intact animal in order to understand what is happening as CKD progresses. This leaves us with no viable alternative to the use of animals for the proposed project.

Which non-animal alternatives did you consider for use in this project?

We have used isolated cells to perform many of the experiments that underpin this project and we will continue to do so where appropriate.

Why were they not suitable?

Isolated cells are useful for providing proof of principle and for testing drugs or understanding at the molecular level how signalling processes occur. Where they are less useful is in trying to understand the more complex interactions that occur in the organ or the whole body, especially in disease states. CKD is a complex disease which can alter the way that the body regulates calcium, ultimately leading to vascular calcification. This process cannot be modelled accurately using cell culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The majority of animals used in this project will be required to generate and maintain breeding colonies of the two strains of genetically altered mice. Hence these numbers are based on the prior experience of both our group and that of numerous other researchers at our establishment and elsewhere.

For the remaining animals, we are able to base our estimates of the number of mice that will be required on our previous experience with the main experimental model.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have designed our experiments using the NC3R's Experimental Design Assistant so that we are able to gain the most possible information from each individual animal.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In maintaining our genetically altered mice colonies we will employ efficient breeding strategies to ensure that the number of excess animals is kept to a minimum. Colony size will be reviewed regularly to ensure that breeding matches the anticipated demand for experimental animals.

We have designed the experimental plan in such a way that there are a number of points at which a decision is made whether to continue with a particular objective(s) or not. Thus if an experimental outcome indicates that there is no value in continuing, that aspect of the work will cease thereby preventing the unnecessary use of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The purpose of the animal model is to induce vascular calcification in mice in a way that mimics disease progression in humans with CKD. To do so, first we need to induce CKD. This can be achieved in a number of ways in the mouse, including exposure to radiation, obstructing the outflow of urine from one of the kidneys and administration of a number of drugs. However none of these methods is suitable for our purpose as they produce pathologies that differ from the type of disease typically seen in patients with vascular calcification.

Therefore, we will employ a surgical procedure to remove 5/6th of the kidney mass as the means to induce CKD. This involves removing kidney tissue in two stages and allowing the animals to recover between procedures. Thereafter, mice begin to develop CKD over a period of several months. As in humans, there are no overt clinical signs or pain

associated with disease progression until the final stages. However, mice will not experience pain or distress due to CKD as the experiment will finish before they have reached this point.

The second part of the process involves feeding the mice a diet containing higher than normal levels of phosphate. We know from a pilot study conducted in earlier experiments how much phosphate the mice will tolerate (1.5%) and how long we need to feed the diet in order to induce the formation of calcium deposits in their blood vessels (8 weeks), so we can have confidence that this model will work in our hands while at the same time causing the least distress to the animals. Vascular calcification associated with CKD will lead to an increase in the animals' blood pressure, but as in humans, there are no overt signs that hypertension causes pain or distress.

Why can't you use animals that are less sentient?

We are not aware of any non-mammalian animal models of vascular calcification that mimic the pathology seen in humans as they age. There is a zebrafish model of generalized arterial calcification of infancy (GACI); however as its name implies, this is a disease that manifests either before birth or early in childhood as it is a rare genetic condition.

All published studies in this area, including our own, have either used isolated cells or rodents. The former are a valuable tool with which to study molecular pathways in specific types of cells. The latter are most frequently used in vivo because of the need to model a complex, multifaceted disease process that involves the kidneys, blood vessels and hormones that regulate calcium.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During the course of earlier work authorised by a previous licence (P217A25EF) we have optimised the dietary conditions necessary to produce the calcification of blood vessels, minimising the time required to reach the scientific endpoint of the experiment while causing the least distress to the animals.

Furthermore, we have refined our surgical procedure and post-operative monitoring regimen to ensure that any animal at risk of acute renal injury can be identified and killed humanely to prevent unnecessary suffering.

We will continue to review our procedures on an ongoing basis and make refinements where ever possible to minimise the welfare costs incurred.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All procedures will be undertaken in accordance with institutional standard operating procedures (SOPs) and guidelines.

The approach to surgical procedures will be further informed by the Laboratory Animal Science Association's (LASA) Guiding Principles for Preparing for and Undertaking Aseptic Surgery (https://www.lasa.co.uk/PDF/LASA_Guiding_Principles_Aseptic_Surgery_2010.2.pdf).

Blood sampling will conform to the LASA Good Practice Guidelines for Collection of Blood Samples (http://www.verutech.com/pdf/lasa_blood_sampling.pdf).

When publishing the outcome of our work we will adhere to the ARRIVE guidelines (https://arriveguidelines.org/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We seek to stay informed of 3Rs advances through innovations published in the literature, discussions with colleagues at other institutions, regular updates provided by named individuals at our own institution and the local NC3Rs Regional Programme Manager and through subscription to the NC3Rs newsletter.

178. Environmental stresses in forages affecting ruminant digestive physiology

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

greenhouse gases, climate change, feed efficiency, ruminants, feed security

Animal types	Life stages
Cattle	adult
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Future climate scenarios are predicted to affect forages grown for ruminant production. Changes in hydration, temperature and carbon dioxide levels are potential stress factors for forage growth and production. Examination of ruminant digestive efficiency as affected by consuming stressed forages requires examination in regards subsequent greenhouse gas production by ruminants and the ability to increase feed efficiency to support the increase in global demand for meat and milk due to population growth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is predicted that global temperatures will rise by 2 degrees Celsius by 2050.
Current forage varieties have been developed under recent ambient levels of carbon dioxide and traditional weather patterns. Moving forwards, it is important to try and account

for changes in the growth efficiency of forages plants and the subsequent effect these have on the nutritional physiology and performance of ruminants. It has previously been shown within the host institution that applying environmental stresses relating to potential future climate scenarios (associated with global warming), such as varying levels of water, temperature or carbon dioxide affects post-harvest plant metabolism and rumen metabolism in vitro. However, these previous experiments have been limited and require further extensive investigation using animal models. Ruminants have the ability to utilise poor quality fibrous forage material and convert it into human edible meat and milk. Examining the effects of future climate scenarios along with the examination of nutritional efficiency will allow for plant breeding targets to be defined and inform decisions moving forwards. Production of stress tolerable forages and improving ruminant nutritional physiology may help delay the rise in global temperature.

What outputs do you think you will see at the end of this project?

This project will address how environmental stress in forage grasses and the plants subsequent response to ingestive stress affects animal production. The outputs will contribute to the understanding of the potential impact of future farming and refine models for the rumen system. It will aid in the understanding of forage feed composition and its utilisation and gain knowledge of plant traits (beneficial and adverse) when used as a forage feed. The outcomes will also relate directly to further the knowledge for animal production and environmental outputs as well as obtaining information for forage breeding for the future.

Who or what will benefit from these outputs, and how?

There will be a range of academic and non academic beneficiaries including; Microbiologists with new information about microbial community development, Plant biologists providing more information on stress responses in plants with implications for crops as well as animal forage, Environmental scientists, to understand more about climate predictors and Ruminant scientists, to gain greater understanding of the metabolism of forage feeds and utilisation within the animal in terms of animal production and potential environmental pollutants. Plant breeders will also gain knowledge of particular plant traits when considering breeding for productive animal forage feed and also Farmers will gain knowledge on beneficial forage types for the future to maximise pasture and animal performance.

How will you look to maximise the outputs of this work?

We will engage with industry practitioners and representatives by attending industry-facing shows and co-operating with the efforts of both local and national farming outreach programs. We will ensure translation of research to product via links with an international grass seed company. The improved understanding of effects of climate change on forage digestion towards the reduction of greenhouse gas emissions and thus meeting emission targets set for livestock will also maximise outputs by informing policy makers.

Species and numbers of animals expected to be used

- Cattle: 58
- Sheep: 102

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mature sheep, that have finished growing may be used as a model to evaluate the effect of environmentally stressed forages on rumen metabolism, apparent whole-tract digestibility, enteric greenhouse gas emissions and rumen microbial community analysis without interference caused by growth, reproduction or lactation. Results obtained using mature sheep can then be used to refine the design of diets for production animals such as growing lambs or lactating dairy cows where performance data can also be recorded, in order to evaluate environmental and economic benefit.

Typically, what will be done to an animal used in your project?

Animals utilised for feeding and metabolism studies may be individually housed and restrained if appropriate for the safety of both operator and animal. The maximum period of time the animals will be restrained in dairy cows will be four periods of 28 days followed by a rest period of at least 56 days.

Sheep will be housed individually in pens with an appropriate floor size, based on their body weight, for the monitoring of individual feed intake for a maximum duration of 112 days. Sheep will be transferred into metabolism crates, where movement is limited for a maximum period of 10 days within a 21 day period.

What are the expected impacts and/or adverse effects for the animals during your project?

Mild transient (1 to 2 hours post procedure) pain is to be expected for blood sampling or oesphageal rumen sampling

Abnormal behaviour may be observed when animals are individually isolated from being able to directly interact with another animal. Animals will always be able to see other animals. From previous experience individual isolation has negligible/transient effect on animal behaviour with feed intakes being normalised within 24 hours.

Weight loss is a potential impact due to stress associated with individual facilities. This will be mediated wherever possible, but if not the animal will be removed from the experiment and observed by a veterinary professional.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All other animals will only experience a mild degree of pain or suffering.

What will happen to animals at the end of this project?

Kept alive
Used in other projects
Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ruminant livestock have a fermentative fore stomach commonly referred to as the rumen. The rumen is the site of fermentation of fibrous plant material by an interaction with an extensive microbial community. Digestion of fibre and protein from forages within the rumen and the rest of the digestive tract can meet the nutrition requirements of the animals, which in turn can produce meat or milk for human consumption.

Which non-animal alternatives did you consider for use in this project?

There are no laboratory assays available for monitoring rumen fermentation or apparent whole-tract digestibility which do not involve the use of an animal donor.

Why were they not suitable?

The rumen represents a part of the entire gastrointestinal tract and can not elude to animal performance or health.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of cattle represents two intensively monitored experiments containing 9 animals per run and a larger production study of 2 treatments containing 20 animals per treatment.

The number of sheep represents a cohort of 6 sheep to be used in intensive monitoring experiments and the use of commercial animals in 2 separate studies examining 4 treatments and utilising 12 animals per treatment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This is based on the minimum number of animals required to obtain valid and robust results without having to repeat the experiment unnecessarily with excess animals. There is local expertise and knowledge based upon previous experimentation in order to justify the choice of animal numbers within an experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to reduce the numbers of animals used within this project pilot in vitro screening studies will be conducted under another authorised project to assess the effect of stressed forages on the rumen in both batch and continuous culture.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Cattle and sheep will be utilised within this project. All experiments relate to better understanding of digestive physiology in response to forages that have been produced under different climate stress scenarios. Previous experience and expertise within the research establishment will allow for the best animal experience possible. All methods chosen are animal and size appropriate and are those most suitable to causing the least amount of pain and distress to the animals.

Why can’t you use animals that are less sentient?

This project requires the use of live ruminant animals in order to complete the project targets. There is no other less sentient option available and terminal euthanasia would not allow for measurement of the desired parameters.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will initially be based upon best practise and refined through experience and discussion with other establishments where similar procedures have previously been undertaken.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Procedures relating to ruminant livestock are typically reported in appropriate animal science journals. Where new procedures are to be undertaken the authors will be contacted and advice sought in order to pre-empt any problems and mitigate animal suffering.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The information on the 3 R's will be regularly reviewed throughout the projects duration to ensure that any changes that need to be implemented during the project can be achieved. Communication between technical animal care staff, project supervisors and the animal care team will be maintained throughout the project.

179. Models for experimental therapeutics of childhood cancers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunotherapy, Paediatrics

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overarching aim is to facilitate improvements in the clinical management of children with cancer by modelling the disease, its detection and its therapies in mouse models that closely resemble the human counterpart.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is the most common cause of death in children over one year of age. Those who are cured achieve this often through administration of very intensive and toxic therapies.

Use of mice with intact tumour structures and immune systems allows refinement of current clinical practice and especially the development of immunotherapies that can avoid the toxicity of conventional approaches.

What outputs do you think you will see at the end of this project?

The expectation is that by the end of the project there will be increased understanding of how drugs (chemicals, antibodies, engineered cells) can work together in combination to eliminate childhood cancers. Moreover, we aim to demonstrate how injectable agents can allow detection of childhood cancers using imaging methods, including during surgery. The net result should be the opening of clinical trials in children to evaluate the new therapeutics and imaging findings.

Who or what will benefit from these outputs, and how?

During the five years that the project is active, the anticipation is that between one and four clinical trials will open in paediatric oncology as a direct result of preclinical evaluations performed in this project.

Moreover, published work emerging from the project should contribute indirectly to rationale and design of clinical trials for childhood cancers both nationally and globally.

How will you look to maximise the outputs of this work?

The greatest impact on the clinical oncology field will be achieved through use of reproducible models that as closely as possible reflect the human disease counterpart. The reagents generated in this project will be made available to the broad community as well as our existing collaborators. New knowledge will be published including where possible robust experimental approaches that show lack of efficacy of a combination treatment.

Species and numbers of animals expected to be used

- Mice: 6050

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All experiments are being performed on experimental mice. Mice are an optimal species for investigations of cancer immunotherapy for the following reasons:

They have a well characterised and understood immune system with a high degree of homology with the human counterpart.

There are already in existence numerous transgenic models of both immunodeficiency and cancer predisposition that are ideal for our studies on the interaction between cancer and the immune system

Typically, what will be done to an animal used in your project?

Mice will be engrafted with tumour cells to form models of solid or liquid human cancer. The purpose of these models is threefold: firstly to gain increased scientific understanding of the basic biology of tumour growth and in particular the interaction between the host tissues and cells with the growing tumour: secondly to use the cancer-bearing animals as subjects for evaluation of anti-cancer agents and interventions in therapeutic trials; thirdly to evaluate the role of cancer imaging to direct or monitor treatments.

A number of different approaches are used to generate the cancer-bearing animals including intravenous or intra-brain injection of tumour cells and, in some cases, genetic modification that promotes tumour growth. Typically the therapy interventions being evaluated will be a combination of immunotherapies or chemotherapies given by mouth or intravenous injection, irradiation of tumour and, in limited numbers of trials, surgical removal of tumour.

What are the expected impacts and/or adverse effects for the animals during your project?

Tumour growth in mice may induce local or systemic side effects. Tumours can impact on important organs or tissues through pressure effects as they grow. A range of side effects are possible depending on the position of the tumours. For example abdominal tumours might impact on the intestine, brain tumours might create local pain or decrease brain functioning. The side effects induced by tumour growth are therefore somewhat broad and will require careful monitoring both of tumour size and general wellbeing (activity, weight, feeding and grimace score for example). Tumours typically develop within 10 days of injection of tumour cells and cause local pain if allowed to grow to a lump greater than 1cm diameter. This can manifest as weight loss, ruffled fur and decrease activity. Administered therapies may alleviate suffering in some mice or worsen it in others if there are toxic side effects.

Duration of clinical trials of anti-cancer therapies is typically 3-5 weeks during which time mice are monitored for tumour size, weight and behaviour. Humane endpoints may limit the duration of trial in mice receiving no benefit from the interventions. In a small proportion of experiments, surgery or radiotherapy to tumour bearing animals may be incorporated to better represent treatments applicable to human subjects; here the total tumour and treatment burden is further enhanced by the increased number of interventions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All work will be performed in experimental mice. Amongst protocols there is a mixture of maximum severities of mild, moderate and severe. Severe symptoms are possible because of the sometimes unexpected side effects or speed of growth. However any mice with severe side effects is likely to be very short lived since humane endpoints will be immediately applied.

Estimate of proportions are as follows:

- Mild: 30%
- Moderate 65%
- Severe 1-5%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project is focussed on experimental therapeutics for childhood cancer that is rooted in clinical translatability. A major development in oncology is immunotherapy but many existing models of childhood cancer fail to reflect that developmental origin of childhood cancers which results in their relative lack of detection by cells of the immune system. Optimal evaluation of therapeutics interventions that evaluate immunotherapy in combination requires the solid tumour model in the context of a natural host immune system, including the system of blood vessels . This can only be achieved using an animal model.

Which non-animal alternatives did you consider for use in this project?

All therapeutics trials agents are first evaluated using cell line and organoid models to ensure proof of concept activity.

Why were they not suitable?

Cell line and three dimensional tumour models growth in tissue culture are not sufficient for evaluation of translatable therapeutics combinations since they lack three dimensional structure, vasculature and host immune response to tumour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Total numbers of animals per protocol through the life of the project have been estimated based on the likely number of experiments to be performed over the course of the project, which in turn could be increased from current level of activity based on success rates of ongoing grant applications. However the estimates are based on the assumption that the number of funded projects will remain at the current level during the course of the license. The principle for individual experiments is that they should be definitive; ie statistical tests will be performed to determine that experiments include sufficient numbers of animals per experimental group to achieve statistical significance so experiments do not require to be repeated. Frequently small pilot experiments are needed to determine likely required group size to achieve this aim.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The main factors determining total mouse numbers for this project is the number of experimental control groups and number of mice per group. The most effective way to reduce total numbers is to power experiments correctly with sufficient numbers of animals to reduce the need for exact experimental replicates. Correct determination of control groups is dependent on correct definition of a research question and consideration that an effect must be attributable to the intervention of interest. To determine numbers of mice per group, formal power calculations must be performed for all experiments using tools such as NC3R's experimental design assistant. For the purposes of this project applications many different research questions will be evaluated and effect sizes are likely to vary. Pragmatically therefore average group sizes of 7 mice per group have been used along size an average of 6 groups per experiment which is a typical number for therapeutics intervention trials in oncology.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding will be used to minimise numbers; a good example from current work is the TH- MYCN-ALK transgenic strain in 129/ScJ background; wild type littermates from these breedings are used in trials not requiring transgenic background. Similarly for

breeding, careful record keeping ensures optimal generation of mice with potentially harmful phenotypes. Avoidance of breeding of old mice also reduces total mouse usage and potential for harm.

Pilot studies are the norm for determining likely effect size and, if there is no effect, in preventing a futile experiment being performed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the work described in the license application are based on experimental mice. For the majority of the work, mice used carry no harmful mutations. All experiments make use of cancer-bearing mice in order to evaluate anti-cancer therapeutics interventions. Experiments on cancer-bearing mice are relatively shortlived with humane endpoints in place so the duration of suffering of any individual animal is weeks or days in duration rather than months and humane endpoints can be applied before burden become moderate or severe. All mice are culled at the end of therapeutics trial interventions or when humane endpoints are reached, whichever occurs first.

Why can't you use animals that are less sentient?

Meaningful evaluation of anti-cancer treatments need to reflect the scheduling of agents that can be achieved in patients. Duration of treatment and evaluation must be sufficiently long to monitor effective cancer regression/remissions. By its nature this entails observation of tumour growth in mice engaged in normal activity over a period of weeks. The interventions used in this study require an intact immune system reflective of the human counterpart and growth of a solid vascularised tumour. There are no less sentient animals available which are suitable for solid tumour growth, administration of multiple therapeutic agents, and in the context of a mammalian immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All experimental work is carried out in our institutions's biological services facilities where mice are monitored daily by the trained technicians for well being as a safeguard to welfare, in addition to the requirement for PIL holders operating under the proposed license to monitor experimental mice undergoing interventions regularly in partnership with

the core animal technicians. An additional refinement for protocol 6 and 7 in which mice undergo surgery is peri and post operative pain relief which will be defined on protocol by protocol basis in discussion with named veterinary surgeon.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following documents and guidelines will form the basis of best practice. All experimental planning is performed following approval of experimental protocol and all deviations or new procedures are discussed with the named vet.

NC3Rs ARRIVE guidelines https://www.nc3rs.org.uk/the-3rs

http://www.3rs-reduction.co.uk/assets/applets/Festing_Altman.pdf Guidelines for the welfare and use of animals in cancer research

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Resources available include the 3Rs webpages at (https://www.nc3rs.org.uk/the-3rs) where there is a link to 3Rs resources. At our institution there are many opportunities to discuss new protocol refinements with named vet, regularly on site and available for meetings and informal discussion, and/or via the ASRU Regulatory Advice Team, both of whom are.

180. Understanding and developing new treatments for neurological diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Brain, Disease, Models, Therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant
Rats	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to improve our understanding of the causes of progressive conditions that affect the brain and to devise effective therapies for these devastating diseases. These conditions have been selected through discussions with clinicians who have no effective therapy to offer their patients and also through the availability of a suitable animal model. Some of these conditions are rare while others are more common, some are caused by genetic mutations while others are an injury but it is the lack of available therapies that brings them together in this project.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diseases that affect the brain are a major cause of disability and death in populations around the world. Some of these diseases are rare and aggressive and cause death in children e.g. Niemann-Pick type C disease and infantile neuroaxonal dystrophy. Others are more common and affect the elderly e.g.

Parkinson's disease. Due to the complexity of the brain, these diseases are difficult to treat and many cause either life-long disability and/or premature death. The outcome for the patient is devastating. For the families, carers and healthcare system it is a huge burden. The socio-economic impact of this is significant. What these conditions have in common is that they remain poorly understood and there is no cure. This project is important because it aims to increase our knowledge of these conditions by studying animal models of these diseases. This information will then be used to design and evaluate new medicines that may have the potential to provide life-saving and life-changing benefits to patients.

What outputs do you think you will see at the end of this project?

The outputs from this project will come in a number of forms.

1. We will generate new information on the biology of the brain diseases that we are studying and on the effectiveness of the medicines and therapies that we are evaluating.

2. We will publish our findings from this project in reputable and peer-reviewed journals so that the information and knowledge is shared widely.

3. We will file patents on new medicines and therapies that we develop and this is important in making them viable products that will benefit patients.

4. We will generate therapeutic products from this project that will benefit society and those suffering from these devastating brain diseases.

Who or what will benefit from these outputs, and how?

There are a number of individuals or groups that will benefit from these outputs.

1. Scientists - Publications that may arise in the short-, medium or long-term stages of the project will benefit the broader scientific community that are studying these diseases, or conditions similar to them. It will enhance their knowledge base and provide new avenues of understanding, research ideas and research direction.

2. Clinicians - Publications and data that may arise in the short-, medium or long-term stages of the project will benefit clinical professionals looking after the patients with these diseases. Published information on new findings relevant to these diseases can help inform on better care, diet, physiotherapy or ways to monitor the progression of these conditions. The development and publication of data that is supportive of a new drug will facilitate early dialogue and communications between the scientific and clinical community that are integral components of the drug development process.

3. Patient and Family Organisations - The patients and their families/carers will benefit from all new information at any stage of this project. This will help them to make important decisions on their lifestyle, care and any new medicines that may be approaching clinical trials in which they may be able to participate in.

4. Industry - The involvement of industry is an important component in developing drugs for brain diseases. Industry partnerships with academics to facilitate or accelerate the process are hugely beneficial and publications and patent filings will help to form these collaborations. The engagement with industry can also take place at any stage of the project.

How will you look to maximise the outputs of this work?

There are a number of ways that we will maximise the outputs of this work.

1. Publication of data and findings in a range of high impact peer reviewed journals that are both field specific (e.g. Journal of Neuroscience) and have a broad readership (e.g. Nature Medicine). This will ensure that our data and findings are disseminated broadly across the scientific and clinical community.

2. The data generated will be used to form new national/international collaborations. This will provide access to new technologies, analytical methods and ideas which will accelerate our objective of understanding the neurological basis of the diseases we study and the generation of new medicines to treat them.

3. Presentations of data as oral or poster communications at national/international conferences. These will include both specialised meetings e.g. targeting neuroscientists or neurologists (e.g. the annual Society for Neuroscience Meeting), or lay audiences as part of public engagement activities e.g. patient and family meetings or public engagement days (e.g. the annual British Society of Gene and Cell Therapy).

4. Responsible and professional dissemination of publications and outputs via social media platforms. This ensures very broad dissemination of outputs across society from lay followers, to students to experts in the field in the most expedient manner.

Species and numbers of animals expected to be used

- Mice: 7500

- Rats: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To achieve the aims of this project, the use of animal models of disease are required. Cell culture models do not have the complexity to fully evaluate what is happening in humans and are not sufficient for regulators to approve a drug for clinical use. These are mouse and rat models of neurological disease. There are a number of reasons why these specific animals have been selected:

The majority of animal models of the neurological conditions that are available for us to study and evaluate new medicines in have been made in mice and rats.

The complexity of the mouse and rat brain in terms of the structure and organisation is sufficient to broadly mimic that of the human brain.

The relatively short breeding times and lifespan of mice and rats means that we can complete studies of disease progression and the effectiveness of medicines we are testing in a feasible time frame.

The tests that we conduct to assess the way that neurological disease progresses and the effectiveness of medicines that prevent this are well established and understood in mouse and rat models. We have spent more than 15 years investing in and developing tests of movement, strength and the ability to walk in a manner that is least stressful for the animals.

Our overarching aim of this project is to develop new medicines that will help treat children and adults with devastating neurological conditions. This requires interactions, advice and ultimately permission from national and international regulators e.g. The UK Medicines and Healthcare Product Regulatory Agency (MHRA) or the European Medicines Agency (EMA). The regulators have approved drugs based on data in mice and rats to progress to clinical trials and the patients who need them most.

These mice and rats will also be used at different life stages ranging from prenatal to new born to adult. This is because the diseases that we are studying are paediatric and affect children before they are born (e.g. Type II Gaucher Disease), shortly after birth (e.g. Hypoxic-Ischemic Encephalopathy) or are adult conditions (e.g. Parkinson's Disease). The use of mice and rats at these different stages reflects the age of onset seen in patients.

Typically, what will be done to an animal used in your project?

The experiences that an animal will go through in the project can be divided into two main categories.

- Studying neurological disease in rodent models - Mice or rats that model a particular genetic disease will be bred in such a way that offspring inherit the defective genes from their biological parents and develop the disease, in the same way that this happens in humans (e.g. Niemann- Pick type C Disease or Gaucher Disease). Another way is to surgically or chemically induce cells in the brain to degenerate and therefore show disease symptoms e.g. a model of hypoxic- ischemic brain injury is induced surgically in mice by ligating the carotid artery that feeds blood to the brain and temporarily reducing the availability of oxygen. Or Parkinson's disease is induced in mice or rats by injecting a specific chemical into the brain that depletes the specific cells that are also degenerating in the patients. Animal models that show these symptoms will be studied to assess how the condition progresses through its lifetime and what the effects are i.e. the natural history of the disease. This can be assessed through a number of means: i) an experienced user observes the animals and measures changes that are visible compared to normal 'control' animals that don't have the disease, ii) weigh the mice to see if they are losing weight, iii) conduct behavioural assessments in the mice to see if they have any deficits in the way they move, strength, co-ordination and memory, iv) biological samples in the form of blood or urine may be collected from animals to see if there are any abnormalities (as in human patients) or 'biomarkers' of the disease and v) the animals may be culled at certain time points to study how and which organs of the body have been affected.

- Once we understand the natural history of the disease in the animal models as described above, we would then use them to test the effectiveness of medicines that we are assessing. This would involve adding the medicine to food or water or injecting them directly into the animal e.g. under the skin, into the bloodstream or directly into the brain. Some medicines require to only be given once (e.g. gene therapy) while others would require to be given repeatedly throughout life, similar to human patients on certain medication. In the case of longer treatments, the ideal scenario would be to have the drug in food or water but in some cases the medicine may require to be injected weekly or less frequently.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts of this projects are as follows:

- Pain - this can range from very transient and localised pain following a single injection of a medicine into a vein to more involved surgery where direct access to the brain is required e.g. to induce a model or deliver a medicine. In the latter case, local and general anaesthetics

are utilised for surgery followed by a course of pain relief and careful observation as the animal recovers.

- Abnormal behaviour - As in human patients, the animal models of neurological disease will have progressive behavioural abnormalities such as reduced mobility, co-ordination, strength and memory function.
- Weight loss - This is observed as the symptoms of neurological disease progress and can be a consequence of losing the ability to feed and drink.
- Weight gain - Food consumption is controlled by specific areas of the brain. We will be studying mouse models of obesity and diabetes and assessing drugs that modulate signals in specific parts of the brain to reduce food intake.
- All of the above are monitored using an agreed scoring system and the humane endpoints to ensure limits on these.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This severity limit of this project is 'moderate' and the humane endpoints and scoring sheets reflect this. Approximately 90% of animals used in this project will be mice and 10% will be rats.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The brain is the most complex organ of the body and is made up of many different cell types. These different cells interact with each other in a very complex way. The brains of rodents such as mice and rats are broadly sufficiently complex to mimic that of human beings. This, taken in combination with the fact that models of neurological diseases or protocols to surgically or chemically induce them already exist in these species, makes them appropriate for studying neurological diseases and also the effectiveness of new therapies. Furthermore, national and international regulators that assess the case for

advancing a new therapy into humans require animal data as part of the assessment criteria. This is especially important in developing new cutting edge therapies that may be used for the first time in humans e.g. gene therapies or novel peptide therapies. Therefore, animal use is of critical importance in achieving the aims of the project which is to further understand these neurological diseases and to develop new treatments for them.

Which non-animal alternatives did you consider for use in this project?

The only non-animal alternatives would be to use brain cells that can be grown in a dish within a lab or post-mortem brain tissue

Why were they not suitable?

Growing brain cells in a dish does not mimic the true complexity of the brain and the myriad of interactions that occur. There is essentially no brain anatomy and so does not help in understanding which of the many regions of the brain are affected and when this starts. Furthermore, it is difficult to capture the many different types of brain cells into a dish. Cell models are also of limited use in trying to assess how well a drug distributes within a complex organ such as the brain (this is called biodistribution). Cell models also don't tell us how long a drug is retained in the brain and how long they are active for (this is called pharmacokinetics and pharmacodynamics).

Post-mortem brain tissue is limited in terms of how much is available for study and this is important for some of the very rare diseases that are being studied in this project e.g. Infantile Neuroaxonal Dystrophy for which there is no post-mortem tissue available. Furthermore, not all areas of the brain will have tissue available. New therapies cannot be tested using post-mortem tissue and important assessments of biodistribution and pharmacokinetics and dynamics cannot be conducted.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we will use in this project is based on a number of factors: i) What we have learned about the models from previous projects, ii) our experience with statistics and using experimental design software that allow us to predict the number of animals required for each study, iii) taking guidance from the principles of the National Centre of Replacement, Refinement and Reduction (NC3Rs) and ARRIVE guidelines, iv) this project is part of an ongoing large funded programme of work and the totals take into account the number of experiments likely to be conducted over the time frame of this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant to ensure that our animal work produces reliable and reproducible results. Through taking into account from the beginning criteria such as statistical analysis, randomisation and blinding of researchers and calculations that help to estimate the required number of animals, we reduce usage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All the therapies we use in animals are first tested on cells in a dish to ensure that they are pure and active. This reduces sources of error and unnecessary animal usage.

Since we also use animals that are at a foetal or newborn stage, wherever possible we use specific strains of mice that have very good maternal instincts and look after their pups well. This increases survival and reduces numbers used.

Some of the models used in this project are induced through alternative surgical or chemical means rather than genetic models and does not require numerous rounds of breeding. This significantly reduces animal usage.

We also archive all tissues that are generated from our experiments at -20, -80 or -150 degrees Celsius. This ensures that unnecessary repetition of experiments is avoided and we can also share these with researchers all over the world without them having to establish their own animal colonies.

We freeze embryos or sperm for all of our mouse lines so that we do not need to breed mice unnecessarily.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models used in this project mimic the human forms of neurological damage and disease. These include more common conditions (Parkinson's Disease and Hypoxic Ischemic Encephalopathy) and much rarer conditions (Gaucher Disease, Batten Disease, Infantile Neuroaxonal Dystrophy, Dopamine Transporter Deficiency Syndrome,

Manganese Transporter Deficiency, Fatty Acid Hydroxylase Deficiency Associated Neurodegeneration, Niemann-Pick Type C Disease). In most cases, these are the only animal models of the disease available. We have over 15 years of experience of working with animals models of neurological diseases and providing the highest levels of welfare.

Why can't you use animals that are less sentient?

Because we are testing new therapies that will be used for downstream clinical use, we need to use animal models that have the required levels of brain complexity and physiology. Mice and rats fulfil this criteria and are accepted by regulators such as the FDA, EMA or MHRA that need this data from these models to assess effectiveness and safety.

Gene therapy is a therapeutic modality that we are researching and assessing and the genetic sequences used should be tested in an animal model that have a genome sequence as similar to human beings as possible. Mice and rats also fulfil this criterion as their gene sequences (particularly the ones we are investigating) are very similar to that of humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continue to minimise harm to animals via various means:

We have invested in buying state of the art behavioural analysis equipment that minimises stress to the animals through handling and maximises data acquisition and analysis e.g. we have a Catwalk XT gait analysis system and the ANY-maze software. We also now film our behavioural analysis so that we can review this later and in slow motion rather have to prolong analysis and stress to the animals.

We have worked with the veterinary and animal care technicians to optimise our post-operative care and pain management.

We have implemented robust monitoring score sheets that separately cater for neonatal and adult animals which monitor animal welfare and have been successfully used.

We have adopted best practice with respect to housing e.g. the use of environmental enrichment and of cylinders to pick up mice and reduce stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The experimental design resources available through the NC3Rs Resource Hub will be used. This provides access to a wealth of guidelines e.g. ARRIVE and information on the design and analysis of experiments at all stages.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advances in the 3Rs and their implementation into this project will be ensured through regular contact with the NC3Rs, the Veterinarian and biological services unit staff. We shall use the NC3Rs Resource Hub to keep up with best practice. All staff working on this project will subscribe to the NC3Rs newsletter and will access NC3R E-learning modules and webinars and those organised by the biological services unit.

181. Alternative pre-mrna splicing control and its contribution to tissue injury and pain

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

pain, nerve damage, arthritis

Animal types	Life stages
Mice	juvenile, adult
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to look at how an RNA editing process - called pre-mRNA splicing or alternative splicing - contributes to inflammation, tissue damage and pain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are many different forms of a protein known as vascular endothelial growth factor (VEGF). VEGFs with only slight differences in their structure can have completely effects

in the body. For example, one causes pain and another blocks pain but they are 96% the same in structure. When people have painful osteoarthritis there is more of the VEGF that causes pain in their joints than in normal joints.

The type of VEGF that's made is controlled by another protein called SRPK1 by changing a process called splicing. SRPK1 might also control splicing in other proteins that are important in pain and joint damage in arthritis. We don't yet know what these other possible SRPK1targets are.

This work is important for the following reasons:

1. Lots of molecules that are known to be important in pain are spliced. We don't know very much about how that works, or how important splicing is in causing pain caused by damage to joints or nerves.

2. We are making new blockers of proteins like SRPK1 that control splicing. One of these is already in a clinical trial to treat damage to the retina in the eye. If we are to develop more new treatments, we must understand more about proteins like SRPK1 and how they affect pain.

3. We know that VEGF is spliced by SRPK1 but we don't what else is. Nerves, blood vessels, and other cells work together to sense pain to protect us, and splicing might change how all these cells function. It's important to understand what sort of splicing happens in different cells and tissues and how that might change, and contribute to pain.

4. Because splicing can change if tissues are damaged, it might mean that it is also part of the body's attempts to repair the damage. Our work will also give us more information on whether controlling splicing can help stop damage in diseases like diabetic nerve damage or arthritis.

What outputs do you think you will see at the end of this project?

1. The generation of new essential knowledge on neuronal and vascular mechanisms contributing to pain, and the changes associated with both acute and chronic pain. This is most likely to be in the form of publications or patents.

2. The application and exchange of knowledge to drive both future mechanistic research and drug discovery strategies.

3. The work we are doing in this area may influence strategies for novel drug design in industry (medicinal chemistry) in addition to identifying possible new targets for drug discovery.

4. As this work involves development of new compounds that may become treatments for pain, new analgesic therapy may be an outcome.

Who or what will benefit from these outputs, and how?

1. The chief beneficiaries of new knowledge generation will be the basic science, clinical science and veterinary science research communities. Our findings and publications will inform other work, in both academic and industrial research communities.

2. The pharmaceutical industry may benefit from this work through access to novel chemistry or information that leads to the re-purposing or reformulation of existing drugs for additional uses.

3. We have established a company through which we will develop potential drugs, and therefore the company will benefit from this work. Partners in the company such as large pharmaceutical companies and investors may also benefit.

4. Our work ultimately aims to benefit people and animals with chronic pain, so the medical and veterinary fields and patients may also benefit from this work.

How will you look to maximise the outputs of this work?

We collaborate widely and have a strong collaborative partnership with a medicinal chemist. This results in maximisation of the impact of his work in designing new molecules, and our work in drug discovery.

We publish and present work through multiple routes, researchers working on the project are encouraged to engage with academic and lay audiences in the dissemination of findings.

We have established a company through which we will develop potential drugs for clinical use.

Species and numbers of animals expected to be used

- Mice: 330
- Rats: 60

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will look at the ways in which specific changes in which proteins are expressed in which tissues contribute to both nervous system changes in response to pain, and tissue injury, and repair, and how we might be able to reverse such changes. As

such we use rodent models of nerve injury (neuropathy). We use adult and juvenile rodents as the conditions that we want to understand - nerve damage from diabetes and chemotherapy, and arthritis, predominantly affect juveniles and adults.

Additionally we know that early life painful experiences in humans and rodents affect later life experiences, and so study in adults cannot fully inform how juveniles perceive or develop pain in later life.

Typically, what will be done to an animal used in your project?

We will use rodent models of nerve injury that include mild surgical damage to one superficial nerve, or systemic treatment with low dose chemotherapy agents, or models of arthritis of one joint, and monitor their behaviour, including measurement of any changes in pain that they may experience. In some experiments animals will be treated with compounds with the potential to reduce pain and protect against injury/promote repair. These experiments may last between 4 and 14 weeks, depending on the aim. In these experiments, a model of nerve injury or arthritis is induced, under general anaesthesia where necessary, and following recovery, depending on the aim, some animals will be treated with analgesic/cell protective agents for up to 12 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

These experiments aim to identify mechanisms of tissue repair and pain, and as such the animals do experience mild - moderate pain resulting from nerve injury or arthritis. All models used are the most refined that still result in the necessary nervous system changes that we aim to target. The animals will experience changes in walking, after surgical nerve injury or arthritis they may guard or have reduced weight bearing on the affected hind limb for up to 3 days. After this animals usually return to using all four limbs with slightly less weight borne on the affected paw for the duration of the experiment. When chemotherapy models are used, animals do not show any change in their walking. The animals only very rarely experience any weight loss in any of the models.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity of the procedures is deemed to be moderate, based on >30 years experience with the models. It is estimated, based on experimental design, that up to 75% of rodents might experience moderate severity, with the remaining animals experience mild severity or be below threshold for naive control animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Physiologically no cell functions on its own. This project focuses on tissue damage, inflammation and pain, which are complex pathophysiological processes involving multiple cell types, systems and interactions that cannot yet be effectively modeled using non-animal alternatives.

Sensory neurones are long cells that connect peripheral tissues in for example limbs, with the spinal cord and brain. If these neurones are removed from the body, their targets and the central nervous system, they are, by definition, damaged as they are cut and disassociated from their peripheral and central connections, which initiates a damage response. Neuronal damage in conditions such as diabetes can affect the long neuronal processes, the spinal cord neurons and blood vessels, and the brain. Using isolated cells or cell lines in vitro cannot tell us how damage in different parts of a neurone, or the nervous system, result in pain. Similarly the joint is a very complex structure where different cells (cartilage cells, bone, synovial cells lining the joint, blood vessels) that are co-dependent on each other for full function. Cell lines not only do not contain all the functional proteins found in, for example, sensory neurons in the body, they can also behave very differently. Some cells, such as neurones and cartilage cells do not normally continue to grow and divide but cell lines do, so there are fundamental differences just in basic behaviour. Using cell lines representing different joint tissue components, such as cartilage cells, cannot provide the same information as the study of cartilage in a joint where there is also movement and load bearing. The use of cell lines can therefore inform, but not replace study of specific cells and cellular interactions in an intact physiological system.

Neurons not only communicate information to the central nervous system, they also contribute to the severity of inflammation and healing responses. Removal from their normal tissue surrounding significantly alters these functions. The complex interactions between neurones, and the cells which surround them in the both CNS and in peripheral tissues are what changes neuronal function, inflammation and pain in a whole animal or person. These complex relationships cannot yet be replicated in vitro, or mathematically in silico.

Use of genetically modified animals, such as those with a gene knockout is required, because although knockout of a specific gene product in a cell tells us how that changes that cell's function, it cannot tell us how this then changes a system in which that cell type is fundamental. This can only be studied in whole animals.

As our aims are to not only study neurons, cartilage, synovium and vessels but also the interactions with their local environment and between cell types to fully understand the consequences and potential benefits of control of alternative pre-mRNA splicing. Ultimately these therefore need to be studied in animals.

Which non-animal alternatives did you consider for use in this project?

We have evaluated several immortalised cell lines that have similarities to sensory neurons, and we use these for initial screening experiments. They are however, only useful non-animal tools to study protection of neurones from damage, or ways in which damaged neurons can be stimulated to recover from existing damage as a first step in understanding how this could be achieved.

We have developed in vitro model of inflammation using human synoviocytes, primary endothelial cells or endothelial cell lines and fluorescently labelled immortalised monocytes. This assay enables us to screen novel inhibitors for effects on inflammatory cell and migration prior to any experiments involving animals. We also use chondrocyte cell lines to progress work and define mechanisms in relation to cartilage damage and repair in arthritis.

Why were they not suitable?

As stated above, cell based models need to effectively replicate the physiological or pathological processes we aim to study or treat, in the conditions under which they occur - pain and inflammation resulting from damage to peripheral tissues, directly to nerves, or to joints. None of the available neuronal cell lines fully replicate the primary neuronal functions that we study, namely the change in function that makes neurones more sensitive and more likely to fire electrical signals, that then lead to the sensation of pain, nor do they provide the capability to assess the interactions with multiple different cell types as found in vivo, as co-culture techniques cannot yet replicate these. These cell lines are therefore not fit for the purposes of this project.

None of the available in vitro cell based approaches can effectively model the complexity of inflammatory pain, or the pain associated with degenerative joint disease or peripheral nerve damage, they can only give indications of potential effects on the isolated cells which need to be validated in primary cells and in animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mice

We have planned experiments for the next 2 years as follows:

Year 1. Determination of the effects of inhibitors of at least 2 kinases in male and female mice treated with chemotherapy agent vincristine, including behavioural and post-hoc tissue outcomes. For our usual experimental design with previously observed effects, this equates to 4 x 24 mice. This will be adjusted should effect sizes with novel inhibitors differ from those previously seen. Prior to these experiments we will need to determine tolerance and dosing for 2 such compounds - we cannot estimate sample sizes for these experiments until they are started so have estimated a maximum of 20 animals (both sexes) for each. Thus in year 1 we estimate use of ~150 mice.

Year 2. We have an ongoing drug discovery programme with new compounds being produced at pace and being screened in vitro. We plan on assessing at least two novel compounds in year 2 as above, so animal number estimates would be as in year 1, or slightly higher depending on experimental outcomes.

Rats

Year 1. Determination of the local (intra-articular) and systemic distribution of at least 3 novel splicing kinase inhibitor chemotypes following systemic and/or intra-articular injection (knee joint) under maintained terminal anaesthesia. This is required before any use of these novel chemotypes in an animal model to enable dosing ranging, possible use of any carrier/formulation, and choice of route of delivery. As with mice, it is not possible to estimate sample sizes yet. Animal number in year 1 is estimated to be 30 rats (5 per chemotype, both sexes), as rats are only needed when intra-articular delivery is to be used (joint size), or use of any specific model that is only available or characterised in the rat.

Year 2. We have an ongoing drug discovery programme with new compounds being produced at pace and being screened in vitro. We plan on assessing at least two novel compounds in year 2 as above, so animal number estimates would be as in year 1, or slightly higher depending on experimental outcomes and rate of movement into models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have recently introduced a new chemotherapy model to the lab and ran a pilot study to determine

a) translatibility of the model to this environment and b) effect size of the model on the primary outcomes. The numbers planned for the first 2 years of this project are primarily based on use of this model. We use various tools, including the NC3Rs experimental design assistant and other statistical support, including consultatation with a statistician who is often a co-applicant and advisor for funding applications, to enable us to estimate numbers of animals as closely as possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. We use current technological advances, such as in data capture software, that increase ability to collect data from multiple recordings in the same animal, and experimental designs that include repeated measurements in the same animals (where and if possible), to ensure that each experiment generates the maximum amount of data from each animal.

2. We use statistical modelling in order to determine the sample sizes needed for experiments before beginning, and in all our applications for funding to support this work. Numbers of animals and experimental designs are thus rigorously peer reviewed prior to any experiments. A priori calculations are based on either our previous data in the same models, or on published work from others working in similar areas, and are used to determine numbers needed.

3. We use historical or literature controls, such as previous sham control groups in which we know (such as vehicles or sham interventions have no observable effects) for example for comparison with experiments using novel pain killers, to ensure that we do not expose additional control animals to painful conditions unnecessarily (such as injections).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use models of peripheral nerve injury in mice, primarily surgical traumatic, and chemotherapy- induced nerve damage. Surgical models may involve a single sensory nerve (e.g. the saphenous nerve) or branches of the sciatic nerve. These models are as refined as possible by inducing damage to only some of the nerve fibres in the nerve and maintaining some nerve supply to the paw, while mimicking trauma such as might occur in accidental injury. Crush injuries or section / ligation injuries allow regeneration to occur or prevent it respectively, enabling investigation of strategies to promote regeneration, or to treat pain in circumstances when regeneration is not possible. The models that we use have been extensively refined (often by us) over the years to minimise the degree of damage and pain to that necessary to drive the changes in the nervous system that we study. Surgical models of nerve damage most commonly involve very superficial nerves, with minimal surgery and nerve trunk damage. Chemotherapy models are all relatively

new compared with many other pain models. The models that we use are based on those with the most recently published refinements using the minimum chemotherapy dose necessary (often significantly lower than the equivalent clinical dose given to humans) to result in mild neuronal injury.

Why can’t you use animals that are less sentient?

Rodents are the least sentient species in which studies of this nature are performed. They are capable of decision making, which is completely necessary in assessment of pain. These attributes are not apparent in species such as amphibia and fish. Rats and mice have been extensively used in studies such as these, and so there is a great deal of published literature against which results can be compared.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Given that the focus of these experiments is mechanisms and treatment of pain, post-operative analgesia is not used. This is because all analgesics known either inhibit the initial activity generated by inflammation/damage that we wish to study, and that drives the development of chronic pain, or enhance nervous system mechanisms that also enhance or block pain mechanisms. This means that post-operative analgesia would interfere with the systems we are studying. We monitor animals frequently, particularly after surgical interventions, and ensure that their access to food and water is easy ie dishes placed on the cage floor, in case they experience some loss in mobility.

The models that we use have been extensively refined (often by us) over the years. As most of the work concentrates on the early changes that lead to chronic pain, the majority of studies do not last a long time, usually less than 1 month. Arthritis/inflammation/injury models are limited to a single joint/limb, and the mildest form of intervention suitable for the experimental aims is used. Models of nerve damage most commonly involve superficial nerves, with minimal necessary surgery.

Chemotherapy for cancer in humans also causes nerve damage, as it does in rodents and can also cause effects in other tissues. Chemotherapy models are all relatively new compared with other pain models; we keep abreast of published refinements, and implement these when appropriate for experimental aims.

We will, where possible and appropriate e.g. in study of pharmacokinetics of novel compounds on intra-articular injection, conduct the studies under terminal anaesthesia, thus reducing the impact on animal welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

As above, the approach to this is the same as the approach to remaining informed about advances in the 3Rs. We consult colleagues on best practice, monitor information on best

practice produced by NC3Rs, UAR and other relevant Learned Societies and organisations, and discuss best practice with animal welfare colleagues who are informed of novel refinements and expectations through AWERB and Establishment Licence holder networks.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We consult colleagues on best practice and discuss refinements to models presented at seminars and conferences, and in published literature, including information produced by NC3Rs (e.g. best practice on mouse handling for minimal stress, and other resources in the NC3Rs resource hub), Understanding Animal Research and Learned Societies such as The Physiological Society and The British Pharmacological Society (e.g. validity and best practice use of the forced swim test). We discuss potential refinements with our animal welfare colleagues in the BioSciences Support Unit,

including the NACWO and NVS, who are often informed of novel refinements through AWERB and Establishment Licence holder networks. New refinements are discussed, and implemented when appropriate for the aims of the project.

182. The physiological roles of clathrin diversity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Clathrin, Type 2 Diabetes, Immune cells, Cell and Tissue Development, Neurons

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Clathrin proteins are required for cells to function, and specialised forms of clathrin enable it to perform specialised activities in different tissues, including in cells that control metabolism, cells that regulate the immune response and nerve cells, amongst others. This project will define how the specialised components of clathrin (clathrin heavy chain (CHC) 22 and clathrin light chains (CLC) a & b) contribute to processes related to health and disease by establishing their function in animal tissues.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Clathrins contribute to a process called membrane traffic, whereby proteins move between the cell surface and the inside of the cell. Through this, clathrins regulate the ways by which cells communicate with each other and their environments. As such, clathrins play vital roles in many cellular functions, including, but not limited to, signalling between cells, tissue development and nutrient uptake. Given the importance of clathrins in so many cellular pathways, it is important to understand how they aid and alter different functions in different cells and tissue to allow clathrin to meet the membrane trafficking demands of a huge range of highly specialised cells.

Although the basic molecular mechanism of how clathrins function is well-studied, how they perform specialised functions in specialised tissues in the body is not yet established. Several different forms of each clathrin subtype (CHC and CLC) exist, and it is this diversity we propose as a mechanism to fine tune clathrin function in different cellular pathways in different tissues to achieve specialised functions.

In initial studies, we have already shown that CHC22 functions within the response to insulin in muscle and fat tissue, a key process to maintain steady blood sugar (glucose) levels. Furthermore, we have shown that common genetic variations within humans can alter this pathway, potentially affecting the rate at which glucose can be absorbed from the blood. Given the rise in patients suffering from Type 2 Diabetes, in which blood sugar levels become dysregulated, there is a fundamental need to understand the mechanisms of CHC22 function, and how these influence glucose balance in both a healthy and diabetic context. We hypothesise that, in the long term (beyond the scope of this project), a clear understanding of the mechanisms by which CHC22 influences blood glucose clearance may lead to the development of small molecules that specifically regulate CHC22 function in order to improve blood glucose regulation in diabetic patients.

In addition, we have already demonstrated that diversity of CLCs, in which humans and mice share the same six common variants, influences the functions of nerve and immune cells, as well as cells in the uterus. Our proposed work will continue these studies in animals to understand more about how CLC diversity affects tissue functions that play a role in metabolism, fertility, infection and brain function.

These studies will link molecular pathways with biological processes that determine health and disease, and thereby inform future preventative and therapeutic strategies. A potential example of this in the long term would be by helping to determine if clathrin pathways are possible druggable targets in cases of infertility.

What outputs do you think you will see at the end of this project?

The aim of this project is to understand how the different clathrin subtypes contribute to the diversity of clathrin function in different cell types and tissues. The project is split into two objectives, i) understanding the roles of CLCs during development of specialised cells and tissues and ii) uncovering the role of CHC22 in the development of Type 2 Diabetes. We

expect to have furthered our understanding of the functions of both CLCs and CHCs by the end of the project. The primary output of this research will be publications that are of interest to the fields of clathrin biology, membrane trafficking, neuronal development, organ development, glucose metabolism and diabetes.

Through using mice lacking specific CLC expression and mice expressing CHC22, we are able to provide tools to further study these proteins to the wider field. We will also disseminate our findings in seminars, conferences and the scientific journals.

Who or what will benefit from these outputs, and how?

Through comprehensively defining the roles of CLCs and CHC22 at the levels of the molecule, cell and organism, our work will benefit research in the field of clathrin biology and provide key missing links in our knowledge of how clathrin performs its critical cellular tasks. The findings and tools from this research programme can immediately be used by other researchers to inform on how clathrin diversity impacts in specific cellular pathways.

As CLC clathrins are involved in many essential biological processes, these studies will be of interest to a wide variety of researchers and, in the longer term, have the potential to provide important information leading to the development of treatments for a diverse range of diseases including, but not limited to, developmental defects, cognitive disease, infertility and cancer metastasis.

Our investigations into the role of CHC22 will help us to understand its function in a whole-body context and provide models to connect the properties of CHC22 identified in vitro to its function in glucose metabolism and diabetes in vivo. In the short term, therefore, those who will benefit most from this element of the research will be researchers in the fields of GLUT4 trafficking and glucose metabolism. Given that CHC22 has a limited expression pattern and is not involved the broader roles performed by other clathrins, it is an attractive target for therapeutic intervention. Therefore, in the long term, beneficiaries of this research include both commercial and academic groups interested in the development of treatments for diabetes, as well as people living with diabetes for whom novel therapies would be greatly valuable.

How will you look to maximise the outputs of this work?

We will actively seek to share our work in a number of ways. Manuscripts for publication that result from this work will be uploaded onto pre-publishing databases such as bioRxiv to ensure knowledge and findings are available to the scientific community as quickly as possible. In addition to publishing results in open access research journals, results will also be presented (prior to publishing) at relevant conferences and seminars, with the aim of both disseminating our findings and also receiving valuable input from fellow researchers and potentially establishing new collaborations. We already have ongoing collaborations relating to both projects, and we regularly meet to discuss results, findings and ideas that help inform our ongoing project directions. We have previously provided labs in several other countries with genetically altered (GA) mouse lines that we have generated in order

to maximise the potential scientific output from these animals. In addition, we routinely collect and store tissues and organs from our animals, which can be shared with the research community upon request.

In addition to presenting at scientific conferences, we are committed to maximising our outreach to the wider community. This will often be through outreach programmes such as Soapbox Science, as well as disseminating the findings of this research to the wider press after publication in scientific journals. In addition, we have established a connection with a Diabetic Patients Group and will discuss findings from the CHC22 mouse lines with this group in order to both guide future work and discuss the best ways to disseminate our work more widely.

Species and numbers of animals expected to be used

- Mice: We estimate to use approximately 5000 mice over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to study the role of CLCs in tissue development, we require an animal model that both closely resembles human biology and expresses homologues of all the human isoforms of the CLCs.

Therefore, we require a mammalian animal model, since mammals express all CLC isoforms with greater than 90% identity. We have chosen mice as our model animal because their biological and genetic characteristics are very similar to those of humans and because the range of tools available to alter their genetic code makes them suitable animals for our project.

CHC22 is a pseudogene in mice, which means that mice do not express CHC22. We are using mice, therefore, as it allows us to investigate how CHC22 regulates blood glucose balance in a biological context which is very similar to humans' but where CHC22 is usually absent. We have observed that the expression of CHC22 in mice leads to the development of a mild diabetic trait. We therefore will use these mice to investigate the link between CHC22 and Type 2 Diabetes.

As we want to understand the role of different CLC isoforms during the tissue development process, we need to examine animals at all ages in order to identify the age of onset of abnormalities. This requires careful examination of embryonic mice, pups and adult mice. In addition, we have observed characteristics in CLCa KO mice that only appear in animals over 4 months of age, suggesting age influences the tolerance of some cells and

tissue to the absence of CLCa. Thus, we will examine older mice in order to identify which biological processes are affected as GA mice age.

Additionally, we want to know how CHC22 function influences blood sugar levels and how the failure of this process is linked to Type 2 Diabetes. As Type 2 Diabetes is associated with age, we will use adult mice for this objective.

Typically, what will be done to an animal used in your project?

GA mice will be bred by trained and competent animal technicians employed by the local animal housing facility, where they will be closely monitored by animal house staff and personal licence holders. For CLC GA animals, most mice used will be humanely killed at various life stages without being subjected to any other procedures. Tissues from these animals will be examined by microscopy for differences between unaltered (wild-type) animals and their GA littermates, in order to identify how the loss of CLC impacts protein expression and localisation, cellular functions and tissue development. Mice may be subjected to minor procedures that do not cause lasting harm, such as injection of non-toxic substances in order to examine cellular function, before being humanely killed and examined.

CHC22 mice will be fed differing diets before being subjected to glucose/insulin tolerance tests, in which blood is drawn at regular time intervals following stimulation by intravenous injection of glucose and/or insulin, in order to examine the link between CHC22 function, diet and diabetes. These minor procedures are well established and do not cause distress to the mice.

What are the expected impacts and/or adverse effects for the animals during your project?

Our protocols do not result in severe pain, distress, or lasting harm. We will breed GA mice that display mild/moderate lasting characteristics. We expect a 50% post-natal (1-3 days after birth) death rate of CLCa KO animals, indicating a critical role for CLCa in development. We do not observe mice fading away, suggesting these mice die very quickly, without prolonged suffering. The surviving mice are slightly smaller than non-GA animals, with on average 5-10% weight loss. In addition, older CLCa GA female mice have a higher risk of developing uterine infections, as shown by an enlarged abdomen.

The CHC22 mice tend to have slightly higher blood sugar levels. Most of our experiments will be performed in order to identify the changes caused by genetic alterations. In some experiments, animals may experience mild anxiety resulting from high/low blood sugar. Some of our protocols require that we collect organs for analysis, so mice will be given terminal anaesthesia before being euthanised via approved methods. At the end of our studies, mice not used in further experiments will be humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Just under half of CLCa KO mice develop enlarged uteri, which means that this line is categorised within the moderate category. This characteristic is only seen in CLCa KO animals (and not mice that lack only one of the two copies of this gene). Given that approximately half of these KO animals die 1-3 days after birth, this means we expect <15% of surviving CLC mice to be this category. CLCb KO mice have no defining negative traits, and thus are classified as mild (75% of CLCb contain a loss of either one or both copies of this gene). We expect 50% of CHC22 mice to have one copy of the gene introduced to their genome. The only detected characteristics of these animals are a mildly elevated blood glucose level, and therefore these animals are categorised as mild.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While we address a lot of our research interests using in vitro methods, a key aim of our work is to understand the impact of clathrin diversity on tissue development as well as disease. We are unable to do this using in vitro techniques alone, as it is not possible to fully recapitulate complex tissue structure in cell culture. As interactions between the different cell types that make up a tissue are critical to tissue development, we require animal models to fully understand the roles of clathrin diversity. Specifically, we need to add (CHC22) or remove (CLCs) the different types of clathrin in order to directly compare the different cells and tissue in these mice to their wild-type equivalents. This will direct our focus to tissues that are specifically affected by altering clathrin expression, and at which developmental stages these abnormalities occur. Overall, these animals will provide us with vital information on the critical roles of the CLCs and CHC22 that it is impossible to obtain without the use of mice.

Which non-animal alternatives did you consider for use in this project?

We will mostly use cultured cell lines, not animals, for our work. Although we will use mouse models in some of the experiments described in our project, we always first attempt to answer our research questions using cultured cells or biochemical experiments. For example, we have begun using the latest techniques in murine organoid cell cultures

(cultures of cells grown in the lab that more closely resemble the structure of an entire organ than single cell culture alone). We have established intestinal and endometrial (uterine) organoids from cells isolated from our GA mice. Now these organoids have been established, they can be grown indefinitely and cryopreserved, greatly reducing the numbers of mice we need to use in our research through replacing the use of further animals with these in vitro systems to study this tissue.

Why were they not suitable?

Traditional in vitro cell culture has been critical to establishing clathrin's multiple functions within the cell. However, since these methods typically involve single immortalised (usually cancerous) cell lines, they are not able to inform us on how clathrin's functions influence the cross-talk between normal (non- cancerous) cells types in vivo that is vital to tissue development. While organoids represent a positive step forward in this regard, and enable us to study multiple cell types in vitro, they still do not fully mimic organs and tissues in vivo because they do not encounter hormones and nutrients in the same way as an organ in the body. Thus findings using organoids should ultimately be verified using appropriate animal models and studies in animals will reveal behaviour of tissues in context. In addition, organoid culture techniques are still relatively new, and there are many organs for which we are not able to produce representative in vitro organoids.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimation is based on our previous experiences and our future experiment plans. Many animals will be used for breeding but not in other experiments. Due to <15% of adult mice are CLCa KO, rather than the expected 25%, due to post-natal lethality in the first 7 days after birth, a higher number of CLCa GA mice are required for breeding to produce sufficient CLCa KO mice for our requirements.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

POWER calculations were used to establish the maximum statistical power for the minimum number of animals possible. In addition, we will perform pilot studies in order to establish single experimental doses and time points for our experiment. This greatly reduces the number of animals used by minimising the number of experimental groups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Since all protocols and procedures used in this study cause no more than moderate (usually only mild) and transient discomfort, mice will be used in multiple protocols where possible in order to reduce the total number of mice used.

In addition, we will reduce the number of animals used by performing pilot studies in order to establish single experimental doses and time points examined, and therefore minimising the number of experimental groups required.

We continue to collect and freeze the tissue from euthanised mice, for long term storage of the tissue we do not examine at the time. This maximises the potential use of the tissue of each mouse, thereby reducing the total number of mice required.

Further to this, we continue to aim to incorporate new in vitro techniques as they are established into our research in order to reduce the number of mice required to meet our experimental aims.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are interested in how biochemical diversity of clathrin generates differential function at the cellular, tissue, and organism levels, and how this relates to human disease (e.g. diabetes). Mice are ideal for our studies as their genetic background and tissue organisation is similar to humans. The majority of our mice will be used for histological and biochemical analysis of cells and tissues, where mice are anaesthetised and killed and, as such, do not experience further pain or distress. Some mice may be used for procedures that cause no more than mild/moderate and transient distress, such as a single dose injection or glucose/insulin tolerance tests. These are the most appropriate systems for our questions, and we will only use mice when the experimental question at hand specifically requires them.

Why can't you use animals that are less sentient?

We have explored using Zebrafish (Danio rerio) and flies (Drosophila melanogaster) instead of mice, however flies only express a single CLC isoform, and so are not a

sufficient representation of human genetics to be useful for our investigation, and zebrafish do not sufficiently mimic human tissue development for our requirements. Mouse and human biology are more similar, and thus will be more informative as to the functions of clathrin in human tissue development and disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will always aim to minimise pain, suffering, distress, and lasting harm in the animals we use. We only propose experiments entailing mild/moderate distress. We will use analgesia and anaesthesia where possible, and have pre-determined humane end-points in place for all of our experiments. We will monitor our mice consistently and carefully, noting unexpected traits of GA mice, and stop procedures immediately if those end-points are reached. In particular, we will monitor female CLCa KO mice over the age of 4 months carefully for the appearance of a swollen abdomen to minimise the harm caused to these animals. In addition, we will perform health assessments regularly and before each experiment. This is important both to reduce suffering in our mice and to ensure scientific best practice for the reliability of our results. When handling mice, we will practice non-aversive mouse handling techniques to reduce the stress of mice, and we will only use each needle once when performing injections.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will practice the general guidelines and the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines published by NC3Rs (https://www.nc3rs.org.uk/3rs-resources and https://arriveguidelines.org). We will also use systematic reviews, such as SyRF (Systematic Review Facility), to ensure we are using the most appropriate methods to minimise suffering, as well as using the fewest possible number of mice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will utilise the NC3R’s (National Centre for the Replacement, Refinement and Reduction of Animal in Research) website for up-to-date information in the best practices in refining and reducing animal models. We will continue to attend training courses for animal use and we will be informed and trained in up-to-date techniques by the NTCO, NVS and NACWO.

183. Breeding and maintenance of genetically altered mice

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Breeding, Maintenance, Mice, Genetically altered

Animal types	Life stages
Mice	embryo, neonate, juvenile, pregnant, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To produce, maintain, and provide genetically altered mice for use under other project licences, or direct supply of tissue/organs for ex vivo use.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Notwithstanding the fact that human and mouse genomes have been fully sequenced and studied in detail in recent decades, the function of many genes, and their involvement in health and disease, is still unknown. Using a range of sophisticated technologies, the DNA

of mice can be safely manipulated to allow for experiments that elucidate the role that candidate genes play in a range of biological processes. In turn, these insights can lead to treatments that can prevent or treat disease and optimise the health of both animals and humans.

This licence application (and previous versions of the licence) is intended to provide an efficient service for breeding genetically altered mice and transferring them to researchers for further study, either as whole animals for use on other project licences, or tissues for use in ex vivo studies. The importance of each mouse colony and the benefits of each project will be described during a formal request process, submitted and reviewed by the Animal Welfare & Ethical Review Board (AWERB), described elsewhere in this application. In recent years, successful applications have been received to launch or continue projects in the following research areas: lung function & disease, chronic pain, cancer, neurodegenerative diseases & cognition, and muscular disorders.

What outputs do you think you will see at the end of this project?

The primary output from this licence will be the supply of genetically altered animals to research groups within, or affiliated to, the University. Use of these animals on other in vivo and ex vivo projects will result in data that will be shared within the scientific community at conferences, symposia, and in publications (these will be summarised at the end of the project).

Who or what will benefit from these outputs, and how?

As mentioned in the 'Aims' section ('Why is it important to undertake this work?'), despite human and mouse genomes being fully sequenced, the function of many genes and their involvement in health and disease is still unknown. This project will benefit people and animals by revealing the genetic contribution to a range of biological processes that are involved in health and disease. Where genes play a role in disease processes, this may provide better diagnosis and/or earlier and better treatment of a disease. Specific benefits will be described in those projects to which animals and tissues will be supplied.

A list of academic outputs from the last five years are provided elsewhere in the application. A brief outline of research areas and how animals have contributed is provided below.

Lung function & disease: the involvement of particular genes in biological mechanisms that underly chronic obstructive pulmonary disease (COPD); the protective effect some genes have over developing pulmonary diseases associated with old age, such as fibrosis.

Chronic pain: vascular and inflammatory contributions to pain disorders, especially those caused by diabetes and arthritis.

Cancer: discovery of novel mechanisms by which cancer cells display resistance or tendency towards metastases; further identification of upregulation of genes in different

types of cancer; how the effectiveness of chemotherapy may be improved in some types of cancer by altering gene expression in tissues that surround the tumour.

Neurodegeneration: characterising behavioural abnormalities in animal models of neurodegeneration; investigating inflammatory mechanisms underlying neurodegenerative diseases and genes that may have protective effects; identifying imaging markers that track and predict disease progression.

Muscular disorders: identification of a therapeutic target to treat muscular disorders.

The benefits of concentrating colony management under a single, central licence are described fully elsewhere but, briefly, this approach allows our technical team to carefully manage every colony to produce high quality animals in numbers that closely match demand. This means the research carried out subsequently will be more likely to show reproducible, useful results and animal numbers are kept low. Centralised management also more easily permits excess animals to be identified and shared to the scientific community, ensuring as many animals as possible contribute to the advancement of knowledge.

How will you look to maximise the outputs of this work?

In accordance with the Home Office's 'Efficient Breeding of Genetically Altered Animals Assessment Framework' - and where confidentiality agreements allow - we will advertise colony details to all research groups to allow for collaboration and cost-sharing. This also helps to minimise wastage.

Species and numbers of animals expected to be used

- Mice: 37500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are biologically very similar to humans and can be genetically manipulated to mimic many pathological conditions, which is not the case for non-protected alternatives such as fruit flies. As this is a breeding licence, all life stages < 15 months may be used (i.e. all stages except for aged animals).

Typically, what will be done to an animal used in your project?

Mice only enter our breeding facility upon satisfactory completion of our internal AWERB review process and verification that mice are of a high health status (described in the Action Plan, 'How do you assure the quality of the products?'). Mice will be initially bred

according to the strategy finalised during discussions between technical staff and the research group in advance of animals arriving. Most animals will not experience any other procedures whilst on this licence; animals will be transferred to other licences or humanely killed, some via a non-schedule 1 technique such as perfusion. Most animals bred will be identified by taking an ear notch and the tissue used for genotyping.

What are the expected impacts and/or adverse effects for the animals during your project?

No mice are expected to have a harmful phenotype. If this is anticipated for new colonies, an amendment to the licence will be submitted.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals to be bred under this licence will expect to be classified as 'sub-threshold'. Animals reported as having experienced 'mild' severity are likely to have undergone a second tissue sample (solely for genotyping) or display a distinct but non-harmful phenotype. Based on previous experience and knowledge of the strains used in research at this establishment, more than half of all animals to be bred under this licence would be expected to have a severity classification of 'sub- threshold'.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This is a service licence for the breeding and maintenance of genetically altered mice. The scientific aim(s) of individual breeding programmes are described in formal breeding requests that are submitted to AWERB, and only after satisfactory review (described elsewhere) would a programme commence. Observations based on live animals are necessary because understanding the overall effects of a modified gene requires the interaction of multiple physiologically-intact organ systems.

Which non-animal alternatives did you consider for use in this project?

Researchers requesting that mice be bred under this licence must describe the non-animals steps that have preceded the in vivo stage. AWERB will determine that animal use is justified by confirming that, as far as is practical, all non-animal steps have been completed. For instance, and where relevant, studying the impact of genetic alterations in vitro (in cells) before progressing to genetic alteration in animals. Furthermore, researchers must explicitly explain to AWERB why non-animal methods are unsuitable.

Why were they not suitable?

Reasons why non-animal alternatives are not suitable will be assessed on a case-by-case basis during AWERB review; broad justification of the use of animals under this licence is provided above. Where animals are being supplied for use in other projects, reasons why non-animal alternatives are not suitable must correspond with reasons provided in the relevant project licence and will be confirmed during AWERB review.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on the annual numbers of animals bred under previous versions of this licence. A turnover of colonies comparable to previous years is anticipated but numbers required to achieve the scientific aims of each individual colony varies. Robust colony management practices are employed to maintain efficient breeding programmes (described elsewhere) and these are reviewed and clarified with researchers as each new line is introduced.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During a research group's application to breed and maintain mice under this licence, the requester is expected to describe the experimental design and this is interrogated during the AWERB review (see below). AWERB and the PPL holder expect to see good practice guidelines being followed such as: minimising background variability in the data; high variability can obscure results which may require additional animals be used to reveal differences between experimental groups (there are several ways to do this such as eliminating unconscious bias by blinding researchers to which experimental group an animal belongs) a description of how the required number of animals has been determined, including justification of key design parameters such as 'effect size' (a parameter that indicates how large a difference between experimental groups a researcher considers meaningful) where possible and appropriate, incorporating the sex of mice into

the experimental design; this ensures more mice from a litter can be used, provides additional data regarding potential sex differences, and can often be performed - with careful choice of experimental design - without an overall increase in animal numbers

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animals are maintained at a high health status by the use of appropriate biological containment, typically the use of individually ventilated cages (IVCs) within a centralised barrier facility. This will reduce the microbiological burden on the animals and lead to a reduced disease incidence and reduced variability in experimental results.

In accordance with the Home Office's 'Efficient Breeding of Genetically Altered Animals Assessment Framework', we will hold regular reviews of colonies in production. This is to ensure that breeding strategies are optimised to achieve the delicate balance of generating the correct genotype and number of animals each research group require, minimising unnecessary breeding, and maintaining sufficient stock to not endanger the survival of a colony. Where research objectives have been met and no short/medium term demand is anticipated, colonies will be either archived or production stopped (typically within 12 months).

The above Home Office Framework dovetails with best practice recommended by the NC3Rs' expert working group on breeding and colony management, which we will also observe where appropriate. These provide practical guidance on elements of the framework that can help reduce numbers of animals used, such as:recognising reproductive life cycles to optimise breeding efficiency and health of litters
recording breeding data to ensure relevant information is captured that can help identify changes in breeding performance and expedite important colony management decisions
refreshing a colony to avoid 'genetic drift', a process that results in colony 'drifting' away from the original genetic identity that can reduce the reproducibility of studies

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will produce, maintain, and provide mice for use in other projects that have successfully completed the AWERB review process (described elsewhere). These mice

constitute animal models of a range of different diseases or disease processes; in recent years, these have included models of lung disease, chronic pain, cancer, neurodegenerative diseases, and muscular disorders. Animals are not expected to exhibit any harmful phenotype and procedural steps are not expected to cause any adverse effect for the animals that is more than mild and transient.

Why can’t you use animals that are less sentient?

As mentioned in the 'Harms' section, mice are biologically very similar to humans and can be genetically manipulated to mimic many pathological conditions, which is not the case for non-protected alternatives such as fruit flies. Nevertheless, as this is a service licence, the breeding request form will ask that requesters explain why their particular area of research cannot utilise non-protected alternatives or less sentient protected animals such as zebrafish. Mice will only be bred if appropriate justification is provided and the request has successfully completed the AWERB review process.

Depending on the genetic alteration and area of research, not all mice may be required to develop into adulthood but it is anticipated that the vast majority will. The only part of the project for which terminal anaesthesia may be appropriate is for non-schedule 1 forms of humane killing, for which authority is sought in the relevant section.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mouse passports are required during the AWERB review process so that the requirements of every new colony can be fully understood and, if necessary, husbandry practices adapted so that we can optimise their care and minimise harms. Upon receipt of a new colony or additional mice for breeding, a thorough welfare assessment is always performed.

Animals are not expected to exhibit any harmful phenotype and procedural steps are not expected to cause any adverse effect for the animals that is more than mild and transient. All technical staff undergo thorough training to ensure they are proficient in daily husbandry duties and adept at identifying any potential welfare concerns. Carefully constructed Standard Operating Procedures (SOPs) and, for practical assessment, Directly-Observed Practical Skills (DOPS) sheets are used within our Unit for these purposes.

We also adhere to best practice guidelines (listed below) and group house colonies as standard, utilise non-aversive handling (which the PPL holder has promoted at national events), and ensure environmental enrichment is present in all cages. Attendance at training events and networks (mentioned above) ensures that staff are made aware of any suitable refinements for the breeding and maintenance of genetically altered mice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The technical team and PPL holder periodically review working practices against the following guidelines:

'Efficient Breeding of Genetically Altered Animals Assessment Framework' (Home Office)

Materials produced by the NC3Rs' 'Expert Working Group for mouse breeding and colony management' and disseminated via the Breeding and colony management hub (NC3Rs)

Welfare assessment recommendations from 'Assessing the welfare of genetically altered mice' (Wells et al. 2006, Lab Animals)

Our University also publicly supports and endorses the ARRIVE guidelines and researchers requesting use of this licence must confirm they will be used and are directed towards appropriate online guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The applicant is the co-organiser of the Regional NC3Rs Symposium and attends other similar regional events to remain up-to-date with advances in the 3Rs. The 'Experience' section lists formal training events the applicant has previously attended and delivered. The technical team also regularly attend training events (supported or delivered by, for example, the NC3Rs, IAT, RSPCA, and LASA) to ensure knowledge is up-to-date and broaden their networks to allow the sharing of best practice. The University also benefits from an NC3Rs Regional Programme Manager to further embed the establishment within wider 3Rs networks.

184. Glymphatic system in the ageing brain

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain, cerebrospinal fluid, glymphatics, ageing

Animal types	Life stages
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to characterise the inflammatory and fibrotic changes in the glymphatics system that occur with ageing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The cerebrospinal fluid (CSF) dynamics system is important for maintaining brain homeostasis. Part of this is the glymphatics system, which ensures efficient fluid clearance from the brain. Impairments in this system have been observed with ageing and have been

associated with age-related diseases such as Alzheimer's disease. Changes have also been observed after acquired brain damage following traumatic brain injury and stroke (ischaemic and haemorrhagic). However we do not fully understand what changes in the brain contribute to alterations in the glymphatics system.

Advancing our knowledge of age-related changes that occur in the glymphatics system could identify a therapeutic target for treating age-related neurological disorders or limiting the damage of acquired injury in older patients.

What outputs do you think you will see at the end of this project?

The main output from this project will be improved fundamental understanding of the age-related changes that contribute to impaired glymphatics and the importance of inflammatory and fibrotic mechanisms.

These outputs will be published in high impact peer-review publications and the data will be used for future grant applications to progress glymphatic research.

Who or what will benefit from these outputs, and how?

In the short term (<5 years) the main beneficiaries of this research would be the academic community. This project will impact researchers interested in inflammation, CSF dynamics, glymphatics, ageing and neurological disorders (hydrocephalus, dementia and stroke).

In the medium term (5-10 years), our outputs will provide fundamental discovery science regarding how the glymphatics system is affected by inflammation and fibrosis that occurs during natural ageing. This will provide the necessary background information to bridge between basic science and identification of potential therapies.

In the long term (>10 years) this research has the potential to identify inflammatory and fibrotic mechanisms that can be targeted therapeutically to improve the outcome for patients with cognitive decline due to ageing, neurodegenerative diseases and acquired brain damage. Therefore, patients and clinicians could benefit from this fundamental research. As many of these disorders are associated with significant disability it requires substantial support from the NHS (and other healthcare providers)

and their families or carers. Therefore, new treatments could improve the outcome of these patients have a positive financial impact on the economy by reducing healthcare costs and allowing family members who are carers to return to work.

How will you look to maximise the outputs of this work?

The results from this study will be important for advancing our knowledge around the ageing, CSF dynamics and the glymphatics system. The results will be disseminated in peer review publications and by social media, whether the results are positive or negative. Publication of negative results are just as important to prevent other researchers from investigating the same thing.

Species and numbers of animals expected to be used

- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Previous glymphatics research has involved rats and mice, and both have been shown to be suitable for assessing glymphatics function using tracers. Rats are larger and have easier access to the glymphatic system for tracer injection and hence fewer adverse events. In addition, there are subtle differences in CSF flow dynamics due to the effect of the larger perivascular spaces in rats compared to mice, which offer less hydraulic resistance to CSF flow. Performing our experiments in rats is therefore more translational and our familiarity in rat models is essential to making timely progress. Aged rats start to show cognitive dysfunction and alterations in the CSF dynamics system after 18 months which is why we have chosen the age range of 18-20 months for our aged animals.

We will also be using young (2-3 month old) rats as a comparison for the age-related changes to CSF dynamics and the glymphatic system.

Typically, what will be done to an animal used in your project?

Some animals will be aged to 18-20 months. All animals will undergo a procedure which is performed under non-recovery anaesthesia. The animals will receive a tracer injection into the cisterna magna, be kept under terminal anaesthesia for up to 1 hour and humanely killed at different time-points during this time, via a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

There may be some adverse effects in the ageing cohort such as behavioural changes, weight loss, or the development of tumours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around half of the animals will undergo a procedure conducted under terminal anaesthesia and therefore will experience non-recovery severity. The rest of the animals will be aged and so will experience mild severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst some elements of CSF dynamics and the glymphatic system can be modelled in cell culture, the complex, clinical picture and interaction of the whole-body systems, including in particular, the immune and nervous systems cannot all be currently modelled in cell-culture or computer-based models. The use of live animals is therefore unavoidable and essential for discovery science in a situation relevant to the human condition. Only mammals have a sufficiently developed immune-system to readily compare to humans, and rodents are the animals of lowest neurophysiological-sensitivity required to achieve our scientific aims. It is not ethical to conduct experiments on humans, especially where those experiments require the removal of parts of the immune or nervous system for ex-vivo investigations.

Zebrafish or other lower sentient animals cannot be used since these species spontaneously regenerate their nervous system and are therefore not representative of the human conditions of disease that aberrant CSF dynamics and glymphatic system cause. Therefore, there is no feasible alternative that can entirely replace the use of a living animal that would allow the objectives to be met. However, we will use in vitro and ex vivo work to inform our animal studies.

Which non-animal alternatives did you consider for use in this project?

There are currently no alternatives to animal work for CSF dynamics and the glymphatic system.

No cell culture-based models exist that encompass all of the aspects of CSF/glymphatics. However, individual aspects will be modelled in vitro and ex vivo. For example, we regularly use in vitro approaches using partial replacement of animals (primary animal cells) or non-animal alternatives (primary human cells) can be used to assess the effects of inflammation and fibrosis on the cells of the glymphatics system.

Why were they not suitable?

The fundamental reason why the use of animals is required is to understand these complex processes that occur in whole animal, which at present no in vitro methods can model the complexities of the systems involved in these systems. It is difficult to use primary cells to culture all of the different types of cells since they require different growth mediums and factors for survival. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment.

Technologies are being developed to address this gap, including the development of 3D cultures and organoids. However, none of these model systems are yet able to replicate the integration and interplay between the numerous cell types that constitute CSF and glymphatic systems.

Reduction

How have you estimated the numbers of animals you will use?

The experiments have quantitative endpoints and an estimated number of 8 animals per group has been established as the minimum required to provide statistically significant results. This has been determined on the basis of previous research into ageing and the glymphatics system.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3R's Experimental Design Assistant to help us to design the experiments to ensure that the experiment uses the minimum number of animals but that it is sufficiently powered to achieve our scientific aims.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will seek to refine protocols, such as the development of other quantitative measures for CSF dynamics/glymphatics such as associated biomarkers that can predict potential age-related changes, which will facilitate “reduction”. Experiments will be planned so that they can be published in accordance with the ARRIVE 2.0 guidelines.

At the end of the experiment, we will harvest the maximal possible number of tissues. Tissues not immediately analysed will be archived and will be made available to other researchers working on similar questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Due to the nature of the scientific question, the only appropriate model is young and aged rats. The method of assessing glymphatic function involves injecting a tracer into the cisterna magna and is the most commonly used method. The procedure is conducted under non-recovery anaesthesia to minimise the pain and suffering of the animals.

Even though, all experiments will be performed under terminal anaesthesia, we also have over 20 years' experience of similar models and injections described in this application and are able to identify adverse signs as early as possible.

For aged rats, we have selected 20 month old rats for our experiments since this is the earliest timepoint where changes in the glymphatic system are measurable rather than a greater lifespan where increased age-associated adverse effects are more evident.

Why can't you use animals that are less sentient?

We cannot use less sentient species (e.g. zebrafish) for this work, because unlike mammals, they are able to regenerate their brain tissues spontaneously and so changes observed as a result of dysregulated CSF and lymphatics are not seen. Rats are typically used for our experiments since they share similar pathophysiology to humans after injury to the CNS and share similar dynamics of CSF flow and glymphatic systems.

In addition, we are using animals that have been terminally anaesthetised and hence potentially minimising adverse effects.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals in the aged cohort will be closely monitored, which increases in frequency when the animals get older (>18 months). While the animals are ageing they will have access to additional enrichment toys and access to a play pen.
This protocol involves the minimum number of interventions possible for assessing glymphatic function. In addition, all animals are terminally anaesthetised and hence unnecessary harm is minimised.
We will review each experiment on completion to see what lessons can be learned from the study in terms of endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment.

Experiments will be conducted in accordance with the guidelines published by the Laboratory Animal Science Association (LASA).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE 2.0 guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will review each experiment on completion to determine any refinements that can be applied to future experiments.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

We will also stay up to date with guidance published by LASA on the most refined experimental methods. We are already signed up to receive the NC3Rs newsletter and will attend local events such as conferences and follow advice in webinars hosted by NC3Rs.

185. Immune responses in tumour development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, immune cells, immunotherapy, tumour, myeloid cells

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to examine how modulation of immune cell activity can enhance tumour suppression. The proposed research will focus on the assessment of interactions between tumour cells and immune cells that orchestrate anti-tumour immunity to better understand the immune mechanisms that shape tumour growth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Certain types of immune cells are able to recognise, kill and remove ‘foreign’ material that grows within a host. However, tumour cells have developed ways to evade the immune system, exploit immune cell functions and compromise anti-tumour responses. Therefore, the development of strategies that aim to educate the immune system for enhanced tumour killing is needed.

Tumour immunotherapy represents a promising therapeutic approach for several types of cancer. However, some cancer patients receiving immunotherapy show limited or no response. This work will investigate how reprogramming of immune cells can increase the efficacy of tumour immunotherapy, thus addressing a timely and unresolved scientific question.

What outputs do you think you will see at the end of this project?

Successful completion of this project will result in the generation of data that will provide a better understanding of immune cell-mediated mechanisms of tumour suppression. These findings will be presented to the scientific community via peer-reviewed publications and at national and international meetings.

Who or what will benefit from these outputs, and how?

Short-term (0-5 year): Identification of immune modulatory agents and mechanisms that prime immune cells to enhance anti-tumour activity in mice and in humanised mice (mice that allow human immune cell production).

Medium/Long-term (5+ years): Findings of this research may benefit cancer patients and clinicians using immunotherapies, especially in oncology

How will you look to maximise the outputs of this work?

Collaboration with experts in regulation of immune cell activity and tumour development in both mouse and human settings will enhance the outputs of this project.

Additionally, any negative data produced in this project will be published in order to share knowledge and avoid repetition of the experiments by other research groups.

Species and numbers of animals expected to be used

- Mice: 1700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Laboratory mice have been extensively studied in the field of tumour immunology and represent the best animal model for this type of study. As this project focuses on the role of immune cells on the modulation of tumour suppression, adult mice, that have a developed immune system, are required. Humanised mice will also be used in order to improve the translational impact of the research.

Typically, what will be done to an animal used in your project?

Administration of substances (up to 2 times) that will modulate immune cell function followed by isolation of cells to examine them in vitro. Cell isolation will take place 1-30 days after administration of substances.

Some animals will be given identified substances plus/minus current immunotherapy drugs followed by tumour cells, and tumour growth (up to 10-12 weeks) will be monitored (via imaging) to examine the effect of the substances on tumour rejection.

Finally, some animals will be irradiated and will be transplanted with cells before their injection with substances and / or tumour cells.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will develop tumours.

In some cases, mice will demonstrate mild or moderate but temporary discomfort. Examples include mild and short-term discomfort due to injections or restrain, and short-term mild or moderate symptoms related to tumour cell injection (e.g. hunched posture, and slightly reduced level of activity). In addition, tumour growth may lead to weight loss of the animals.

Hypothermia may occur during in vivo imaging. Therefore, temperature monitoring and controlled heating during imaging will be used.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

30% of animals will only receive injection with substances, and will experience mild severity.

70% of animals will receive injection with substances and tumour cells, and may experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project focuses on the role of immune modulators in shaping anti-tumour activity. Production of immune cells in the bone marrow is a major determinant in the induction of anti-tumour activity.

Therefore, the use of animals is necessary for the characterisation of immune cells in bone marrow, periphery (spleen) and at the tumour site as a result of immune modulator administration.

Which non-animal alternatives did you consider for use in this project?

Search at the Animal Welfare Information Centre (listed in NC3Rs website) has been used to provide alternatives.

In addition, in vitro research will include the stimulation of immune cells with immune modulators in the presence or absence of tumour cells using cell culture. This alternative is expected to be used to inform

in vivo work.

Why were they not suitable?

The use of in vitro cell culture does not allow simultaneous assessment of the interactions between different tissues (bone marrow, spleen, tumour) that take place in a whole animal model and therefore has limited physiological relevance.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were estimated based on previous experience with the types of experiments proposed in this project and published datasets.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Quantitative analysis of findings obtained from previous research projects and information available through collaborators and from the literature were used.

Freezing of tissues of interest creates tissue bank to test hypotheses without need for new animals. In addition, mathematical and computational tools have been applied.

Experimental design will be supported with NC3Rs Experimental Design Assistant

(https://www.nc3rs.org.uk/experimental-design-assistant-eda) and results will be published according to

ARRIVE guidelines.

Statistical advice sought from Hull York Medical School statistical consultancy service (http://www.hyms.ac.uk/research/resources-for-researchers/statistical-consultancy).

Planning of the in vivo research will be based on the PREPARE guidelines (https://norecopa.no/prepare) will be used to plan in vivo research.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When required, pilot experiments will be performed to generate data to calculate the number of mice required to obtain meaningful, reliable results. Small pilot studies will also be used to validate the effect of novel compounds or techniques before performing larger experiments.

Best practice for pilot studies will be used ((https://www.nc3rs.org.uk/conducting-pilot-study)).

In addition, the analysis of as many organs as possible from each mouse and sharing tissue with in- house collaborators will reduce the number of mice required for pilot studies, and maximise the output of data per mouse.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use analysis of tumour growth by in vivo imaging. The model used will be adult mice. In all cases, we will use the most refined ways to induce modulation of the immune system and tumour challenge models required to arrive at meaningful results. These ways of immune modulation are in general very well tolerated by mice with only mild to moderate transient discomfort. In all cases, strict monitoring and humane end points will ensure maximum reduction of pain, suffering, distress, or lasting harm to the animals.

Why can't you use animals that are less sentient?

As this project focuses on the role of immune cells on the shaping of anti-tumour activity, it is critical that adult subjects are used in the experiments, so that immune cell production and differentiation is developed in both bone marrow and in the periphery (spleen).

Laboratory mice have been widely used for the study of tumour immunology. Of note, research studies applying injection of mouse tumour cell lines in mice have contributed significantly to the development of immunotherapeutic approaches. In addition, high availability of genetically-engineered animals and reagents further supports the utilisation of mice in comparison to other laboratory rodents.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The welfare of animals will be frequently monitored, and a detailed welfare assessment scoring system will be applied. The grimace scale will also be used to monitor quality of animals' life. Whenever applicable, use of anaesthesia will minimize distress. In addition, enriched housing, tube handling and single-use needles will be used.

In vivo imaging may be used to identify end points allowing the S1K of animals before they show clinical signs of tumour progression.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

PREPARE guidelines for experimental planning:

Smith, AJ, Clutton, RE, Lilley, E, Hansen KEAa, Brattelid, T. (2018): PREPARE: Guidelines for planning animal research and testing. Laboratory Animals, 52(2): 135-141.

https://norecopa.no/PREPARE

NC3Rs refinement info: https://nc3rs.org.uk/3rs-advice-project-licence-applicants-refinement

The guidelines for the welfare and use of animals in cancer research published by Workman et al will

be considered (https://www.nature.com/articles/6605642).

ARRIVE guidelines will ensure experiments are performed in the most refined way. Additionally, we will follow the updates by the NC3Rs (https://www.nc3rs.org.uk).

The Laboratory Animal and Science Association (LASA) regarding the routes of administration of immunomodulators and transplantation of cells (https://www.lasa.co.uk/PDF/LASA- NC3RsDoseLevelSelection.pdf), the BVAAW / FRAME / RSPCA / UFAW Joint Working Group on

refinement (Laboratory Animals 2001. 35:1-41) and the IQ 3Rs Leadership Group (https://iqconsortium.org/images/LG-3Rs/IQ-

CRO_Recommended_Dose_Volumes_for_Common_Laboratory_Animals_June_2016_%282%29.pdf)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The host institute and establishment organise mandatory and frequent training as well as expert users' forums with the latest advances in the 3Rs.

Additionally, we will follow the updates by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and by the Laboratory Animal and Science Association (LASA) newsletters.

186. Central nervous system control of physiological functions

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

neuroscience, cardiovascular, stem cells, brain, spinal cord

Animal types	Life stages
Mice	neonate, juvenile, adult, embryo, pregnant, aged
Rats	juvenile, adult, aged, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to increase understanding of how the central nervous system is involved in the control of body functions, such as those controlling heart rate and blood pressure. In addition, it aims to understand how to new cells made in the adult central nervous system may interact with these circuits.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Modulating the activity of the nervous system by direct electrical or chemical intervention is increasingly under investigation for treatments of disorders such as hypertension, heart

failure and multiple sclerosis. However, knowledge of the neuronal circuitry underlying such modulation is far from complete and furthering such understanding is likely to contribute to development of more targeted and better treatments. Recent technological advances have improved the ability to gain this understanding and such a project is therefore timely.

What outputs do you think you will see at the end of this project?

The most likely outputs will be new information, which may lead to improved or new treatment for diseases that are influenced by nerve cell connections in in the spinal cord and brain, for example hypertension, heart failure, multiple sclerosis, spinal cord injury.

Who or what will benefit from these outputs, and how?

In the short term the most likely benefits will be to scientific researchers, who will use the outputs to build upon and further increase knowledge.

In the medium to longer term these advances in fundamental understanding may provide potential translational benefits. For example, understanding of central control of autonomic function gained from previous animal work has encouraged exploration of modulating the activity of the nervous system in humans through non-invasive electrical stimulation with the potential for treatment of diseases such as heart failure, hypertension and arthritis and indeed benefit some signs of aging. This fundamental work will examine the mechanisms underpinning such functions e.g. by identifying the anatomical and functional properties of constituent cells, how the cells are connected to each other and the functions of the networks. Understanding these will contribute to ongoing studies in humans.

How will you look to maximise the outputs of this work?

Collaboration is a mainstay in the laboratory - most of our publications have collaborative authors from other labs and indeed, from abroad. This increases the potential for the work to be seen by a larger audience and increase citations, disseminating knowledge effectively. Such collaboration will at least remain at the same level or indeed will likely increase.

We will also aim to present the findings at national and international conferences, where audiences often view outside of their close research area.

When appropriate we also produce press releases, which have led to widespread international media coverage and brought our research to the attention of the public. We will also continue with our public engagement where presentations based on our work have been made to events such as the national Pint of Science and events held by our University which are run annually, with around 1200 participants per day from the local community.

Species and numbers of animals expected to be used

- Mice: 8600
- Rats: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use predominantly juvenile and adult mice and on some occasions, rats. Many of the fundamental processes that are controlled by neuronal circuits that we aim to understand are comparable to those in humans e.g. the baroreceptor reflex that controls blood pressure. In addition, increasing availability of transgenic mouse lines which enable specific cells to be identified and/or manipulated increase precision and specificity of studies in a manner that is not available in other species. To allow for development of circuitry we will mostly use adult animals, but in some cases they will require intervention at a younger age (from neonate) to promote expression of genes in specific cells.

Typically, what will be done to an animal used in your project?

In a typical experiment an animal will be terminally anaesthetised and either perfused with a fixative for anatomical studies, or will have tissue removed and sliced or en bloc for recording activity of cells ex vivo.

In some cases there will be a prior to inject substances will allow identification of specific cells in the nervous system.. This may require surgical intervention under anaesthesia, Animals will recover for up to 6 months, but more usually less than 4 weeks. Following this animals will be terminally anaesthetised and prepared as above.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals used only for anatomical studies or tissue slices do not recover from anaesthesia.

Post-surgical animals routinely receive suitable analgesia. Weight loss which is typically less than 10% is often seen on the first day following surgery and weight gain is within two days post surgery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Preparing animals for anatomical studies or tissue slices is non-recovery. This is likely to account for 40% of the animals used in this project.

Animals which have had injections into the CNS may exhibit moderate severity (hunched posture, piloerection, transient anorexia, up to 10% weight loss) outcomes for a day following procedures. This is likely to account for 30% of the animals used.

Animals which have had intraperitoneal injections of substances typically exhibit mild severity (transient underactivity, piloerection), likely to account for approximately 30% of the project

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The work will study how the CNS controls body functions, and at times how manipulating outflows of these circuits can influence progression of disease. These will necessarily involve placing tracers onto peripheral nerves to identify the cells or their origin, determine the effects of stimulating particular nerves or manipulate the signalling in the CNS to influence stem cells. Therefore, to provide physiological relevance whole animals are required. However, in vitro work will be undertaken where possible e.g. use of acutely prepared spinal cord slices for electrophysiology. In addition, use of cultured spinal cord slices will facilitate some experiments in vitro.. This allows for greater numbers of tests to be performed in vitro, reducing the number required in vivo.

Which non-animal alternatives did you consider for use in this project?

A possible longer term alternative is to use organoids derived from induced pluripotent stem cells or via cell reprogramming.

Why were they not suitable?

It is not yet possible to derive organoids that recapitulate the circuitry as they do not have the appropriate physiological inputs, such as fluctuations in blood pressure, changes in respiration etc. In addition, there is not enough information on circuitry to know if such organoids are faithful to the intact brainstem or spinal cord. Cell lines and cell cultures also do not have the necessary connections and appropriate circuitry.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated with our experience of previous projects and accounting for breeding of transgenic animal lines. They allow for appropriate blinding of researchers as well as the use of either sex. We will conduct our experiments to be able to publish to the Arrive guidelines: https://www.nc3rs.org.uk/arrive- guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Most of our experiments do not have prior knowledge of effect size. When this can be estimated from our pilot studies we have used online resources such as the NC3Rs Experimental Design Assistant (https://eda.nc3rs.org.uk/experimental-design) to help calculate the number of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We aim to breed as efficiently as possible. For example, cross breeding from homozygotes is preferred as this ensures that offspring carry the desired genes. Our institution has an online database that enable us to follow such breeding carefully.

If possible we conduct pilot studies on tissue slices, since many slices can be obtained from one animal and this enables pilot testing where several animals may otherwise be required.

The number of animals used will be optimised in several ways:

Tissue from the same animal will be used for different objectives where possible. This reduces the total number of animals that would otherwise be required if a single animal was used for each objective.

We have also developed a method of storing tissue for long term which also reduces animal use - this tissue is also available to other labs.

In addition, each experiment is designed to maximise the amount of information gleaned since they often combine different approaches to verify this information.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and mice will be used since they contain cell types and assemblies of cells that are similar to those known in humans as far as can be told so far. Transgenic animals will be used when they make identifying and/or manipulating specific cell types possible with fluorescent markers, helping to minimise numbers used.

Suffering of animals will be minimised as the majority of the procedures performed will have a minor severity where the animal is killed by anaesthesia prior to organ removal. In some cases experiments will require recovery from anaesthesia following surgical procedures. Post-operative analgesia will be applied in these cases to limit suffering of the animals.

Why can't you use animals that are less sentient?

We cannot use more immature animals as we are studying the control of the autonomic nervous system and this is not properly developed until the adult stages.

Less sentient species (such as flies and worms) do not have the same autonomic nervous system control.

We will use terminally anaesthetised animals in many of our experiments, but some will require surgical intervention with recovery to allow expression of markers or functional controllers in sets of cells

beforehand or to mark the terminations of specific nerves. There is no current approach to do this without surgery.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Suffering of animals will be minimised as the majority of the procedures performed will have a minor severity where the animal is killed by anaesthesia prior to organ removal. In some cases experiments will require recovery from anaesthesia following surgical procedures. Post-operative analgesia will be applied in these cases to limit suffering of the animals. Examples of refinements that we have made include, peri--operative administration of warm saline to ensure that the animals remain hydrated, adding food mashed with water to the cages after surgery so that there is easy access for eating and maintaining hydration post-surgery, housing with other mice wherever possible (which is usually the case).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs have published best practice guidance: (Prescott MJ, Lidster K. Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Anim (NY). 2017 Mar 22;46(4):152-156. doi: 10.1038/laban.1217. PMID: 28328893) and this and subequent publications will be referred to. We attend webinars from Nc3R like "the best practice in experimental design": https://www.nc3rs.org.uk/events/webinar-best-practice-experimental-design.

In addition, the ARRIVE 2.0 guidelines (https://journals.plos.org/plosbiology/article?id=10.1371/journal.pbio.3000410) will be referred to assist with good design as well as reporting.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I, and my lab members, take part in CPD regularly. This includes courses run internally as well as reading appropriate literature including N3CR resources such as web sites and the newsletters we receive. In some conferences, there are posters and sessions dedicated to the 3Rs. We discuss our experiments with other researchers, NACWO and the vet, implementing appropriate changes as we go through projects.

187. Neuronal circuits regulating metabolic and cardiovascular health

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Obesity, Cardiovascular Disease, Metabolic Disease, Neuroscience, Stress

Animal types	Life stages
Mice	juvenile, adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Obesity, diabetes and cardiovascular disease are increasingly prevalent conditions in our society, often exacerbated by mood disorders, including stress and anxiety. This project aims to provide a precise understanding of the brain circuitry regulating and linking these processes with the ultimate goal of devising better treatments to treat and to prevent these diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Obesity, diabetes and cardiovascular disease are a major health burden for the individual suffering from it as well as a financial and social burden for our society as a whole. These diseases are interlinked, and it is becoming increasingly clear that our nervous system, particularly the autonomic nervous system, that is not under cognitive control, regulates the variables such as energy balance, blood glucose levels or blood pressure and heart rate which go wrong in these diseases.

The hormone GLP-1 is perhaps the single most promising therapeutic target for the treatment of these disorders with several GLP-1-based therapies already approved for the treatment of obesity and diabetes. Our work (and that of other research laboratories) over the past decade focussing on GLP-1 has demonstrated that the robust appetite-suppressive effects of GLP-1 are mediated by the brain and that GLP-1 produced by the gut and GLP-1 produced by the brain work independently to decrease food intake. This highlights an untapped potential for brain GLP-1 in the treatment of obesity, but the neural circuits underlying the effects of brain-produced GLP-1 on feeding are largely unknown. In addition, recent work by our group and others suggests that GLP-1 released within the brain may not simply suppress appetite but also drives responses to stress, including increased heart rate, stress hormone release, and anxiety-like behaviours. Further studies have highlighted that GLP-1 within the brain reduces the reward value of food (and also of substances of abuse) and furthermore reduced loss of neurons in neurodegenerative diseases such as Alzheimer's dementia has been ascribed to actions of GLP-1 on the brain. The neuronal circuitry underlying the regulation of these various responses to GLP-1 is currently largely unknown, but this knowledge is essential to tailor clinical treatment strategies, primarily for obesity, but potentially also for substance abuse and neuroprotection linked to stroke and neurodegenerative disease, and keep unwanted side effects at a minimum.

Research covered under this project will provide a detailed understanding of the neuronal circuitry and functionality underlying both the effects of systemically administered GLP-1 receptor agonists, and those triggering the release of native GLP-1 within the brain. This is expected to lead to the development of improved strategies for weight control, by refinement of current approaches for blanket activation of GLP-1 signalling pathways to those allowing targeted activation of functional subcircuits within the brain. This level of insight can only be achieved by utilising the latest developments in genetic manipulation available in animal models, selective viral gene transfer and imaging of neuronal activity in living brain tissue. Currently this is only possible in specific mouse strains which provide us with unique opportunities of gaining this level of functional insight into a mammalian brain.

What outputs do you think you will see at the end of this project?

This project is likely to increase understanding of how autonomic nervous system function in general, and GLP-1 in particular, affect food intake, bodyweight, blood sugar and cardiovascular control. All results will be published in scientific journals, and thus be publicly available. Depending on its results, this programme of work might influence policy on the use of GLP-1 analogues, such as liraglutide, as anti-diabetic and anti-obesity drug.

It will also generate data to establish the contribution of autonomic nervous system dysregulation to diabetes and obesity and thus open new treatment avenues.

Who or what will benefit from these outputs, and how?

The primary output from this project will be a stream of publications throughout the duration of this project. This will incrementally add more information to our knowledge of the neuronal circuits regulating energy balance. Thus, the earliest beneficiary will be the scientific community, as our studies will inform future studies of ourselves and other laboratories worldwide. The second level of impact is likely to be the potential impact on drug development projects by the pharmaceutical industry and on the way how clinicians think about the diseases and treatment strategies. The final long-term benefit for patients would be realised when/if our results lead to new/altered clinical treatment regimes.

How will you look to maximise the outputs of this work?

We are looking at maximising both quality and quantity of output as well as impact of this work. The former we achieve by ensuring we always use the most appropriate experimental strategies that provide clear, unequivocal results. This is achieved by keeping informed about the latest developments in the field and collaborating with the best international laboratories. We are able to do this, because our laboratory has an excellent international reputation in our field and consequently the top laboratories are happy to work with us. We also constantly disseminate our results to the scientific community via conference presentations, invited seminars and publications (both primary and review articles). Additionally, we talk directly to industry stakeholders and we have recently started a dialogue with a biotech company aiming at developing a novel small molecule GLP-1 receptor agonist with bespoke properties in terms of brain penetration.

Species and numbers of animals expected to be used

- Mice: A maximum number of 5500 mice will be bred and used under this licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This work involves evaluation of the functional interaction between various organ systems (e.g. brain, digestive tract, heart). Such complex interaction cannot be reproduced with cell cultures and thus has to be performed using live subjects. Since the organ systems should be as similar as possible to humans, these experiments have to be performed on mammals. Additionally, the functional manipulation of the specific cellpopulations inside the brain that are the subject of this project are only possible in transgenic animals.

Consequently, only a select few transgenic mouse strains are able to support this project and provide the precision in the manipulation required to succeed.

Finally, type 2 diabetes mellitus, obesity and cardiovascular disease are conditions that mainly afflict the adult (and aged) population. Consequently, wherever possible the experiments under this licence will be performed on adult (and sometimes aged) mice, and manipulation of the functionality will be performed at this developmental stage by employing viral gene transfer, rather than using transgenic mouse strains that e.g. lack specific genes from conception and thus can be prone to developmental compensation or exacerbation. In contrast, our transgenic strains only enable the viral manipulation in the adult animal, thus avoiding any potential effects during development.

Typically, what will be done to an animal used in your project?

This project uses transgenic mice which enable us to both visualise as well as manipulate the neuronal circuitry involved in mediating GLP-1 effects in the living organism. Thus a large proportion of the animals utilised will be needed as tissue donors for subsequent analysis of functionality and anatomical organisation of this circuitry in the isolated tissue. These animals will simply be euthanised under terminal anaesthesia. More complex experiments aim at understanding the consequences of manipulation of the neural circuits under investigation in the living animal. For those experiments transgenic mice will undergo stereotaxic injection of viral constructs into the brain followed by behavioural tests a couple of weeks later to assess the impact of interfering with specific brain circuitry on e.g. food intake, stress resistance, cardiovascular health, etc.

What are the expected impacts and/or adverse effects for the animals during your project?

The functional consequences of the viral manipulation of the neural circuitry under investigation are expected to be benign. Work under our previous licence has shown less adverse effects (such as nausea) than what is described by patients who take GLP-1 based drugs as anti-diabetes medication. Similarly, the transgenic mouse strains that we use do not show any adverse effect in themselves.

The main adverse effects that we expect are transient, and result from the surgery itself. Thus, the mice tend to suffer from post-operative pain for up to 24h after virus injection through the skull, and for up to 48h after injection into brainstem or spinal cord, because this involved some damage to muscle tissue in neck or back. Similar recovery times are seen after implantation of cannulae into the brain parenchyma or ventricles, or implantation of telemetry devices to monitor blood pressure and heart rate. After this time no difference in behaviour is observed with post-surgical mice compared to untreated littermates.

Additionally, when undergoing specific behavioural tests or measurement of food intake, the animals will experience stress in form of handling, injection, exposure to novel environments and novel food. Where diets are changes longer term to highly palatable or

high fat diet, this generates an obesogenic and consequently diabetogenic environment. Thus, they are monitored for any signs of overt diabetes or other adverse effects of excessive weight gain. All of these protocol steps are classified as mild.

Finally, a subset of mice will be exposed to acute or chronic stress in established rodent stress models. This is expected (and indeed intended) to elicit a level of distress for a period of time, usually limited to hours in the case of acute stress and a few weeks in the case of chronic stress. These types of stressful experiences are essential to understanding the neural circuits mediating harmful effects of stress. The mice are carefully monitored throughout these procedures.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of animals used under this project are experiencing 'mild' severity. This is the case because breeding of transgenic strains is per definition 'mild'. The only invasive procedure is ear notching for genotyping, and otherwise just handling of the mice for husbandry. The severity for those animals that are simply tissue donors or undergo procedures under terminal anaesthesia is 'subthreshold', as they only experience induction of anaesthesia, and for those animals undergoing recovery surgery it is 'moderate', because of surgical trauma and the healing process. None of the behavioural and other tests the animals are undergoing prior and or after surgery produce any significant or lasting discomfort that would require classification as 'moderate'.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work involves evaluation of the functional interaction between various organ systems (e.g. brain, digestive tract, heart). Such complex interaction cannot be reproduced with cell cultures and thus has to be performed using live subjects. Additionally, the precision of the manipulation of brain cells can currently only be achieved in transgenic mice.

Which non-animal alternatives did you consider for use in this project?

For the reasons outlined in the paragraph above, there are no non-animal alternatives applicable for this project. All work under this licence will be performed using the least

sentient preparation possible. This means that for those parts of the project that involve analysis of brain anatomy only, or functional responses that can be elicited directly on the neurons under investigation and are measurable as direct cellular responses, animals will only be used as tissue donors. Even for this part of the project the use of cell lines is not applicable, because results depend on the expression of the specific set of receptors by the specific set of neurons in the mature brain.

Why were they not suitable?

Neurons are not proliferating, thus there cannot be a cell line replicating the properties of these specific neurons, and primary cell culture would still require the use of donor animals, with the caveat that even primary cultures tend to change the expression of receptor proteins and have to be obtained from immature animals, which puts the phenotype of the actual cells investigated in such a preparation into question.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in this project over the duration of five years can only be a rough estimate and is designed to give a maximal number that will definitely not be exceeded. This is because the majority of experiments built upon each other, and thus it is extremely difficult to accurately calculate the exact number of animals needed. This is very different for each individual experiment, which are powered based on the magnitude of the effects observed previously with similar genetic models and experimental paradigms. Sex-balanced cohorts of 8 animals will typically allow us to resolve significant changes in food intake when manipulating the GLP-1 system.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

While our experiments will generate valuable data resulting from novel manipulations of neuronal populations, the majority of behavioural analyses used to determine the effects of these manipulations have been optimised and standardised in the lab over many years. They have therefore undergone considerable empirical refinement, and been confirmed as appropriately powered and designed with G*Power 3.1.9 and EDA. Two examples of protocol optimisations which reduce animal numbers are our approach to experimental controls when using new chemogenetic effectors, and our treatment of sex as a biological variable (SABV). When new chemogenetic effectors are used, behavioural control experiments will be conducted using 2x2 mixed model designs, whereby mice are

transduced with either the effector or a Cre-dependent fluorescent reporter control virus. The effect of the activating ligand (CNO) will then be quantified in both groups. A lack of difference between the virus groups in the control condition will confirm the effector has no constitutive effect. Observation that the effect in the active condition (CNO) is restricted to the group transduced with the effector will confirm that the effect is not driven by off-target actions of CNO. To balance experimental rigour with the need to reduce animal numbers and refine experimental designs, once the functional specificity of each new effector has been validated, subsequent experiments using the same approach will be conducted using 1x2 within-subjects designs in chemogenetic effector-expressing mice only. This will increase statistical power by minimising the influence of inter-animal variability, and substantially reduce the total number of animals required for the project. In our experiments to date, we rarely observe significant effects of sex on our dependent variables. All behavioural experiments are nevertheless designed to balance consideration of SABV with the need to reduce animal numbers. Therefore, sex-balanced experimental cohorts are used of sizes which are appropriately powered to detect effects which are present in both sexes, and sufficient to provide a reasonable indication when they are not. In the latter case, experiments are repeated in a second sex-balanced cohort, such that results can be appropriately pooled and analysed for sex effects, without the confound of batch effects.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Since all genotypes are useful and we use both males and females, we use virtually all mice produced through breeding. In addition, individual animals will be subjected to more than one test each and after the in vivo program their tissue will be used for further in vitro analysis, thus reducing the overall number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project requires the use of mammals, because the control of food intake and responses to stress by the brain are too different from man in other vertebrates, or invertebrates. Since these functions are fulfilled mainly by ‘lower’ parts of the brain rather than cerebral cortex, rodents are seen as adequate model systems. Mouse and rat can be bred and maintained in a laboratory setting without too much impact on the welfare of the

individual animal. In this case we have to use mice for our work, because the genetic modifications required for this project are only available in mice. Individual animals will receive viral gene transfer that will incorporate a ‘switch’ into their GLP-1 producing cells, cells upstream of these, GLP-1 responsive cells, or into their parasympathetic vagal neurons, that allows us to ‘switch on or off’ these cells at will. The effect of such manipulation on food intake, body weight, blood glucose control and blood pressure or heart rate will then be measured. These measurements will be performed as much as possible with implanted devices that transmit data remotely (telemetry) which reduces handling, and therefore stress, for the animals, leading to better data with smaller variations, and thus might also lead to a reduction of the number of animals needed.

Why can’t you use animals that are less sentient?

The GLP-1 system that is the main subject of our studies appear to be remarkably conserved throughout vertebrate species from fish to man. Thus, some of the anatomical and descriptive experiments could potentially be performed in other vertebrate species than mouse. However, this project relies on our ability to functionally manipulate those neurons producing GLP-1 or those neurons responding to GLP-1. Currently this is only possible using transgenic mice and not in either higher or lower vertebrates. Outside of vertebrates we would expect to find somewhat equivalent control circuits for food intake, stress, etc, but the applicability of the findings to humans would be a lot more questionable.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Due to the relatively large number of surgeries required to generate experimental cohorts, we consider optimisation of our protocols for surgical anaesthesia/analgesia and post-operative care of particular importance, and hence regularly review these in conjunction with the NACWO and/or NVS to ensure any updates to best practice are swiftly implemented. For example, we have recently refined our post- operative care protocol to provide a warmed home-cage recovery environment for mice for the first night after surgery, and post-operative analgesia in an edible formulation that ensures consistent doses without the need to perform injections. We have also refined our protocol for automated food intake monitoring by upgrading to the FED3 system, which allows pre-programmed timed feeding schedules to reduce the stress of manual food removal and return during fast/refeed protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experimental design and procedural practice will be informed by best practice guidance published from a variety of sources. In particular, we will utilise the comprehensive list of recommended resources curated by the UCL BSU Named Information Officers, including information from the Home Office, NC3Rs, Laboratory

Animal Science Association (LASA), and Federation of European Laboratory Animal Science Associations (FELASA).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Biological Services Unit (BSU) is very proactive in disseminating the latest advances and best practice guidance regarding the 3Rs to all users of their facilities. In addition to this excellent source of information, we keep ourselves regularly appraised of general and field-specific advances via social media (e.g. by following The National Centre for the 3 Rs twitter account and blog). Opportunities to implement new 3Rs advances will be taken as soon as possible, via formal and/or ad hoc online and in-person BSU training courses, and refinement of our specific methodologies.

188. Analysis and therapy of cerebellar disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cerebellum, ataxia, neurodegeneration, Purkinje cells, therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to better understand the disease-causing mechanisms underlying cerebellar disorders with a focus on cerebellar ataxia and to develop effective therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The cerebellar ataxias are a complex group of brain disorders. Patients suffering from ataxia have problems with their movement, balance and speech, and sometimes develop cognitive disabilities. These clinical symptoms strongly impair patients' quality of life, and

many ataxias lead to premature death. The many genes implicated in cerebellar ataxia together with the clinical complexity present a challenge in our understanding of the underlying disease-causing mechanisms and has hampered the development of effective therapeutics. As a result, to date no effective treatments exist to slow or halt cerebellar ataxia. Current clinical care remains largely symptomatic and has only modest benefits.

This project will provide a better understanding of the disease mechanisms in cerebellar ataxia and identify novel clinical intervention points and potential therapies. This will improve the quality of life for ataxia patients and their families.

What outputs do you think you will see at the end of this project?

This project will generate new scientific knowledge about the disease mechanisms and treatment options for cerebellar ataxia. We will communicate our findings through open-access, peer-reviewed publications and accompanying press releases. Research findings will also be shared through presentations at national and international conferences and invited seminars. In addition to publications and presentations, we expect the development of new scientific collaborations and funding applications as a direct result of this project. Finally, this project aims to identify candidate therapeutic compounds that will lead to novel IP and the future commercialisation of therapeutics for the treatment of cerebellar ataxia.

Who or what will benefit from these outputs, and how?

In the short-term, the knowledge generated in this project will provide a better understanding of cerebellar ataxia and will benefit the scientific community. In addition to basic scientists, this work will also be important for clinicians and clinical geneticists in cerebellar ataxia as it will provide important insights into human genetic variants in cerebellar ataxia and thus help to improve molecular diagnoses for ataxia patients. Ultimately, the project aims to identify and test novel therapeutics for cerebellar ataxia. This will lead to the development of an effective treatment for this group of disorders and improve the quality of life for patients and their families. The latter benefit is unlikely to be fully realised after five years. However, we hope to have identified at least one compound that could be taken further into clinical studies.

How will you look to maximise the outputs of this work?

We regard the dissemination of our research findings as a high priority and will communicate our findings through open-access, peer-reviewed publications, presentations at conferences, and invited seminars. Our developed methods, materials, and models will be shared with the scientific community. We have established collaborations with clinical geneticists and neurologists both in the UK and internationally and we will share our findings with them so that our results can have an immediate impact in the clinic. We will also actively engage with patient organisations to share our research findings. Finally, we are committed to public engagement of science and will widely communicate our research activities through participation in outreach events such as science festivals, public talks and school visits.

Species and numbers of animals expected to be used

- Mice: 33,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used for this project because their cerebellum is very similar to the human cerebellum in both its structure and physiology. This allows the study of specific structures and cell types that are specifically affected in cerebellar disorders and that are not present in lower species. The genetic standardization and toolkit available for mice also make this animal an ideal model to study the functional effects of genetic mutations. Moreover, the mouse is well-suited for behavioural testing and pharmacological interventions that are directly applicable to humans.

Cerebellar ataxias are degenerative brain disorders with an onset of disease throughout lifetime. We therefore need to use adult and ageing mice for our project. We will also study the developing cerebellum in mouse embryos and juvenile mice as many of the cerebellar disorders that we investigate cause early changes during brain development.

Typically, what will be done to an animal used in your project?

Typically, a mouse in this project will undergo a series of non-invasive, behavioural tests at different times during its lifetime, from neonatal stages through to ageing, to assess motor and cognitive function. The order and timing of the behavioural tests used in this project will be planned to cause the least stress to the animals while still providing the most biologically relevant data. Generally, a testing regime over a number of days will begin with the least stressful first and will have the most stressful test at the end of the protocol. No more than ten non-invasive tests will be carried out per testing period with a maximum of six testing periods over the course of the animal's lifetime.

A mouse might be given a compound for up to three months to improve motor behaviour and to test potential therapeutic approaches for cerebellar ataxia. We will aim to administer compounds orally as this is the most refined route, but occasionally compounds might need to be administered via injection.

At the end of these studies, the mouse will be humanely killed to collect tissue for pathological and biochemical studies.

What are the expected impacts and/or adverse effects for the animals during your project?

The most likely adverse effects will come from the genetic modification of the used mutant mice. The project uses mouse models of cerebellar disease that display features similar to human patients, i.e., progressive dysfunction and loss of cerebellar nerve cells that will result in movement problems.

Typical symptoms might include ataxia, tremor, weight loss, and altered activity. These

symptoms are expected to start within the first three months and will progressively worsen over the animal's lifetime. Mice will be monitored and scored to assess welfare and will be treated with nutritional support where appropriate.

Animals may undergo procedures such as repeated motor function tests and injection, which are minimally invasive, and no significant adverse effects are expected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Sub-threshold (10% of animals)
- Mild (30% of animals)
- Moderate (60% of animals)
-

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Central to this project is the characterisation and treatment of human brain disorders. This requires the study of the brain in a living animal. Moreover, the studied diseases manifest as deficits in complex behaviours, which cannot be examined in cell or other models. Also, it is not possible to mimic the action of a drug on the brain from cell lines alone as the drugs for treatment will have to be delivered by the blood stream. Regulatory authorities also demand that we have pre-clinical data in mice before going to human clinical trials.

Which non-animal alternatives did you consider for use in this project?

Post-mortem brain material could be used to gain insight into pathological changes in the human brain; for example, to determine which cell types are lost and in which regions of the patient cerebellum.

Tissue culture models are used where appropriate; for example, to investigate cellular pathology and to see if any therapeutic compounds can correct the disease at the level of the single cell.

Moreover, our group has developed a reliable method to generate cerebellar nerve cells from human induced pluripotent stem cells (hiPSCs). These can be derived from control and patient fibroblasts and offer the possibility to investigate pathology in disease-relevant living human nerve cells.

Why were they not suitable?

Post-mortem brain material is scarce and not available for all genetic subtypes of cerebellar ataxia. Moreover, human post-mortem tissue is usually obtained at an advanced and/or end-stage of the disease and therefore offers only limited insight into early pathological changes.

While hiPSC-based models are an exciting new technology, the generated neurons are relatively immature and do not yet recapitulate changes that occur in the adult brain.

Importantly, studies of brain behaviour and function are currently not possible in vitro as cell-based systems do not replicate the complex in vivo interactions of the brain. Also, no cell model can offer an alternative to behavioural studies in an intact animal.

Finally, although the screening of therapeutic compounds is initially performed in cell models, it is still necessary to determine whether these treatments have any therapeutic benefit in intact living animals prior to translational studies in patients. This is also a regulatory requirement.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in this license has been arrived at through statistical advice and from our own personal experience of similar work carried out previously. The majority of animals will be used for breeding.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments have been designed using the online NC3R's Experimental Design Assistant and in consultation with experts in experimental design.

In our experimental design, we will carefully consider minimal group sizes, number of groups to be studied, using one or both sexes of animals as appropriate. We will consider factorial design of the experiments to increase the amount of information gained. For behavioural testing, we will consider controlled multiple testing, which facilitates obtaining the maximal amount of information from an individual animal. Where practical, we will use computer-generated randomisation protocols to randomise experimental groups. Experiments as well data analysis will be performed blinded to minimise bias introduced by the experimenter. For behavioural experiments, counterbalancing of the experimental design is important to ensure that results are not attributed to technical variation, for example a specific apparatus or other variables (e.g., starting position in a test or order in which stimuli are presented).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The use of in vitro methods, for example in cell models prior to the animal experiments, will reduce the number of animals required to attain statistical significance.

We will set up the minimum number of matings required to ensure adequate numbers of the desired genotypes are produced. We will maintain a minimum colony size for each mouse model by using data generated by our mouse database. We will constantly analyse and review our data to ensure that the lowest possible number of animals per group are used. We will continue to ask for advice from experts in experimental design and others in the field whenever required to maintain a rigorous approach to experimental planning and data analysis.

As group sizes needed for any study are based on the effect size being measured, we will use small- scale pilot studies to inform us on effect size so that the main study can be designed to be adequately powered and avoid over-use of animals.

A wide selection of tissue samples will be taken from each animal used in a study to try to cover every eventuality with regards to any potential additional analyses which we may want to perform and prevent having to use more mice in a repeat experiment. This ensures maximum use of every animal that we work with. Samples are put in long-term storage enabling us to access them if and when required at any time in the future.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models of human cerebellar disease will be employed as these are the lowest vertebrate model that we can use to achieve the purpose of this project with enough aspects of genetics, anatomy, physiology and behaviour shared with humans to generate biologically relevant data that can ultimately be used to develop novel therapies.

We will use the most refined methods according to published literature and in consultation with experts in the field. Regular examination of the animals by trained staff and experienced technicians will ensure that steps are taken to minimise any distress or discomfort to the animals. Veterinary advice will always be sought where and when necessary.

Why can't you use animals that are less sentient?

The aim of this project is to employ accurate models of human cerebellar disorders to better understand these diseases and develop novel therapies. This aim can only be achieved in animals that mimic the human condition and show clinically relevant phenotypes such as progressive loss of neurons in the adult brain and behavioural impairments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have photo and video material of the ataxia models available that we will share with the team to provide detailed information about the expected disease phenotypes. Animals will be monitored appropriately dependent on their phenotype or known adverse effects and stage in a specific protocol. We will also continue to assess the disease endpoints used to minimise suffering. We will keep abreast of the literature and adopt more refined disease models, e.g., inducible and/or conditional models, when these become available.

Care and husbandry refinements will be made including the use of mash and jelly in the diet of the mice to ensure they can feed even if mobility is reduced. This is expected to result in improved health and extended lifespan of the animals.

For behavioural testing, we will continue to refine the protocols with respect to both scientific merit and animal welfare at all times by review of the literature and communication within the establishment and other experts in the field. The order and timing of the behavioural experiments will be planned to cause the least stress to the animals while still providing the most biologically relevant data. Generally, a testing regime over a number of days will begin with the least stressful test first and with the most stressful test at the end of the protocol.

For the testing of potential therapeutic compounds, we will base dosages on published work with close consultation with other experienced research groups so that the most refined approach is used. When a novel compound is used, information from other experimental data such as in vitro studies will be used to predict toxicity and estimate predictable doses; a pilot study will also be carried out initially.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice guidance according to the Handbook of Laboratory Animal Management and Welfare by Wolfensohn and Lloyd, as well as published literature on most refined methods in the field. For behavioural protocols, we will use published and regularly updated protocols where available, for example from the International Mouse Phenotyping Consortium (IMPC). We will also consult the publications from LASA (Laboratory Animal Science Association) and AHWLA (Assessing the Health and Welfare of Laboratory Animals) for useful guiding principles. We will conduct and report experiments according to the published ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advances in the 3Rs are regularly communicated by the establishment and its dedicated 3Rs information officer and local 3Rs regional programme manager. We will attend an annual 3Rs Research Day, where researchers inform the community about advances and best practices in animal research with respect to the 3Rs. Advances in the 3Rs that are relevant to this project will also be discussed and implemented in close consultation with the named people.

189. Vascular protective genes in angiogenesis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Pregnancy, Angiogenesis, Preeclampsia, Cardiovascular, Antioxidant genes

Animal types	Life stages
Mice	pregnant, adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to investigate whether certain natural protective factors can reduce the severity of two medical conditions: preeclampsia (PE) and cardiovascular disease. The research team aims to understand more about the underlying mechanisms involved in these disorders. To achieve this, they will be using established models of PE and atherosclerosis in mice to study the role of certain genes, such as heme oxygenase, in these conditions. The study has two main parts: i) Testing the role of genes that have been shown to help alleviate the symptoms of PE and cardiovascular disease. ii) Utilizing two new models of PE to identify important genes in the development of this condition. The first model is a surgical model that mimics PE, but without any genetic manipulation. The

second model involves manipulating specific placental cells to understand the role of different genes in PE.

In short, the project aims to further our understanding of the factors involved in preeclampsia and cardiovascular disease and how they can be mitigated.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Disorders related to the placenta during pregnancy can result in a range of complications for both the mother and her baby, including preeclampsia (PE) and fetal growth restriction (FGR). PE is characterized by high blood pressure and poor kidney function and FGR affects approximately 10% of all pregnancies. These conditions also increase the risk of heart disease and other adult diseases like diabetes for both the mother and baby in the future. Despite the importance of PE and FGR, there are currently no therapies to treat them. This is due to a lack of understanding about why some placentas don't function properly during pregnancy and the reluctance of drug companies to invest in treatments for use during pregnancy due to the potential risks to both the mother and baby. To do this, it is important to test existing and new drugs, especially those that are considered safe during pregnancy, in animal models of PE and FGR to see if they have the potential to be used in human patients. By improving our understanding of why some placentas don't function properly and testing new treatments, we can work towards improving outcomes for mothers and babies affected by PE and FGR.

What outputs do you think you will see at the end of this project?

The aim of this research program is to improve our understanding of the processes involved in blood vessel growth, known as angiogenesis. Angiogenesis is critical for many physiological and pathological conditions, including peripheral vascular diseases, heart attacks, strokes, wounds, tumors, and retinal disorders. The ability to both promote and inhibit blood vessel growth is crucial for addressing these conditions. To date, most of the research on angiogenesis has been done in laboratory conditions using cells grown in a dish. However, these conditions are not representative of the complexity and variability of angiogenesis in living organisms. Therefore, this research program aims to study angiogenesis in live animals to gain a more accurate understanding of the mechanisms involved.

The primary focus of this licence is to determine the role of specific genes in angiogenesis, and to complement the in vitro studies on endothelial cells that have indicated a potential role for these genes in supporting capillary growth. Additionally, the long-term objectives of the research include identifying new targets for the treatment of vascular disorders such as

preeclampsia and understanding the molecular basis of blood vessel growth and remodeling.

Our research is unique, both nationally and internationally, in its studies on angiogenesis in vivo. Such studies are crucial for advancing our understanding of the mechanisms involved in angiogenesis and for translating this knowledge into the clinical setting. The results of this research have the potential to provide new insights into the treatment of various vascular disorders and could lead to the development of more effective therapies

Who or what will benefit from these outputs, and how?

In short, this project will provide valuable information and insights into the causes of poor pregnancy outcomes and cardiovascular diseases. The findings from this study will be of benefit to scientists, clinicians, and medical professionals in the fields of reproductive health and vascular diseases. Additionally, this research will directly benefit patients, particularly women who are suffering from disorders of pregnancy. In the long term, the results from this project will contribute to the development of new and effective treatments for these conditions.

How will you look to maximize the outputs of this work?

The results of the project will be shared with the scientific community through publication in scientific journals and presentations at scientific conferences. This will be done with the goal of reaching both specialists in the reproductive and cardiovascular fields, as well as a broader audience through multidisciplinary journals. The team will also continue to build new collaborations and seek out new knowledge to improve understanding of the causes of poor placental function and to identify potential new treatments for vascular diseases. The researchers will also be in regular communication with their patient information panel to ensure that the research is being done with the patients' needs in mind and will work to educate the public about their findings through community events.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of mice to study the role of vascular genes in normal angiogenesis and in pregnancy is a well-established and highly valuable approach in scientific research. The development of transgenic mouse models that are susceptible to changes in vascular

factors that allow for the investigation of specific mediators and pathways has greatly increased the use of mice in this field. These models provide the best and most versatile models of vascular disease. Additionally, the use of mice has been further improved through the development of techniques such as transient knockdown strains, surgical procedures, and high-resolution imaging.

However, it is important to note that not all results from murine models can accurately predict the effects of treatments in humans. Therefore, it is often necessary to confirm positive findings in additional models. In this project, three novel models will be used to investigate complications during pregnancy and related vascular disorders. This multi-model approach will provide a more comprehensive understanding of the underlying mechanisms involved.

The main aim of this project is to understand the role of vascular genes in controlling in vivo angiogenesis. This will be achieved through surgical manipulation of the vascular system in mice, combined with a high-fat diet in some instances. The process of remodeling will also be manipulated in some cases, by altering maternal blood pressure, altering vascular factor concentrations of proteins in circulation, or administering pharmacological agents. The use of genetically modified mice will help to investigate the role of specific molecular pathways in angiogenesis. At the end of the experiments, the animals will be sacrificed to obtain tissue samples for laboratory analysis. The results will be compared to laboratory experiments using cell cultures or placental samples from humans. To imitate preeclampsia in mice, adenoviral gene transfer will be used, and the reduced uterine perfusion pressure (RUPP) model will also be utilized. The RUPP model mimics the hypertension, immune system abnormalities, systemic and renal vasoconstriction, and oxidative stress in the mother and intrauterine growth restriction in the offspring. This allows for investigation of the origins of preeclampsia phenotype without the influence of a specific gene.

Typically, what will be done to an animal used in your project?

The experiments will aim to study the effect of different factors on vascular remodeling and how they contribute to pregnancy complications and related disorders. This will be done by inducing vascular remodeling through surgical manipulation of the vascular system and, in some cases, by combining it with a high-fat diet in mice. At the end of the experiments, the animals will be sacrificed, and their tissues will be collected for laboratory analysis.

Additionally, the use of genetically modified rodents will allow for investigation of the role of specific molecular pathways in these processes. The experiments will be designed and conducted based on previous research and findings in the field and will also be supplemented by laboratory experiments using cell cultures or biological samples from humans. This project will provide insight into the molecular mechanisms underlying angiogenesis and vascular disorders and contribute to the development of new treatments for related health issues.

All surgical procedures and experimental protocols will be reviewed and approved by an institutional ethics committee. The use of animal models is necessary to advance our understanding of the role of angiogenic and antioxidant genes in placental function and to identify new treatment options for vascular diseases. However, every effort will be made to minimize animal suffering and use the minimum number of animals required to obtain valid scientific results.

a) Induction of preeclampsia – i) Maternal Vascular Disease - In non-pregnant mice, we will investigate the underlying molecular mechanisms of maternal vascular disease using a high-fat diet-induced model of oxidative stress and inflammation. This will help us understand the effect of oxidative stress and inflammation on the maternal vasculature and the resulting long-term endothelial cell dysfunction. ii) Atherosclerosis - In non-pregnant mice, we will use the high-fat diet-induced model of atherosclerosis to investigate the underlying molecular mechanisms of this disease. We will examine the role of specific mediators and pathways in the development of atherosclerosis and the resulting cardiovascular complications. iii) Angiogenesis - In non-pregnant mice, we will investigate the molecular mechanisms underlying angiogenesis using various models such as the inhibition of angiogenic factors and the stimulation of angiogenic pathways. This will allow us to understand the role of angiogenic factors in the development of various diseases, including cardiovascular disease and cancer. All the mice used in this project will be maintained with the use of appropriate anesthetics, analgesics, and euthanasia methods to minimize animal suffering.

b) To replicate these diseases in rodents, adenoviral gene transfer and reduced uterine perfusion pressure (RUPP) models will be used. In the adenoviral gene transfer model, antiangiogenic genes will be transferred, leading to angiogenic imbalances and clinical symptoms of preeclampsia. The RUPP model simulates hypertension, immune system abnormalities, systemic and renal vasoconstriction, oxidative stress, and intrauterine growth restriction in the mother and offspring. This allows for investigation of the origins of preeclampsia without the influence of specific genes through their loss or overexpression. Preeclampsia will typically be induced in mid-gestation pregnant mice and the experiment will be terminated near term. The users has gained experience and confidence with this procedure over the last five years, with no adverse outcomes reported during experimentation.

c) Modulation of atherosclerosis – The mice used in this project will be given a high-fat diet to induce atherosclerosis, which is the build-up of plaque in the arteries. This will be done by modifying their diet for 4-12 weeks. The dietary modification will take place in both wild-type and genetically altered mice. The goal of this experiment is to study the biological processes and interactions that underlie the development of atherosclerosis and to examine how genetic alterations affect this process. The mice will be allowed to have unlimited access to the modified diet during the experiment.

d) Induction of angiogenesis – the use of animal models in the study of angiogenesis aims to provide a deeper understanding of the mechanisms underlying the regulation of

new blood vessel formation. Three complementary models will be used: physiological angiogenesis, corneal micro-pocket assay, and pathological angiogenesis. These models will help to clarify the mechanisms of regulation and allow the evaluation of potential therapeutic options. The experiments will last up to 14 days, with monitoring of mice and assessment of angiogenesis using relevant imaging techniques. The study may include species other than mice, such as transgenic animals, to improve the relevance of the results. These parameters may include changes in blood vessel size, structure, function, and permeability. Non-invasive imaging techniques such as ultrasound scans can be used to visualize and quantify these changes. Additionally, histological analysis of blood vessel tissue can provide detailed information on changes in the tissue architecture and cellular composition. Other measurements that may be made include changes in blood flow and pressure, as well as changes in the expression of key signaling molecules and growth factors involved in vessel remodeling. By combining these different measurements, researchers can gain a comprehensive understanding of the underlying mechanisms of vessel remodeling and their role in the development of cardiovascular disease.

Measurements of vessel remodeling: The mechanisms of vessel remodeling will be assessed by analysis of appropriate parameters before / during or after vascular remodeling.

a) Blood pressure – Tail cuff plethysmography and radiotelemetry are two methods used to measure blood pressure in conscious animals. Tail cuff plethysmography is a non-invasive method that involves placing a cuff around the tail to measure the blood pressure in the tail artery. Radiotelemetry, on the other hand, involves implanting a telemetry probe into the animal to directly measure blood pressure. We will first use tail cuff plethysmography to determine the success of the RUPP (reduced uterine pregnancy pressure) surgery, which is a model for hypertension in pregnancy. Once the RUPP model is established and reproducible, the researchers will then proceed to implant telemetry probes into the animals to monitor blood pressure in real-time. This combination of methods will provide a more comprehensive understanding of the mechanisms of vessel remodeling and the role of vasoactive and anti-oxidative genes.

b) In vivo imaging – Using the expertise and resources available within the institute, we plan to utilize methods that allow for repeatable, non-invasive assessment of vessel remodeling. High quality, in vivo imaging would be achieved via administration of suitable contrast agent. A variety of methodologies will be used to determine the optimal state-of-the-art in vivo imaging technologies for our vascular disease models. A high-resolution ultrasound scan is a diagnostic technique, which uses high-frequency sound waves to create an image of the internal organs and would allow for measurements blood flow in specific areas of placenta.

c) Physical parameters and blood sampling – Samples of blood will be taken to assess circulating angiogenic and anti-angiogenic proteins following viral injection and/or drug concentrations where therapy is given. We may also collect 24h urine from the treatment groups.

Interventions and therapy:

a) Treatments - Therapies may be used that stimulate and/or inhibit or aid in the imaging of vessel remodeling. Treatments may be given before and/or after induction of vessel remodeling by single, repeated, or continuous application.

b) Routes of administration – Treatments may be given by; i) injection (subcutaneous, intravenous, intraperitoneal, intramuscular), ii) inhalation, iii) orally (ad libitum in food/ drinking water or by gavage),

iv) mini-pump implantation, v) subcutaneous pellet implantation, vi) topical application to the skin. vii) Cornea micro-pocket assay.

Adequate measures will be taken to minimize pain and distress, and every effort will be made to provide the best possible conditions for the animals. Pain relief measures will be provided where necessary, and animals will be euthanized in a humane manner at the end of the experiments, if required.GA animals bred under this PPL may also be used under other PPLs with the appropriate authority.

What are the expected impacts and/or adverse effects for the animals during your project?

The experiments planned in this project aim to investigate the mechanisms of preeclampsia and cardiovascular diseases and evaluate potential therapeutic options. To do this, a variety of animal models will be utilized to demonstrate the vascular aspects of these diseases, such as hypertension, elevated pro-oxidant proteins in circulation and onset of renal disease. These models will provide a platform for investigating the underlying mechanisms of regulation of new blood vessel formation and provide a way to evaluate potential therapeutic options.

The animal models will be subjected to a range of procedures, including viral infections, drug treatments, and implantation of devices to deliver substances. Most treatments will be given via intravenous or intraperitoneal injections and are not expected to result in any adverse effects. However, these procedures may result in momentary discomfort or pain, which will be treated with appropriate pain management strategies. In addition, surgical procedures will be performed under general anesthesia, and animals are expected to demonstrate normal behavior within a day of the procedure, although mild pain or discomfort may be present, which will be controlled with painkillers.

When measuring blood pressure in mice, the animals will be restrained, which will result in brief discomfort, but is unlikely to cause long-lasting harm or stress. The length of the experiments will vary, with studies in pregnant mice lasting for the duration of the mouse pregnancy (19 days), and studies investigating the role of angiogenic genes on the cardiovascular system being conducted for between 4 and 12 weeks.

It is not expected that these models will result in serious adverse effects or abnormal behavior. However, if any adverse effects are observed, they will be monitored and treated appropriately to minimize any suffering.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

In the study, most of the procedures performed on the animals will not cause significant harm or stress, and therefore have a mild severity classification. The transient mild discomfort associated with these procedures will likely include brief restraint during blood pressure measurement, as well as momentary discomfort during injections.

For some of the animals, however, repeat procedures may be necessary to assess blood flow, which can move their classification to moderate severity. Additionally, animals undergoing general anesthesia may also experience a moderate severity classification, due to the duration and nature of their recovery period.

It is important to note that any procedures causing moderate or severe distress to the animals will be performed in accordance with ethical guidelines, and steps will be taken to minimize suffering and promote animal welfare. This may include the use of pain control medications and monitoring the animals for any adverse effects following the procedure.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In our opinion, animal models are necessary to study the complex mechanisms of vascular remodeling and angiogenesis, and the effects of various treatments on these processes, in a more realistic and biologically relevant manner. The use of animal models is considered essential to the aims and objectives of this project and no alternative methods have been found that would allow us to achieve these goals.

Which non-animal alternatives did you consider for use in this project?

The use of animal models is necessary for the success of our research in this project. Although in vitro methods may provide some supplementary information, they are not able to fully replicate the complex and dynamic in vivo environment. The integrative nature of in situ tissue function and the differences between in vitro and in vivo processes make the use of animal models an essential component of our research. Our research is unique in its ability to study these factors in vivo, and the observational studies in animals will form the foundation for our work. However, we recognize the importance of minimizing animal use and will strive to replace animal studies with non-animal methods whenever possible.

Why were they not suitable?

In this project, the study of whole organisms is essential for the scientific understanding of placental and vascular systems that control resource allocation. The interplay between the mother and the placenta or the development of the vasculature during wound healing can only be fully understood using physiological assays in living mice.

While in vitro systems are useful for investigating molecular pathways, they do not have the level of complexity that is required to study the behavior and interaction of different cell populations in a living animal. This is a crucial aspect of our research as it is not possible to understand the whole-body complexity in cell culture-based experiments.

To reduce the number of animals required and to optimize experimental design, we will run experiments in cells as much as possible. In addition, we will use appropriate human term placental samples to translate our mouse studies into human populations. This is important for the translation of fundamental biomedical research into clinically useful products or protocols.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimize numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used are usually set with the help of a mathematical model. It allows us to calculate the minimal number of animals we need to use. For a particular experiment, to find differences between groups of animals, whilst making sure that those differences we may find are not due to chance.

In addition, we make every effort to reduce the number of animals used by using optimal experimental design and refining our procedures. We also use appropriate statistical

analysis to ensure that the smallest number of animals are used to provide statistically meaningful results. In line with the 3Rs (Replace, Reduce, Refine) principles, we constantly evaluate and refine our methods to ensure that the use of animals is minimized and that their welfare is maximized. Additionally, we follow the guidelines set by relevant animal welfare organizations to ensure that all animal use follows the highest ethical standards.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To optimize the number of animals used in the project, we will adopt and implement the 3R principles, make as many observations/measurements as possible on individual animals, and use ex-vivo and in vitro methods where appropriate. We will also use efficient breeding regimes, perform pilot work in cells growing in a dish, and follow local and national guidelines for experiment design and data preparation / publication. Additionally, we will write comprehensive study plans for each experiment to ensure the ethical and scientifically robust conduct of the research while minimizing the use of animals to the greatest extent possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimize welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are committed to adhering to the highest ethical standards in our research and will take all necessary measures to minimize animal usage and ensure the well-being of the animals used in our studies. In addition to our experience and expertise in the use of these models, we will utilize the 3R principles of Replacement, Reduction, and Refinement in all aspects of our work.

To minimize the discomfort, pain, and stress experienced by the animals, we will employ humane endpoints, refine surgical techniques, and use appropriate anesthetic and analgesic protocols. Our goal is to carry out the research in a scientifically robust and ethical manner, while minimizing animal usage to the greatest extent possible.

We will continue to write comprehensive study plans for each experiment and keep detailed records of our methods and observations, to ensure that our research is

scientifically rigorous, transparent, and in compliance with relevant ethical standards. We are committed to working with the NC3R and other relevant organizations to promote the responsible use of animals in research and to develop new, innovative methods that reduce the need for animal usage while maintaining the scientific validity of our results.

Why can't you use animals that are less sentient?

We have not considered the use of less sentient animals, and mice being the least sentient in which our work can be carried out. To achieve our objectives, we need to use a mammalian species that have a placenta and that can be manipulated genetically.

Mice will be the major targets because the use of transgenic and knockout technology. The use of genetically altered animals is critical to this programme of work in that, in nearly all cases, this is the only way to establish the functional role of a protein in supporting angiogenesis. Dose setting studies will be undertaken, at a low dose in no more than two animals initially. Pharmacological dose will be selected based on previous animal studies with the type of compound, or by extrapolation from in vitro work or other appropriate data.

How will you refine the procedures you're using to minimize the welfare costs (harms) for the animals?

To improve the quality of life of the animals, we will continue to:

Reduce contingent harm by group housing where possible to keep singly housed mice to a minimum. This in turn reduces any stress and stereotypical behavior.

Use environmental enrichment EE, within what is available to us at our animal facility. In general, EE is an animal housing technique composed of increased space, physical activity, and social interactions, which in turn increases sensory, cognitive, motor, and social stimulation. Igloos, running wheels, saucer wheels, fun tunnels, and other objects in the housing environment foster this sensory cognitive, social, and motor stimulation by promoting exploration and interaction. EE can be maintained through restraining (e.g., Handling tunnels), thus minimizing stress when for example an injection is needed.

Keep animal transportation to a minimum (majority of our mice are bred in house and kept in one facility).

Use analgesics to lessen pain.

Provide 'behavioral' training to mice undergoing specific procedures (e.g., blood pressure measurements by tail cuff; acclimatization to hypoxic chambers; acclimatization to metabolic cages)

Use scoring sheets to monitor the health of animals undergoing procedures.

Use mash, with improved nutritional composition/palatability, for animals likely to lose weight- e.g., before they start a treatment where weight loss is expected and kept for the duration of the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Laboratory Animal Science Association (LASA) guiding principles documents of aseptic technique (https://www.ubs.admin.cam.ac.uk/files/lasa_aseptic_surg.pdf)

ARRIVE (Animal Research: Reporting of In Vivo Experiment) guidelines for preparing papers for publication (https://www.nc3rs.org.uk/arrive-guidelines)

PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for planning our experiments (15 topics including formulation of the study, dialogue between scientists and the animal facility, and methods) (https://www.ncbi.nlm.nih.gov/pubmed/28771074).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the NC3R's website and engage fully with the regional programme manager of the NC3R's to ensure we are kept informed of the latest developments and opportunities to implement new alternatives/refinements; an example of this is our commitment to the recent drive by the NC3R's to avoid picking the mice up by the base of the tail, even for brief periods, which has been shown to increase levels of anxiety/stress. In addition, we will keep up to date with relevant literature within the field, including attendance at research conferences, to refine our experiments and/or reduce/replace the animals we use. When alternative models or approaches are available which represent an improvement upon current practices, we will perform studies (including pilot studies) to confirm their effectiveness and ensure training for all users and adopt these approaches.

190. Role of natriuretic peptides in cardiovascular homeostasis and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Natriuretic peptide, Cardiovascular, Homeostasis, Disease, Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This programme of work will investigate the physiological and pathological actions of a family of substances produced by the body, natriuretic peptides, in the cardiovascular system and how targeting these peptides might be of therapeutic benefit.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease (CVD) is the leading cause of death and disability in the UK and accounts for a significant proportion of total healthcare costs. Whilst the introduction of targeted therapies over the last decades (e.g. anti-hypertensives, anti-platelet, lipid-lowering) has reduced this burden, significant mortality remains alongside increasing levels of morbidity. The programme of work described in this project licence will provide information that will enhance our understanding of the mechanisms involved in the maintenance of normal cardiovascular function and give insight into the pathogenic mechanisms responsible for CVD, with the ultimate goal of identifying novel therapeutics to treat these disorders.

What outputs do you think you will see at the end of this project?

1. Generation of unique strains of mice that are genetically modified to delete members of the natriuretic peptide family of hormones and their cell-surface receptor proteins. Investigation of these mouse models will provide insight into the mechanisms underpinning cardiovascular disease (CVD) and reveal new pathways involved in the inherent protective functions of natriuretic peptides in the cardiovascular system, potentially involving new systems (e.g. immune cells, fat cells, neurones).

2. Development of new treatments for CVD. The major goal of our research is to identify novel therapies for CVD, based on a greater understanding of the pathogenic mechanisms underpinning these disorders, with specific focus on the actions of natriuretic peptides. Thus, we will undertake investigations exploring the functional pharmacology of interventions targeting natriuretic peptide signalling in realistic models of human CVD. To this end, we have an active academic drug development programme in progress to identify novel small molecules modulating natriuretic peptide signalling.

Who or what will benefit from these outputs, and how?

Academic research: The findings from our studies will guide future research to better target CVD.

Industrial research: A better understanding of the biology of natriuretic peptides will aid the development of new medicines in the pharmaceutical industry

Clinical medicine: Results from this work should provide a better understanding of the pathogenic mechanisms underpinning CVD thereby helping with the diagnosis and prognosis of such disorders, including the implementation of existing and new medicines targeting natriuretic peptides.

How will you look to maximise the outputs of this work?

1. Towards the end of this programme of work we anticipate to have several publications in press to share our findings with both the scientific and medical communities. We also frequently attend professional meetings to keep up to date and discuss our findings.

2. We will engage actively with members of the lay public and patient population through events such as 'Pint of Science' and 'Let's talk hearts'.

3. We have ongoing collaborations with both national and international teams focused on CVD research. Through these collaborations we share data including problems, unsuccessful approaches, and the development of better animal models of disease.

Species and numbers of animals expected to be used

- Mice: 9000
- Rats: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This proposal adopts a multidisciplinary approach to elucidate the role(s) natriuretic peptides play in the pathogenesis of CVD that will require validation in isolated cells, tissues, and in experimental models of disease. There are no existing well-validated alternatives to using laboratory animals for such studies. However, a sizeable portion of the work will be carried out using cell-based assays (including human samples) thereby limiting the number of animals used. The project involves the use of mice and rats since the applicant has considerable experience and expertise in pharmacological experimentation in rodent models. Moreover, rodents have been used extensively for modelling many aspects of CVD since they closely mimic the human pathobiology and are well-characterised. Finally, the use of mice allows exploitation of knockout technology which is key in the setting of natriuretic peptide biology since, whilst pharmacological tools exist, they are limited in terms of potency and selectivity. We have developed in-house several unique transgenic strains for this purpose, which will be widely utilised in this project. Whilst the vast majority of the work will involve the use of mice, the project necessitates the use of rats for a number of important reasons, including differential actions of natriuretic peptides in the microvasculature of rats compared to mice, more apparent phenotypes in rats in certain models (e.g. right ventricular hypertrophy in pulmonary hypertension) enabling more focused study, and the need for rat functional pharmacological data for novel therapeutics that will align with downstream pharmacokinetic/toxicological workups.

Typically, what will be done to an animal used in your project?

Animals will undergo ONE of the models of cardiovascular disease (e.g. heart failure, pulmonary hypertension, cardiometabolic disease) permitted. In addition, some animals will receive existing or novel pharmacological interventions selectively targeting natriuretic

peptide signalling which are not anticipated to have a significant adverse effect profile. A small cohort of animals will also undergo implantation of catheters or radiotelemetric devices to permit longitudinal study of cardiovascular parameters in as least invasive manner as possible. We will use non-invasive methods of assessment (e.g. imaging) to determine the structure and function of the heart and blood vessels. Model duration and experimental treatment are relatively short, typically 12 weeks maximum. Animals will be appropriately anaesthetised for any surgical interventions with close monitoring and appropriate analgesic use post-surgery. Aseptic techniques will be used routinely. During the 5-year period for the project we anticipate the use of approximately 9000 mice spread over nine protocols.

What are the expected impacts and/or adverse effects for the animals during your project?

The experimental models utilised in this project are classified as mild or moderate. The animals tolerate these procedures well and, although this is a marked cardiac and/or vascular impairment, there are no overt signs of stress/adverse effects. These experimental models are not associated with mortality since the dietary interventions, genetic modifications and surgery are well refined and extensively used in my group and the time course relatively short term. Regardless, any animal showing signs of adverse effects will be discussed immediately with the named veterinary surgeon (NVS) and/or named animal care & welfare office (NACWO) and monitored closely and/or administered appropriate analgesia, or killed by a Schedule 1 method, whichever is deemed necessary.

Expected severity categories and the proportion of animals in each category, per species.

- What are the expected severities and the proportion of animals in each category (per animal type)?

In the breeding protocol we do not expect any harmful effects from the genetically modified strains we will investigate and from experience these protocols are therefore of mild severity with the majority of animals experiencing sub-threshold severity. All other protocols have either a mild or moderate severity. We do not expect any severe effects in our protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Numerous cell-based techniques are now available to aid the development of new classes of drug for the treatment of CVD. However, because of the dynamic cellular interactions that typify the initiation and maintenance of cardiovascular pathology, to facilitate the identification and subsequent development of such agents it is also necessary to use animal models. Whilst there are few animal models that faithfully reproduce all the pathology of the analogous human condition, it is possible to produce certain fundamental processes that may either reveal new targets or act as screens for drug testing. Thus, provided one is aware of the limitations of animal models they can play a valuable role in the development of novel and more efficacious drugs.

Which non-animal alternatives did you consider for use in this project?

In order to minimise animal usage, we are utilising highly sophisticated cell- and tissue-based models (e.g. cell-based assays, organ-on-a-chip), and cells/tissues from patients with CVD. We are also integrating our laboratory research with the extensive bioinformatics platforms available at the Institution that enables us to refine interventions/targeting before administration to whole animals. Only new interventions that demonstrate repeated efficacy in these early-stage studies will be further examined in live animals. We have already minimised the number of animals that will be needed by developing these non-animal models and will continue to improve and expand these during the course of this project.

Why were they not suitable?

Although these cell- and tissue- based techniques are the most sophisticated models of cardiac and vascular function that are available, they fail to model critical aspects of the live animal situation. These include pharmacokinetics, pharmacodynamics and interactions with other organ systems. These aspects can only be assessed in representative models of CVD in whole animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Sample sizes have been calculated according to our previously published work and pilot data on the effects of natriuretic peptides on vascular & cardiac function. Total numbers are based on the planned studies using appropriate power calculations and the usage, in matching models, during the 5 year tenure of a previous licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

By undertaking studies with adequate statistical power, definitive positive or negative data can be generated from a single experiment, thus avoiding under-powered experiments that may be futile and wasteful. The minimum numbers of breeding pairs will be mated to provide offspring to enable experimentation. Working on the basis that a breeding pair produces a litter once a month of approximately 8 animals and that 50% of these are WT or KO, we would need approximately 4-6 breeding pairs to provide a minimum of 1 animal per day for experimentation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The studies will only include interventions that have been identified using our sophisticated and comprehensive. cell- and tissue- based models of cardiovascular physiology and pathology. We have incorporated whole animal imaging in many of protocols to enable smaller cohorts of animals to be observed longitudinally throughout an experiment rather than relying on killing of separate groups of animals at each time point. By first exploring conditions in small pilot experiments the final conditions can be optimised and also reduce the number of animals subjected to unexpected side-effects. When possible, the same groups of control animals (untreated or sham-treated) will be used in several studies to minimise the number of animals used. Tissues/plasma samples will be harvested from each study for laboratory investigation to collect all available information from each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the models described in this licence are mild to moderate; there are no models that fall into the severe category. Each is well-validated and widely-used for investigation of the mechanisms underpinning CVD, and gleans robust and informative information with minimal animal suffering; analgesics and anaesthetics are used whenever necessary, and close monitoring of all animals undergoing licensed procedures is undertaken.

Specifically, sepsis (a systemic inflammatory/immune response) can be induced by the administration of lipopolysaccharide or by caecal ligation and puncture. Two other CVDs in which natriuretic peptides have been implicated are pulmonary hypertension and heart

failure, and we can investigate these diseases using established techniques that involve subjecting animals to chronic hypoxia that results in the progressive development of pulmonary hypertension which is associated often with an outcome of heart failure. But we can look more specifically at heart failure using the technique of aortic banding (to create a back pressure on the left ventricle resulting in enlargement), by administration of vasoconstrictor agents or by closure of the left anterior descending coronary artery to induce a heart attack (leading to heart failure). Predominantly dietary interventions will be used to study cardiometabolic and liver disease.

Why can’t you use animals that are less sentient?

These models are the most representative of the human disorders available and reflect the most up-to- date information about human CVD. More immature life forms are not suitable due to the significant differences between such species (e.g. worms, flies, and fish) and humans and, and the lack of relevant circulatory (and immune) systems.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In the course of the current project we have significantly refined our procedures with the help of the NVS, the facility managers and the animal technicians. Surgical procedures and postoperative care including pain management are always discussed with the NVS if the study has not previously been performed. Another refinement is the continued and increased use of imaging in our studies that enables us to follow each animal over longer periods of time rather than harvesting tissues from numerous animals at several timepoints, thereby maximising the information obtained from each animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Curtis et al. 2018. Experimental design and analysis and their reporting II: updated and simplified guidance for authors and peer reviewers. Br J Pharmacol. 175:987-993. doi: 10.1111/bph.14153.

Smith et al. 2018. Classification and reporting of severity experienced by animals used in scientific procedures: FELASA/ECLAM/ESLAV Working Group report. Lab Anim. 52:5-57. doi: 10.1177/0023677217744587.

Charan & Kantharia. 2013. How to calculate sample size in animal studies? J Pharmacol Pharmacother. 4:303-6. doi: 10.4103/0976-500X.119726.

All recent advances and practices on NC3Rs website (https://www.nc3rs.org.uk/). The Home Office regulations (online material).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

PIL holders working under this licence will regularly attend NC3R or similar meetings to keep abreast of new developments, and to maintain awareness of current best practices. The applicant is on the NC3Rs mailing list and are regularly informed of seminars and workshops that train users in new techniques, and inform on regulations. We receive regular updates on new applications and regulations at an Institute-wide users committee and from the NVS.

191. Vaccine candidates for group a streptococcus infections

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Group A Streptococcus (Group A Strep, GAS), Vaccine, Immune response, carbohydrate

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to identify vaccine candidates that can induce a strong and specific immune response, ultimately for the treatment of Group A Streptococcus infections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our research addresses the prevention of human infections caused by the human-exclusive pathogen Group A Streptococcus (GAS). GAS causes a range of mild and severe diseases such as scarlet fever and streptococcal toxic shock, with more than

500,000 deaths annually worldwide. The effectiveness of current treatments for some infections is waning because of antibiotic resistance and the emergence of hypervirulent strains (those that can adapt to cause organ-invasive serious infections). In 2013 there were more than 1400 cases reported of invasive GAS infection in the UK alone, with mortality rate of > 30% within 30 days. To date, no vaccine has been successfully developed against GAS. This is due to the high number of GAS variants (serotypes), meaning that there are too many targets to generate a specific vaccine. However, a molecule that is common to most of these variants has now been identified and we wish to explore the possibility that it will be a good target for vaccination.

What outputs do you think you will see at the end of this project?

The main outputs from this study are expected to be one or two vaccine candidates validated to trigger a strong and specific immune response to GAS species, to take them further into additional preclinical trials. Importantly, this is also the first approach that has the potential to target other closely related bacteria. The findings from this study will be published after peer review in an international (open access) journal.

Who or what will benefit from these outputs, and how?

In the short term, these outputs will benefit justification to conduct subsequent research studies (preclinical trials). The studies will obtain knowledge of immunogen/vaccine candidate effectiveness to trigger specific immune response. In the long term, these vaccine candidates will have a potential benefit to the patients, preventing infections in humans. Should the proposed work lead to the development of one more more efficacious vaccine candidates (e.g. prevention and eradication of bacterial disease in the animal model (late preclinical studies), they will be tested in humans clinical trials.

How will you look to maximise the outputs of this work?

We have established collaborations with experts in this area of research, who are also co-applicants and collaborators on the 2-year funded grant. The main outputs of the studies will be peer reviewed publications in scientific journals and attendance at national and international conferences.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Because of the very significant similarities in the immune systems of mice and humans, the mouse is a good model in which to test vaccine efficacy. There are also excellent reagents and procedures with which to test the immune response in the mouse. We will use adult mice from around 10 weeks old, when the immune system is fully mature.

Typically, what will be done to an animal used in your project?

Typically mice will be injected with a vaccine candidate, together with a suitable adjuvant (a substance intended to ensure a robust immune response) and boosted at intervals thereafter, much as human vaccinations are performed. Blood samples will be taken at intervals to monitor antibody levels and other indicators of an immune response. Mice will be killed humanely at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

We have previously performed pilot studies and have optimised the composition of the adjuvant to avoid adverse effects. We do not anticipate any adverse effects from the vaccine candidates.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the severity experienced by all the animals to be "mild".

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to develop and test vaccine candidates, we need to challenge an intact immune system, which cannot yet be modeled satisfactorily without using a living animal.

Which non-animal alternatives did you consider for use in this project?

We considered the following models:

1) Reconstituting the immune system in sufficient detail and complexity in a cell culture dish and testing vaccine candidates in this model;

2) Moving straight to studies using human volunteers would be an excellent system in which to test our vaccine candidates;serve as an excellent model to study the role of the glycoconjugate vaccines against Group A Streptooccus (GAS), as they naturally colonise and infect only humans.

Why were they not suitable?

The immune system cannot yet be reconstituted in a cell culture dish in sufficient complexity to produce the types of responses seen in intact animals and humans (for example, we cannot "input" a vaccine in a cell culture system and measure antibody production as an "output"). Direct human trials will not be not feasible until there is sufficient evidence of safety and the ability of the vaccine candidates to induce the desired response in animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will perform a number of small pilot studies to validate, optimise and screen vaccine candidates and compare them, where applicable, to recently reported candidates.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our preliminary pilot studies have allowed us to estimate the likely variation in immune responses and to choose a default group size for future experiments. Further small-scale studies with new candidate vaccines will ensure that we can optimise the dosing regimes and the number of animals in each experimental group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will share tissues with other groups highly experienced in dissecting the immune response to aid us in our investigations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a standard mouse model of immunisation to induce an immune response. The use of adjuvant and subsequent boosters may be required to enhance the immune response to the vaccine candidate, but we do not expect these to cause significant adverse welfare effects.

Why can’t you use animals that are less sentient?

We require adult mice in which the immune system is fully mature and to keep these animals for a few months in order to measure the development of the immune response to a vaccine candidate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use clinical scoring systems in order to monitor mice during experimental phases. Mice will be handled in advance of starting experiments, in order to acclimatise them. Procedures will be carried out by experienced and competent staff.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the NC3Rs for best handling and procedure practise, and will adhere to LASA guidelines on dosing.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive the NC3Rs email updates on recent advances, as well as staying informed via our local NIO and animal users group forum.

192. Novel mechanisms of co2 signalling in the physiological systems

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

breathing, neuropathy, neural circuits, metabolism

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We wish to understand how CO2 can act as a signalling molecule to control physiological processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

CO2 is an unavoidable by product of cellular metabolism. Historically, CO2 has been regarded as a waste product rather than a molecule that carries information. Even for physiological processes that are well known to be “CO2 sensitive”, such as breathing or cerebral blood flow, the actions of CO2 are often considered to occur only via consequent changes to pH. This is because CO2, through its ready reaction with water and production of bicarbonate and hydrogen ions, is a prime determinant of physiological pH.

Our work, over the past 10 years, has changed this by identifying a small group of membrane channels called connexins that directly interact with CO2, which controls their opening and closing. The CO2 sensitive connexins are expressed in many organs of the body including brain, liver, kidney and skin. Mutations of these connexins cause a range of pathological conditions that include hearing loss, fatal syndromes such as Keratitis Ichthyosis Deafness Syndrome (KIDS), and neurodegenerative diseases that include X-linked Charcot Marie Tooth disease. Some of these pathological mutations affect the CO2 sensitivity of these connexins, suggesting that this property could be important physiologically and its loss could contribute to disease. We have already shown that one of the CO2-sensitive connexins, Cx26 plays a key role in the sensory control of breathing. This programme of work seeks to uncover further roles of CO2 signalling mediated by the connexins. Given the pivotal role of connexins in human health and disease, our work is likely to provide better knowledge of the mechanisms of disease and hence enable earlier diagnosis and better treatments

What outputs do you think you will see at the end of this project?

1. Creation of fundamental new knowledge concerning the control of physiological processes such as breathing, arousal, maintenance of myelin via CO2 signalling including identification of the molecules that are critical to this process and the neural cells and circuits that are involved.

2. Molecular and genetic tools that will allow analysis of CO2 dependent signalling. These will include methods to directly measure the production of CO2 in tissue with subcellular resolution, and to alter the CO2 sensitivity of endogenously expressed connexins to test the role of CO2 dependent signalling in physiological processes.

Who or what will benefit from these outputs, and how?

<u>Primary benefits</u>

1. Dissemination of novel information by publishing papers in international journals and presenting our findings at scientific meetings and conferences. This will benefit the research community as the outcomes of this project will provide significant advances in knowledge in the following fundamental areas of neuroscience: understanding the mechanisms of how CO2 triggers arousal and wakefulness; the neural circuits and signalling controlling breathing; and the signals that are required for the development and maintenance of healthy myelinated nerves.

2. The research community will benefit from the molecular and genetic tools that we generate and plan to make available for use by others. These will be validated by our own work and will enable others to use them in their own discovery-led research. For example the genetically encoded sensors will be critical for others to examine the production of CO2 other physiological contexts and even other organ systems.

<u>Secondary benefits</u>

1) **Pharmaceutical industry**

The results generated from this project will be of significant interest to the pharmaceutical industry in respect of identifying potential new targets for drug development (connexins) and new ways to target them. Our work will provide understanding for the scientific basis of pharmaceutical intervention in respect of the pathophysiological outcomes of connexin mutations which will manifest as central apneas (with resulting comorbidities such as enhanced risk of diabetes and cardiovascular disease), defects of arousal from sleep, and diseases of myelin.

2) Government, society and economy

Connexin mutations are relatively common. For example mutations of Cx26 cause deafness in ~1:3000 people. Mutations in Cx32 cause X-linked Charcot Marie Tooth disease (CMTX, a peripheral sensory and motor neuropathy, sometimes accompanied by cognitive deficits). In the UK about 25,000 people are estimated to have CMT making it the commonest inheritable neurological condition and about 10% of these will have the X-linked form caused by Cx32 mutations.

Our data shows that some of the pathological mutations affect the ability of these connexins to detect CO2. In the case of Cx26, this implies that the CO2-dependent processes such as control of breathing, and arousal will be altered in these people and they may be at greater risk of developing sleep apnoea and consequent comorbidities. Our work could help to predict these outcomes and in turn could lead to timely preventative treatment that would improve their quality of life and have a large impact on the NHS. For Cx32, our work may permit better stratification of risk in CMTX patients, and possibly tailored treatments depending on the nature of the mutations and their effect on the molecule.

How will you look to maximise the outputs of this work?

Dissemination of results and knowledge to the scientific community via scientific papers and meetings. Putting novel resources onto searchable databases and repositories so that others can access and use them.

Collaboration with other groups to assist them in applying our methods, resources and tools in their own research. Dissemination of knowledge to the wider community through public engagement activities, engagement with relevant charities (e.g. Deafness, CMTX).

Press releases on publication of key findings that will have major impact.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice throughout the project as they are an excellent genetic model. This gives the advantage of a rich suite of genetic strategies to target specific cell populations in the brain and nervous system either to specifically record their activity, manipulate their activity, or alter their gene expression. These strategies are essential to allow rigorous analysis of the underlying mechanisms. Genetic manipulation of mice to introduce key mutations in connexin genes or to delete these genes recapitulates the pathologies that occur in the human diseases associated with mutations in these genes.

Typically, what will be done to an animal used in your project?

A small hole will be made in the skull to enable precise injection of virus particles to give expression of a gene that will: delete expression of a key gene or genes in a specific cell population; introduce altered function of endogenous genes; activate or inhibit populations of cells to test their function; or report the activity of the cells that it is expressed in by its intensity of fluorescence.

Where possible the mouse will be killed under terminal anaesthesia to provide tissue to allow us to study signalling mechanisms and function in vitro. Where this is not possible, because for example we need to study behaviour such as breathing or arousal from sleep, we shall keep the mouse for up to two months post surgery. During this time we will use a variety of non-invasive tests to measure arousal or breathing to examine the effect of our manipulations.

In mice where we need to directly measure the activity of neurons or other cells during behaviour, 2 weeks after recovery from injection of viral particles, another hole will be made into the skull and a special lens implanted into the brain so that the fluorescence from active cells can be measured. At this time electrodes may also be implanted to allow the recording of brain waves. The mouse will be allowed to recover and a further week later a special baseplate will be glued to the head in a final minor surgical procedure. This baseplate allows mounting of a minimicroscope that will allow recording of neural activity as the mouse behaves normally. We shall keep the mouse for up to 2 months following the final procedure to allow behavioural and physiological testing.

What are the expected impacts and/or adverse effects for the animals during your project?

The surgical procedures cause short lasting pain that will be mitigated using analgesia, but following recovery there are minimal adverse signs. Our behavioural testing is non-

invasive and does not cause adverse effects. We do not expect the viral genetic manipulations to cause harmful phenotypes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities are moderate in all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project seeks to understand: the contribution of CO2-sensitive connexins to functioning of the nervous system –specifically CO2-evoked reflexes involved in the control of breathing and arousal; axon-myelin communication in the context of the causes of peripheral neuropathies. As these are phenomena that arise in the whole organism they can only be studied in whole animals and tissues taken from animals. Rodents are generally accepted as being good models for these aspects of human physiology. It would be unethical to use human subjects in these experiments.

Although we will still need to perform the viral transduction procedures to label, manipulate or monitor key populations of cells, we shall also use ex vivo preparations to assess the effects of these manipulations as much as possible. Additionally, we have replaced use of animals in our molecular/biochemical investigations. For example our use of the HeLa cell expression system will allow us to the test the effects of connexin mutations prior to development of viruses for in vivo experiments. Together this combination of ex vivo and in vitro work will act as a replacement, minimizing rodent numbers by only using effective mutations and genetic tools and remove risk from subsequent work on whole animals.

Which non-animal alternatives did you consider for use in this project?

Cultured cell lines, organoids, computer modelling.

Why were they not suitable?

Cultured cell lines. While these can be useful for examining properties of mutant connexins or evaluating genetic tools prior to use in vivo (and we use them for this), these cells

cannot reproduce the complete physiological functions such as breathing, arousal, nerve conduction that we wish to study.

Organoids. These have not reached the level where they can reproduce the mechanisms and interacting systems that we need to study to advance the field.

Computer modelling. All good models require data to allow them to be realistically specified and hence useful as predicted tools. We simply lack sufficient data to enable this approach as a realistic way forward.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have considered the range of experiments and manipulations that we need to perform to advance knowledge. Using information from our prior work or the work of others we can calculate the numbers we need to give definitive results that we can be confident will be reproducible by others.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used the best estimate of effect size based on pilot data or published literature to inform our power calculations. As the behavioural tests we use are non-invasive, we can use a "repeated measures" design to increase the confidence in our data without causing suffering, and hence use this design to reduce overall animal usage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We shall ensure all personnel are highly trained and skilled so that very few experiments will fail for technical reasons.

Pilot studies will be performed to get good estimates of effect size, feasibility, and ensuring that all technical problems have been anticipated and solved. Should our program demonstrate that our estimates of effect size are wrong (either too big or too small) we shall reperform the power calculations to ensure we arrive at a rigorous outcome. If it appears that the effect size is much smaller than anticipated for a particular experiment, we shall consider abandoning that part of the program. We shall routinely harvest tissue to

enable biochemical, genetic, cellular and morphological analyses and share this tissue with our collaborators.

We shall use efficient breeding strategies to minimize the number of animals that are bred. In some case we may have to maintain lines as heterozygotes meaning that animals (which do not carry the gene of interest) cannot be used. Where at all possible such animals will be used for control comparisons giving the benefit of identical genetic background, however this means that we will unavoidably breed more animals than we will use in procedures.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents are a well-established model for studying the breathing and arousal. They are also used to examine mechanisms of myelination and the effects of connexin mutations more generally. This gives a robust literature and wealth of potential data obviating the need to repeat past findings. Rodents in general are seen as a simplified and experimentally tractable model for far more complex mammals such as humans.

Wherever possible, physiological testing of phenotypes will be achieved by using non-invasive methods such as: whole body plethysmography for detection of breathing movements. More invasive procedures will be used only when there is good reason (from the non-invasive experiments) to expect mechanistic insight.

We shall use ex vivo tissue as much as possible to study cellular mechanisms relating to the neural circuits relaying chemosensory signals, and axon-myelin communication. This will enable future in vivo experiments to be appropriately designed to minimize animal usage.

Why can’t you use animals that are less sentient?

We wish to examine these phenomena in a mammalian system to have maximum applicability to the human condition. By choosing mice, we have chosen a model that has the lowest sentience.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have considerable experience with the in vivo imaging methods and have considerably refined them already over the past 2-3 years. We have implemented standardised post-operative monitoring methods to ensure that outcomes and adverse effects from our surgical procedures are carefully assessed. We use this information to optimise post-operative care and pain management.

We shall use rigorous aseptic techniques to protect against infection of the animals.

We train the animals with a dummy camera to acclimate them to the imaging procedure and to the imaging cage to minimize stress.

As imprecise targeting of viral injections can increase animal usage, we shall be very careful in this aspect of our procedure. We shall ensure we use calibrated stereotaxic frames, check the alignments thoroughly and regularly use the injection of fluorescent beads (in a non-recovery terminal procedure) to ensure that correct targeting is achieved.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We shall take careful note of advice from collaborators and researchers highly experienced in these methodologies to ensure that we refine our experiments as much as possible. We shall follow the Laboratory Animal Science Association guidelines on performing aseptic surgery to ensure best practice for the recovery surgery involved in all surgical procedures.

To ensure effective and rigorous reporting of our results, we shall write papers according to the ARRIVE guidelines which are recognised as providing excellent transparent standards for reporting of research using animals and were developed by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular communications from NC3Rs and Laboratory Animal Science Association (LASA) via a newsletter, colleagues who advise on best practice, and the NACWO, NTCO, NIO and AWERB at our establishment. We consult the NC3Rs and

193. Nutrition of growing and mature ruminant livestock

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
    - Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Ruminants, Production, Feeds, Efficiency, Methane

Animal types	Life stages
Cattle	adult, pregnant, juvenile
Sheep	adult, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

There is a need to maintain the home-grown production of foods produced by livestock (i.e., milk and meat) in the UK, to support the agricultural industry (including for non-food products, e.g., novel packaging) and reduce the reliance on imported foods. The aim of this programme is to increase our understanding of the mechanisms that contribute to the inefficient use of feeds by cattle and sheep, and therefore enable us to reduce the output of pollutants such as nitrates, ammonia, and methane while continuing to produce nutritious food for people.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will allow an improved understanding of the interactions between feed and rumen microbes (colonisation, degradation, fermentation, and microbial protein synthesis) that will improve the efficiency of diet utilisation. This will improve the output of ruminant livestock products and help reduce the environmental impact of ruminant agriculture. For example, an improvement in the use of feed protein for meat and milk production will reduce the amount that is excreted, thereby reducing nitrous oxide (a greenhouse gas) and ammonia release into the atmosphere. Improved understanding of the roles of the rumen microbiota has the potential for development of new products for industrial application based on the specialist activities needed for fibre degradation.

What outputs do you think you will see at the end of this project?

The outputs of this project will likely be new information that will be disseminated to farmers, to other scientists, and to policy-makers in government. The information will be published as reports, information sheets, articles in popular magazines and specialist periodicals, and in the peer-reviewed literature.

Who or what will benefit from these outputs, and how?

Beneficiaries of these outputs are envisaged to include, i) the general public and the farming industry, through an improvement in the production efficiencies of meat and milk and associated reductions in pollutant emissions, and ii) government departments (e.g., Defra) and devolved administrations (e.g., Welsh government) with improved knowledge of the consequences of the development of novel feeds and feeding strategies. Ruminant livestock are vital to the livelihoods and nutrition of the global population, by consuming and converting feeds that humans cannot eat into highly nutritious foods that we can eat. However, we know that ruminants contribute to climate change through the emissions of greenhouse gases (methane and nitrous oxide), and we therefore need to continue to develop ways of improving production systems that minimise pollutant outputs and maximise useful products.

How will you look to maximise the outputs of this work?

We always aim to publish the results of work that we carry out in the peer-reviewed scientific literature, regardless of whether the work was deemed successful or otherwise. Some work is funded in collaboration with industrial partners, and even in those cases we aim to publish results, although sometimes there is an agreed delay to this to allow the companies to exploit an intellectual property that is generated. We aim to maximise the availability of publications by publishing open access articles.

This means that the information is available to anyone, not just those individuals or organisations that subscribe to the journals that we publish in.

Species and numbers of animals expected to be used

- Cattle: 400
- Sheep: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To understand the benefits, or otherwise, of feeding different diets to animals, and to measure the effects on the production of meat or milk, it is essential to use growing or lactating livestock. The way young animals are cared for in early life can have significant consequences on how they grow or how well they produce milk later in life. For this reason, it is important to be able to work with animals, from just after birth, until they reach maturity and are productive in later life.

Typically, what will be done to an animal used in your project?

A small number of animals, approximately 20, will be fistulated at the rumen (cattle and sheep). Fistulation is a surgical procedure that creates is a hole (fistula) in the side of the animal (similar to a colostomy procedure in humans) to allow direct access to the rumen and its contents. The fistula is maintained by a rubber cannula that seals the hole, but which can be opened when samples of rumen contents are required. Following surgery, these, and other animals used by the project, will be subjected to regulated procedures such as restraining them in stalls to measure feed intake, taking blood samples, and collecting outputs of faeces and urine using harnesses and chutes. Some animals will be used in short-term research that may last for between 2 to 4 months, whereas other animals will be monitored for several years as part of their normal growth and development. These procedures carry a mild level of severity. At the end of the procedures, those animals that have not been surgically modified will be re-homed in the establishment's herd or flock, sold to another farm, or will be sent to slaughter as part of the normal supply chain for human consumption. Those animals that have been surgically modified are a valuable resource, and if their general health and well-being is still good they will be transferred to another project licence. Fistulated animals often live for longer than a cow or sheep on a commercial farm and will be euthanised when their general health and well-being starts to deteriorate, for example with the onset of arthritis.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may be restrained in metabolic crates or by using neck yokes, which prevent full freedom of movement necessary to allow the collection of data and samples for experimental purposes. This restraint may last from a few minutes during the collection of rumen fluid from fistulated cattle to several weeks during a feeding experiment. Animals are likely to experience pain for a few days following fistulation surgery, although this will

be managed using suitable pain relief medication. Animals that are blood sampled or have substances administered using a needle and syringe (e.g., anaesthetics) may experience mild transient pain when the needle is inserted. The collection of urine from cattle requires the use of equipment that is temporarily glued over the vulva of the animal for a few days - this sometimes causes skin irritation that is treated with a soothing ointment and there is no lasting harm caused by this procedure. Collection of rumen contents using a stomach tube through the mouth may cause temporary discomfort lasting a few moments as the tube is inserted, although this is minimised by temporary restraint of the animal, and the fitting of a halter that enables the animal's head to be appropriately positioned to allow easy swallowing of the tube or probe. The use of equipment to collected breath samples from the animals requires the use of head collars and/or neck collars to attach sampling tubes and collection cylinders; this may initially cause mild distress in some animals for a few minutes but the risk of this is minimised by training them to become used to the equipment before it is used for experimental collections.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The surgery for fistulation, for both sheep and cattle, is a moderate level of severity. Approximately 5% or less of the animals studied will be fistulated - all other animals will only experience procedures that are expected to be mild or sub-threshold.

What will happen to animals at the end of this project?

- Killed
- Kept alive Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For some of the work, measurement of growth or milk production of animals fed well-defined diets is required. In addition, whole-body utilisation and partitioning of nutrients between productive and non- productive (pollutant) outputs may be measured. These data cannot be collected using in vitro techniques, and therefore animals must be used for those parts of the work. The rumen microbiota cannot be maintained outside the animal. Therefore, access to fresh, well-characterised rumen fluid samples are essential for the primary research objectives of this project.

Which non-animal alternatives did you consider for use in this project?

We already use some laboratory methods for initial screening of feeds for, e.g., the potential to produce methane when fed to ruminant animals. These methods are very helpful in being able to rapidly and cheaply assess large numbers of feed samples that are available only in small quantities and allow us to prioritise those to produce in larger amounts for further study.

Why were they not suitable?

Although in vitro methods are very useful, they still require the use of fistulated animals to act as donors of well-characterised and consistent rumen fluid. Rumen fluid sourced from, e.g., abattoir, is not representative of that obtained from a live animal because livestock sent for slaughter have feed withheld for a day before. Furthermore, investigations requiring the measurement of growth or milk yields, and samples of meat or milk, need to use live animals to do this.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated based on experience of previous experimental work in this area.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The minimum number of animals required to carry out an experiment, using an appropriate experimental design, that produces statistically valid results will be used. The type of experimental design chosen will depend on the animal type and measurements being collected. For lactating dairy cows being offered different dietary treatments, for example, changeover design (e.g., Latin square) experiments are particularly efficient because each animal receives each treatment, and therefore each animal effectively acts as its own control. However, changeover design experiments are not appropriate for some studies (e.g., growth studies), and therefore more animals are typically required per treatment in order to control variation. In this type of experiment, a set of measurement steps may be carried out on animals of different ages (e.g., 4, 6, 9 and 12 months of age) to assess the interaction between an imposed treatment and age.

For all experiments, it is important to consider what data and statistical analysis methods will be used

before the start of the data collection. This ensures that appropriate measurements are made and can be analysed in a statistically valid manner. Consultation with a statistician during the planning of an experiment is important, to make sure that animal numbers are appropriate, and that the latest statistical methods can be employed during the data analysis part of the experimental process.

Statistical blocking of animals during the experimental stage is important to reduce variation caused by known factors, such as breed, age, gender, stage of lactation and parity. Careful choice of animals, and grouping to reduce known variation, is important to help reduce the numbers of animals needed for an experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Work to be carried out on this project licence will generally benefit from prior knowledge of variation in expected data that will be collected. This helps define the numbers of animals needed for an experiment. This knowledge can be gained from previous work carried out by the applicant, or from studies published in the literature. However, if a particularly novel treatment will be applied, where the effects are completely unknown, a pilot study will be carried out to with a small number of animals to generate data that will be used to inform the design of a larger study using more animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For much of the work the effects of treatments on feed intake, live weight change, milk production, milk composition, and/or nitrogen and methane excretion in/from cattle and sheep is required. Therefore, sheep and dairy cows are the animals most suitable for use in this work.

Assessment of animals prior to fistulation in Protocol 1 is vital to the long-term success of the use of these animals. Animals are initially selected from a larger group on the basis of age, parity, fitness (e.g., no history of mastitis leading to loss of udder quarters), and

knowledge of temperament (e.g. not known to kick while being milked), and candidates for fistulation are housed temporarily in the metabolism unit stalls to ensure they are able to use them comfortably. For example, some animals are not able to easily stand up or lie down in the stalls, and these are rejected before surgery.

Sampling of digesta contents that leave the rumen (and enter the omasum) may be carried out using the omasal sampling technique. This entails inserting a sampling line through the rumen fistula and through the reticulo-omasa orifice. It allows the collection of samples of digesta that have undergone fermentation in the rumen but have not been digested within the omasum/abomasum. This is important for studying, e.g., rumen passage rate (coupled with the infusion of digesta markers into the rumen at known rates), and can be done using animals that have not been fistulated at the duodenum. However, it can only be done in mature cattle because the omasal sampling line must be inserted manually by a technician placing an arm through the rumen fistula. However, the use of this method means that duodenal fistulation is not required.

Why can’t you use animals that are less sentient?

This work needs to be carried out on growing and mature productive animals, to assess the effects of treatments on growth and lactation

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For those procedures requiring surgery (i.e., gut fisulation), a sedative will be administered to reduce the stress of anaesthesia on the animal. Forrumen fistulation of mature dairy cows, sedated animals will be supported using a belly-strap and a radial block will be induced using administration of local anaesthetic. Rumen fistulation of young cattle and of sheep will be carried out under general anaesthesia induced and maintained by inhalation following tracheal intubation. The sedation and anaesthetic regime will be devised and refined under the advice and supervision of a veterinary surgeon. To ensure correct operation of the anaesthetic machine, it is serviced and calibrated by a qualified specialist anaesthetic equipment technician prior to a series of surgeries.

Fistulation of the rumen in adult cows is carried out under sedation and local block anaesthesia. Recovery from this is much quicker than from general anaesthesia, so normal behaviour tends to resume more quickly (e.g., feed intake) and a lactating cow can be returned to a stall and be milked there. Surgically modified cows are not run with the main herd cows and are milked in stalls using a milking line, rather than being milked through the main herd milking parlour equipment (currently milking robots). This reduces the risk of cannulae being knocked out by other cows or by rubbing against farm gates/walls in a packed herd. The latter can still happen in a smaller group, but the risk is markedly reduced.

Food and water are withdrawn before surgery to reduce the amount of gut contents, thereby reducing the risk of inhalation of rumen contents during intubation and induction of

anaesthesia, and also reducing the risk of leakage of digesta during cannula placement. During surgeries that last longer than approximately 1.5 hours, a saline drip is infused into the jugular vein to reduce animal dehydration.

Following surgery, digesta contents may leak past the cannula through the fistula causing local skin irritation. Fistulation sites will be washed daily, and if any signs of skin irritation are apparent (e.g., dry/discoloured skin, sores or lesions, hair loss), they will be treated with a soothing ointment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Procedures requiring surgery will be carried out using aseptic techniques employed as recommended by the LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery (second edition).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Discussions with NACWOs and other PPL holders is an important part of ensuring that the latest and most appropriate methods in animal research are understood and used where possible. The 3Rs is a standing item on the organisation's AWERB agenda, which allows an open discussion at each meeting to ensure new methods of good practice are shared among all named persons. The NC3Rs has a monthly newsletter that provides updates on funding opportunities and publications, some of which may be relevant to the work and animal species that will be carried out and used under the authority of this project.

194. Investigation into the mechanisms causing acrodysostosis type 2 and related therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Acrodysostosis Type 2, Skeletal dysplasia, Cognitive function, Hormone resistance, Therapy

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to characterise a novel mouse model for the rare childhood and developmental disease Acrodysostosis Type 2 (ACRDYS 2). This disease is caused by a single change in a gene called phosphodiesterase-4 subtype D (PDE4D). This mouse model will allow us to better understand how mutations in the PDE4D gene leads to the different ACRDYS 2 symptoms in various tissues (e.g. brain, bone, fat) in the body and develop treatments that target specific tissues or the whole-body that can be brought forward to patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Acrodysostosis type 2 (ACRDYS 2) is a rare developmental disease where patients have a variety of symptoms such as small birth size, short height in adulthood, obesity, facial malformations, bone defects, reduced response to certain hormones and impaired brain functions. ACRDYS 2 is caused by genetic changes in the phosphodiesterase-4 subtype D (PDE4D) gene. The main role of PDE4D is directing the activity of key functions across several cells and organs throughout the body. In ACRDYS 2, the activity of PDE4D is abnormally increased. While the genetic cause of ACRDYS 2 is well understood, it is not clear how the increased activity of PDE4D leads to the range of symptoms observed in patients. Furthermore, there are several commercially available drugs that block the activity of PDE4D that could benefit ACRDYS 2 patients. Unfortunately, there are currently no animal models of the disease to allow these research questions to be correctly and thoroughly addressed. We therefore propose to characterise a novel mouse model for ACRDYS 2 that will carry the same genetic change found in ACRDYS 2 patients, termed S190A. This specific S190A change was chosen as it has previously been demonstrated to be defective in cell models and is located in a very important area that regulates its activity and function in cells. The animals will be observed to ensure that they have similar symptoms as ACRDYS 2 patients. This novel PDE4D S190A mouse model will be an invaluable tool for scientists, doctors and patients to help better understand the different components of the disease and importantly, develop new treatments that can prevent and/or slow down its progression.

What outputs do you think you will see at the end of this project?

SHORT-TERM:

- Characterisation of a novel ACRDYS 2 mouse model that will be made available to other researchers
- Evaluation of the therapeutic potential of commercially available PDE4D inhibitors
- Attendance and presentation of results at several national and international conferences
- Open access publications that adhere to ARRIVE guidelines

LONG-TERM:

- Mechanistic insights into ACRDYS 2 pathophysiology
- Development of new treatments
- New collaborations with clinical teams and industrial partners
- Acquisition of follow-up funding

Who or what will benefit from these outputs, and how?

This new transgenic mouse model will directly contribute to fundamental researchers and clinicians in the ACRDYS 2 field, providing a valuable pre-clinical model to better understand the pathophysiology of the condition and evaluate the potential of drug repurposing strategies. In addition, this model will be beneficial to academics and clinicians in the larger field of pseudohypoparathyroidism (PHP) and related disorders (e.g. PHP type 1A, PHP type 1B, pseudopseudohypoparathyroidism (PPHP), progressive osseous heteroplasia (POH) and ACRDYS 1), allowing the deciphering of pathological similarities and distinctions between each condition and providing an additional resource to evaluate potential treatments across a family of related conditions.

Interestingly, there has been a recent interest in the PDE4D gene as it has been implicated in Alzheimer’s disease and general cognitive performance. Thus, once we have completed the preliminary assessment of cognitive (dys)function in this transgenic mouse model, we believe that it will generate great interest from fundamental researchers and clinicians in the ageing and neuroscience fields alike and be used for further mechanistic and therapeutic investigations.

Finally, as these transgenic mice are predicted to display a range of distinct symptoms, we anticipate that they will also be useful to academics and clinicians in a number of research fields such as bone development and growth, endocrinology and metabolism.

Thus, by characterising a novel mouse model of ACRDYS 2, we will also be contributing to wider national and international scientific, clinical and public communities.

How will you look to maximise the outputs of this work?

Dissemination of results will be achieved by presenting our work at national and international conferences, publishing in open access journals and through wider public engagement endeavors (e.g. general awareness events, academic profile page, professional Twitter account). Furthermore, our collaboration with the patient organisations will provide multiple opportunities to share our work with the Acrodysostosis community.

Species and numbers of animals expected to be used

- Mice: A maximum of 1425 mice is estimated to be used during this 5-year project, which includes breeders and experimental mice (genetically modified and wild type).

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To understand how ACRDYS 2-causing mutations in the PDE4D gene lead to the whole-body presentation of ACRDYS 2 over the life course and to evaluate the impact of

therapeutic interventions on these symptoms during disease progression, a whole-body complex system such as a representative mouse model is required.

Typically, what will be done to an animal used in your project?

Typically, an animal will be aged to 3, 6 and/or 12 months, be weighed weekly and undergo a learning and memory test. A small number of animals will also be given a drug by daily injections.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects expected are based on the manifestation of this rare disease in patients: bone malformations, underdevelopment of facial bones, learning disabilities, delays in motor and coordination abilities, impaired response to hormones, obesity and delayed growth and development (at birth and subsequently). These symptoms occur equally in males and females and are either present at birth or in the early stages of life. With early diagnosis and interventions, children with Acrodysostosis Type 2 can reach their full potential and expect a normal life expectancy. We therefore expect the novel transgenic mice to have a smaller birth weight, a delayed growth spurt, shorter or malformed bones, impaired learning and memory abilities throughout life and increased weight gain over time. In addition to these adverse symptoms directly related to the PDE4D S190A mutation, brief instances of pain may also be felt during drug injections. All adverse effects are minimised by very close monitoring of mice with designated score sheets and selecting appropriate humane endpoints.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Subthreshold: 5%
- Mild: 20%
- Moderate: 75%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is a scientific need for an ACRDYS 2 mouse model to inform on how the disease starts and how it progresses as well as evaluate and develop new treatments. As ACRDYS 2 affects several organs and systems across the whole-body, a whole biological system is required to optimally investigate how different tissues and organs act individually and together to cause the disease.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives such as mathematical modelling, cells and tissues were considered and not deemed appropriate to achieve the aim of this project.

Why were they not suitable?

To understand how ACRDYS 2-causing mutations in the PDE4D gene lead to the whole-body presentation of ACRDYS 2 over the life course and to evaluate the impact of therapeutic interventions on these symptoms during disease progression, a whole-body complex system such as a representative mouse model is required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Using commonly used and approved software programmes and guidelines such as the NC3Rs Experimental Design Assistant, ARRIVE Guidelines 2.0 and G*Power software as well as previous relevant experience with similar studies, both from our research group and published by others. Power calculations were based on previous literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Using commonly used and approved software programmes and guidelines such as the NC3Rs Experimental Design Assistant, ARRIVE Guidelines 2.0 and G*Power software. Power calculations were based on previous literature .

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Efficient breeding strategy to produce the maximal number of experimental mice of the desired genotype (genetically modified and wild type).
- Use of both females and males.
- Use of control cohorts across several analyses.

- Collection of blood and multiple tissues from one single animal for multiple analyses.
- Use of the same animal to undergo the same memory and learning test at different ages.
- Tissue sharing (if appropriate).
- Constant review of results to amend experimental plan if necessary.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- We will be using genetically modified mice that harbor a single mutation in the PDE4D gene (PDE4D S190A) to produce a model of ACRDYS 2.
- We will also use non-genetically modified animals.
- The memory and learning and motor function tests are commonly used and they have been designed to provide scientifically valid data whilst minimising exposure to pain, suffering, distress or lasting harm to the animals.
- In instances where drugs are administered, they will be administered via a brief prick to minimise pain and lasting harm to animals.

Why can’t you use animals that are less sentient?

We have considered less sentient animals such as fish, worms and flies but these are inadequate for the successful achievement of the aims of our project as:

- There is a scientific need for a mammalian animal model of ACRDYS 2 that closely resembles the human disease.
- Different ages (e.g. juvenile, adult, aged) are required to assess the progression of whole-body symptoms during the life course of the animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Undertake an initial study with only a small number of animals to begin with. A larger study with more animals will only be undertaken following discussions with expert personnel (e.g. veterinarian).
- Review and adapt experimental plan (e.g. ages used) as data in earlier ages are analysed.
- Use score sheets to monitor well-being of aging animals or those undergoing memory and learning tests. The score sheets will be developed and reviewed by expert personnel (e.g. veterinarian).
- Have a habituation session for animals undergoing memory and learning tests to allow them to adapt and familiarise themselves with the test.

- Add padding to elevated tests (e.g. rotarod) to avoid injury.
- Place animals in a warming chamber to keep them warm after the memory and learning tests.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to the resources provided on the NC3Rs website and the ARRIVE Guidelines 2.0.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

- By accessing the information on the NC3Rs website: https://nc3rs.org.uk/experimental-design
- By participating in relevant workshops.
- By updating the NC3Rs Experimental Design Assistant diagrams as the project progresses.

195. Neural mechanisms of visual cortical plasticity

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

vision, rodent, cortical plasticity, imaging, electrophysiology

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The goal of this project is to reveal key cellular and circuit mechanisms employed by the adult brain to adapt and change in response to natural and artificial experience. We will combine genetic manipulation with chronic imaging / electrophysiology to study various forms of neuroplasticity in the intact adult animals, at synaptic, cellular, and circuit level.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
The limited plasticity in the adult brain is responsible for reduced visual learning ability and incomplete vision recovery from injury, diseases, and ageing. The successful completion of this project will uncover important biological principles governing plasticity that can be generalised to other visual pathways and higher species, providing us a mechanistic framework for potential therapeutic interventions to promote rehabilitation and visual perceptual learning in adult human patients.

What outputs do you think you will see at the end of this project?

Completion of these objectives will provide a biological basis how visual plasticity in the adult brain can be achieved through interactions within local cortex and interaction with other brain areas. In the process, we may uncover important principles governing plasticity that can be generalised to other cortical areas and in higher species.

Who or what will benefit from these outputs, and how?

In the short-term, the research output is of direct interest to neuroscientists in the field of sensory development and plasticity. The brain maintains a lifelong capacity to undergo structural and physiological changes, which was once thought to happen only in the developing brain. This project will reveal key cellular and circuit mechanisms employed by the adult brain to maintain this capacity, especially emphasising on the less studied interneurons and neuromodulatory pathways.

In addition, the physiological and anatomical results in vivo and ex vivo will be useful for comparative analysis, enabling the field to form a comprehensive view of cortical plasticity and promoting the computational modelling and ex vivo research that can replace in vivo work.

In the long run, our knowledge in neuroplasticity might contribute to translational research for designing mechanism-based therapies for cortical functional recovery. For example, understanding the process of cortical plasticity resulting from electrical stimulation is critical for optimal design of stimulation-based therapies in treating human patients with malfunctional brain.

How will you look to maximise the outputs of this work?

Our scientific findings and other resources will be provided to broad communities through publications and presentations. We will also partner with bioengineers and clinical

scientists to promote translational research focusing on enhancement of brain function or recovery from disease and injuries.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used as the animal model in the proposed project to study visual cortical functions and plasticity. This choice is in line with prevalent opinions in the past decades, due to 3 major reasons.

First, rodent visual system shares important similarities with that of larger mammals, like carnivores and primates. For example, functional and anatomical evidence confirmed that visual information in mice is also streamed in ventral-like and dorsal-like pathways, together with a complexification of the processed features along the hierarchy. These across-species preserved architectures suggest fundamental commonalities in the underlying computations.

Furthermore, the accessibility of increasingly powerful experimental approaches in mice, including transgenic manipulation, optogenetics, and two-photon imaging, that makes it an ideal model to dissect the underlying neural circuits.

Finally, rodent models also offer great potential to explore behavioural and cognitive processes that rely on vision, including visual perception, vision-guided choice, and vision-innate behaviour link.

Typically, what will be done to an animal used in your project?

Wild type and genetically altered (GA) mice will be bred, genotyped, and maintained. Animals will go through surgical procedures to allow chronic imaging/recording over days (no water restriction, usually 1-2 hours each day, for a few days to months). After recording in intact animals either in awake behaving states or under anaesthesia, the brain issue might be collected for ex vivo anatomical and/or physiological characterization for comparative analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

To allow access to the brain via optical or electronic means, the mice undergo surgical procedures. During these procedures they are fully anaesthetised and they do not experience pain. Effective analgesia is provided after each surgery. Use of sterile techniques, strict analgesic regimes and careful monitoring of the animals during and after the surgery minimises any potential pain or distress experienced by the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severities are expected for the experimental animals.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our experiments aim to understand the long-term of brain activities that result from natural and/or artificial experiences. Therefore, we will perform experiment in the intact animal, and in various behavioural states (running, still, anesthetized).

Which non-animal alternatives did you consider for use in this project?

In vitro preparations and neuron network modelling are considered to study the neuronal circuit plasticity as non-animal alternative.

Why were they not suitable?

Sole in vitro preparations are unable to answer the proposed answers, because 1) we want to understand the long-term (days to weeks) changes of neural network activities in intact animals; 2) we aim to study how animal's behavioural states (running or still) change affect this process. However, we will keep track of research literature about specific 2D/3D cortical organoid model in the field to seek appropriate alternatives. We also propose to conduct research using in vitro preparation after in vivo measurement to enhance the general scientific conclusions and build links between the two systems, providing a basis for the replacement in the future studies.

Computer modelling requires the in-depth knowledge of the connections between cells and visual function. The parameters for modelling needed to constrain such simulations are currently unclear. In fact, a side benefit of our research is to provide some of these parameters to enable in vitro preparations and computational studies in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We aim to use the minimal number of animals consistent with previous knowledge and experience working in the field of visual neuroscience. We estimate the total numbers of

the animals based on the transgenic breeding, successful rate of the surgical procedures, and completion rate of the trainings.

The historical and published data for all the techniques named in this project also provide an estimation of variance for many planned experiments, which allows us to decide the number of animals required to provide robust experimental results using statistical power calculations.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experiments are carefully planned in order to minimise the number of animals needed to obtain enough data to achieve the aims of the different projects.

Experiments will be designed according to the NC3Rs ARRIVE Guidelines to ensure experimental rigour (blinding, randomisation etc) whenever possible. When necessary, we will also seek for statistical advice from professional services, such as the NC3R's Experimental Design Assistant https://eda.nc3rs.org.uk/guide.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

First, we will seek for advice on breeding transgenic lines, to avoid unnecessary production of animals. When possible, we will share common transgenic lines with other laboratories, instead of breeding them ourselves. Depending on the breeding performance of specific strains, we will strive to use intermittent breeding instead of constant mating to avoid unnecessary wastage of animals, following advice from https://nc3rs.org.uk/worked-example-intermittent-breeding.

In addition, data previously taken will be used to answer new question and we will resort to available databases (e.g. NeuroData without borders: http://www.nwb.org/allen-cell-types-database/).

Third, we have perfected techniques to record from vast numbers of neurons simultaneously and chronically. We will image/record the same population of hundreds of neurons using miniscope / 2- photon imaging / electrodes, and the animals will be tested for periods of several days to weeks and thus considerable information is obtained from each animal, minimising the total number used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project?

Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the species of choice because rodent visual system shares important similarities with that of larger mammals, and transgenic strains allow for multiple measurement/ manipulation.

Chronic optical/electric recordings in mice cause minimal pain / suffering, moreover, because they are either in an awake behaving state (head-fixed to run on a 2D/3D treadmill or freely moving), or in a well- maintained anesthetized state.

Why can't you use animals that are less sentient?

We need to study brain plasticity in the adult animals because the adult brain is less capable of change and adaptation and mechanistically different from juvenile animals. There is an urgent need to understand neural basis and find ways to promote plasticity in the adult brain. Our project will address aspects of this.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will minimise pain and discomfort during and after all the procedures performed with animals:

Surgeries will be performed under general anaesthesia. Analgesics and antibiotics will be administered as needed during and after surgery to minimise pain and reduce the risk of infection, respectively. The surgeries will be performed by fully trained and competent staff to minimise side effects and the length of the surgery. All animals will receive post-operative care to ensure a normal recovery. If any animal fails to recover from the surgery, it will be humanely euthanized by a Schedule One Method immediately.

To minimise discomfort after surgery, we will use low-weight head-plate and brain implants (the head- plate is less than 1gram, and in some cases with additional implant but less than 10% of the animal's body weight), so that the mice can move normally in their home cages and have minimized brain insults. And most of our techniques in subsequent experiments are minimally invasive, as they involve imaging through the skull or through a cranial window. If being head-fixed in a test/training rig, mice will be progressively habituated to the behavioural rigs so that they are not scared of spending time there.

Mice are cohoused wherever possible. Stress during experiment will be minimised by gently handling the animals with refined methods (e.g. cupping), and by getting them used to the experimenter. Where head restraint is required to avoid animal movement, distress will be minimised by gradual habituation– for example, 15 mins on the first day, 30 mins on the second day, and 45-60 mins by the third day.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the webinar offered by NC3Rs as a guidance to refined approach to our procedures (https://www.nc3rs.org.uk/events/nc3rs-webinar-refining-rodent-stereotactic-surgeries).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will get refresher training promptly and consult with Named ASPA personnel, i.e. NIO , NVS, NACWO, etc to keep up with the lasted information in the 3Rs. We will also follow up regularly with the NC3Rs advocate in our institute, who regularly disseminates new information about experiment design, methods and replacement technologies to all investigators involved in animal research.

196. Immune and inflammatory mechanisms of cardiovascular disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Atherosclerosis, Cardiovascular disease (CVD), Hypertension, Immune response, Inflammation

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main objective of this research program is to define the critical turning points of processes leading to the overactivation of immune defences in diseases of blood vessels and high blood pressure.

Through proposed research, we will address one of the most important unmet clinical needs in cardiology. We will identify new and improved treatments for plaque build-up in arteries (atherosclerosis) and high blood pressure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

High blood pressure and dysfunction of blood vessels are causing at least 20 million deaths/year, exceeding any underlying cause, including the recent coronavirus pandemic.

Work carried out in this project will identify the essential interactions in cells and particles responsible for body defence from bacteria and viruses (immune system) underlying the initiation and development of cardiovascular disease leading to heart attack and stroke. These studies will show how, when and where these interactions occur between different cell types, which drive overactivation of body immune defences in high blood pressure and associated cardiovascular diseases. This information is fundamental as it will reveal new ways we could use to treat these diseases using newly developed drugs.

Large international studies in patients are recently starting to demonstrate the utility of medications affecting body immune defences in diseases of vessels and the heart; however, none of these medications is currently used in standard care. The current proposal will identify the best ways to modulate body immune defences in the heart and vessel pathologies. Based on this, we will be able to design better medications, modify existing drugs, and apply them more rationally in patients with high blood pressure and heart and vessel diseases. This will bring benefits to patients in areas where there is an unmet clinical need.

What outputs do you think you will see at the end of this project?

Outputs can be considered on several levels: New scientific knowledge regarding mechanisms of overactivation of immune body defences in diseases of blood vessels. The aim is to publish findings in academic journals, disseminate them promptly to the scientific community and translate them to clinical impact. We will present data to our scientific colleagues at conferences, other universities, researchers within pharmaceutical companies, clinicians, and the lay public.

The immediate outcome will add to the knowledge of what causes heart attacks and high blood pressure. Based on this knowledge, rational design of new medications will be possible to target body immune defences. This would be of enormous potential benefit to human health, animal welfare and the economy.

Who or what will benefit from these outputs, and how?

Scientists - New scientific knowledge regarding mechanisms of overactivation of immune body defences in diseases of blood vessels.

Society – Discovery of new methods to treat high blood pressure or plaque build-up in blood vessels will bring potential to improve the health and quality of life of millions of patients worldwide.

Economic benefits – Reduction of the burden of cardiovascular disease will result in huge savings of health systems worldwide. Thanks to more advanced methods, the therapies proposed will be more effective and better tailored to the needs of patients. This will make them more financially feasible for the pharmaceutical industry to provide to patients.

How will you look to maximise the outputs of this work?

These studies would provide needed information to clinicians and scientists involved in research understanding the role of body immune defences in heart and vessel diseases. We aim to publish novel findings in the highest quality journals. We consider this as the primary medium for the communication of the outcomes from this research. Publications will be made open access and presented at national and international conferences, policy briefs, and social media. Critical data obtained will be shared freely with the scientific community by posting on data repositories.

Finally, we are strongly committed to outreach and science communication. In the last three years, we have been leading the organisation and delivering an exhibit at major science festivals interacting face-to-face or online with more than 60,000 people. We routinely communicate scientific advances to the public via social media.

Species and numbers of animals expected to be used

- Mice: 9500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We propose to use mice, as the smallest animals on the evolutionary scale, in which suitable models are available to use in studies of the role of overactivated immune responses in cardiovascular disease. Furthermore, the genetically modified models that we propose to use have only been developed in mice. Adult mice will be used because the development of cardiovascular disease studied occurs at the adult stage of life.

Typically, what will be done to an animal used in your project?

The animals will be subjected to the factors leading to high blood pressure and vascular disease. This will involve the administration of substances that increase blood pressure or circulating levels of cholesterol. Body immune defences will be changed through the administration of specific drugs or molecules via different routes (e.g. intraperitoneal,

intravenous, and subcutaneous under the skin or using specific delivery osmotic minipump). In some cases, transfer of blood forming cells preceded by irradiation is needed to provide a long lasting and specific change in body immune defenses. Mouse models of high blood pressure are advantageous as the duration of experiments is generally 14 days. We will carefully monitor blood pressure throughout the experiment using either tail-cuff. The animals will then be killed for analysis of their blood vessels, kidneys and other organs. Models of plaque build up inside the arteries are evoked by feeding animals a high-fat diet for usually at least three months.

The animals will then be killed for post-mortem measurements of plaque build-up inside the arteries.

What are the expected impacts and/or adverse effects for the animals during your project?

Protocols are subthreshold, mild or moderate. The animals may experience different adverse effects depending on the protocol. For example, weight loss and diarrhoea following irradiation, skin irritation following feeding with a high-fat diet may be observed. The expected adverse effects are transient with estimated times between maximally 48 hours (diarrhea, skin irritation) – 2 weeks (weight loss; skin irritation on HFD).

Anesthetised and conscious animals will be used in these studies, and surgical techniques will be kept to a minimum. Any surgical techniques will be carried out under general anaesthesia. Analgesia will be used.

In the end, animals will be euthanised.

We will closely monitor all animals. Any animal displaying deviation from normal health, other than due to the inevitable effects of the procedure, will be promptly killed or withdrawn from the procedure and referred for veterinary attention. We will keep the procedures to the minimum duration possible.

For each protocol, specific monitoring systems will be used. These will be reassessed and reviewed throughout the study. Detailed and up-to-date guidance will be monitored and followed via the NC3Rs website (http://www.nc3rs.org.uk/).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Sub-threshold - 2000 mice - 21%
- Mild - 3000 mice - 31%
- Moderate - 4500 mice - 48%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cardiovascular disease and inflammation result from a complex interplay of environmental and genetic factors on multiple target organs. Such mechanisms are impossible to be adequately reproduced in the cell culture models or using computer modelling. Therefore, further work in living animals is required to address these questions. We will continue to carefully observe a broad range of portals and websites (e.g. FRAME, CAAT-Europe, NC3Rs) to keep abreast of the development of new and valid methods that could replace the need for laboratory animals in medical and scientific research. These resources offer no specific alternatives at present.

Which non-animal alternatives did you consider for use in this project?

Studies in cultured cells and isolated human blood vessels will be employed where possible, having a variety of collaborators with whom we regularly discuss the potential options for replacement.

Why were they not suitable?

These models are suitable to address few selective questions. Still, they cannot fully reproduce the interplay of multiple environmental and genetic factors that affect numerous target organs in cardiovascular disease in animal models. Thus, alternative approaches can provide correlative type data, and powerful cause-effect reasoning requires the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A balance between keeping animal numbers to a minimum and achieving statistical validity in experiments has to be achieved. Previous extensive experience has enabled us to ensure that animal usage in our studies is kept to a minimum. Each experiment is carefully

designed to provide the minimum use of animals necessary to achieve our scientific aims. We have estimated to use around 9,500 mice in the five years of the licence. This will include 5,000 mice within the breeding and maintenance; 500 mice for irradiation protocol and 2,000 mice for atherosclerosis and 2,000 mice for hypertension protocol. The balance between these numbers is related to the balance of ongoing projects we have been conducting in each of these areas.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The statistical framework for our experiments has been developed with advice from a statistician. Each protocol is based on extensive experience and is optimised to ensure minimal suffering for the animals involved. We routinely use the sample size calculator provided in the Experimental Design Assistant (EDA) to determine study sample sizes. We will use appropriate study designs. For example, we will use factorial design when studying the effects of pro-hypertensive substances in male and female mice. We will also use block randomisation when appropriate.

We minimise possible unintended error and data distortions (bias) by directly and objectively measuring the properties of blood vessels, cholesterol and blood pressure. Subjective scoring by investigators will only be used where objective methods are not available. Mice will be randomly assigned to groups by staff blind to experimental details using dedicated software (https://www.r- project.org/).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use whole-body imaging systems to monitor disease onset in a minimally invasive fashion. Thus, repeated imaging of the same animal can be carried out to improve our data quality and reduce the number of animals required for time-dependent studies.

To further reduce the need for extensive backcrossing of transgenic and knockout animals, we will use a recently developed method to induce plaque build-up in blood vessels by a single vector injection.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are used in this project as they represent the least developed small animal group where models of cardiovascular disease directly relevant to the human pathology can be developed. At the same time, there is an extensive understanding of the immune/inflammatory system of the mouse. Moreover, several genetically modified models are only available in mice.

We propose to use established models of high blood pressure and arterial plaque build-up, corresponding to properties of human cardiovascular disease. The protocols have been chosen to provide maximally detailed information while ensuring that the animals under investigation experience the lowest possible pain, suffering, distress, or lasting harm. For example, the administration of substances will be carried out by the least severe/painful method available. Animals will always be acclimatized to handling within each procedure. For metabolic cage studies, animals will always be housed in pairs or groups unless individual housing is required due to welfare reasons or for scientific purposes. We usually use in-house modified metabolic cages that have tinted walls and a solid platform so that animals feel more secure and comfortable. Moreover, experiments will be carried out for short periods (e.g. overnight). For blood pressure measurements we will limit the use of invasive telemetry to only selected animals/experiments, as it requires surgical telemeter implantation and will use tail-cuff in more routine experiments. The use of telemetry is required to establish a fully objective measure of blood pressure changes in similarity to 24-hour blood pressure monitoring in humans that is required for diagnosis.

Animals bought from accredited breeders are always given a period of acclimatization and handling before use experimentally. Our staff always uses delicate handling. Mice are lifted using a tunnel rather than by their tail. This can lower their anxiety, enhance welfare, and increase the chances of obtaining more precise research results. Our models of cardiovascular disease have been developed and refined and give repeatable results of low variability and high quality. Each protocol is based on extensive experience and has been optimized to ensure minimal suffering for the animals involved. Throughout, we will ensure that we apply the least invasive methods of dosing and sampling. We will carry out surgical procedures aseptically, using an anaesthesia during procedures and analgesia to control post-operative pain. When multiple subcutaneous injections are called for, we will use osmotic mini-pumps to minimize suffering wherever appropriate. Where procedures are known to cause adverse effects, we will initially use the method using the least severe adverse effect. Animals will be given soft bedding and soft food to alleviate suffering where appropriate.

The humane endpoints have been established so that veterinary opinion should not be required before animals are killed. However, any animal displaying deviation from normal health, other than due to the inevitable effects of the procedure, will be promptly euthanized or withdrawn from the procedure and referred for veterinary attention. The procedures will be kept to the minimum duration possible.

For each protocol, we will use specific monitoring and scoring systems. These will be reassessed and reviewed throughout the study. Up to date, we will carefully monitor guidance via the NC3Rs website (http://www.nc3rs.org.uk/).

Why can't you use animals that are less sentient?

We cannot use animals that are less sentient because, for both high blood pressure and plaque development inside the arteries, the mouse is the least sentient species allowing to reproduce cardiovascular features relevant for human pathology. Plaque buildup assessment and blood pressure outcomes cannot be relevantly measured in less sentient animals. We use adult mice as atherosclerosis and hypertension are primarily diseases of adulthood. In addition, cardiovascular diseases are chronic disorders that cannot be studied in terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our models of cardiovascular disease have been developed and refined and give repeatable results of low variability and high quality. Many of the models and methods to be employed have been refined to reduce suffering to the minimum levels likely to give satisfactory results. Animals will be given soft bedding and soft food to alleviate suffering where appropriate. Analgesia is used for all procedures that may cause pain.

We are constantly performing refinement of our procedures.

Whenever alternative possibly better methods/models appear we aim to perform and publish refinement work in similarity to what was described above.

The humane endpoints described have been established such that veterinary opinion should not be required before animals are euthanized. However, any animal displaying deviation from normal health, other than due to the inevitable effects of the procedure, will be promptly euthanised or withdrawn from the procedure and referred for veterinary attention. The procedures will be kept to the minimum duration possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be following the ARRIVE guidelines to ensure good laboratory practice and transparent scientific reporting (e.g. randomisation and blinding to reduce bias, power calculations to avoid Type I and II errors and integration of the 3Rs).

Experiments on experimental plaque development in arteries as well as high blood pressure and hypertension will be performed in line with the most recent recommendations on the design, execution, and reporting of studies in animal models published by the American Heart Association.

Up to date guidance will be monitored via the NC3Rs website (http://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Up to date guidance will be monitored via the NC3Rs website (http://www.nc3rs.org.uk/). In addition, we will follow internal 3Rs activity and communication (such as Culture of Care meetings, 3Rs days, etc.).

197. The aberystwyth liver fluke sample-bank for the evaluation of diagnostic tests

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Liver fluke, Rumen fluke, Diagnostic tests, Sheep

Animal types	Life stages
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To test the ability of two new diagnostic tests to differentiate between sheep that are infected and those that are not infected with liver fluke (Fasciola hepatica). The samples that are collected will also be used to create a bank of blood-sera samples which will be available to evaluate further liver fluke diagnostic tests in the future.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Liver fluke (Fasciola hepatica) is a trematode parasite with significant effects on human health and currently infects around 2.4 million people worldwide. It is also a parasite with extensive impacts on the livestock industry and is estimated to cost €2.5 billion globally per

year, mainly due to impacts on animal health and food security. The UK Government's recently published Life Sciences Vision (https://www.gov.uk/government/publications/life-sciences-vision) highlights the strategic importance of the Life Sciences sector and emphasises the need to grow capacity in translating basic scientific research to real world applications. This work will be key in delivering the next crucial steps to develop novel diagnostic tests for liver fluke.

The 'Gold Standard' method for identifying liver fluke infection (fascioliasis) is by conducting a post- mortem and examining the liver and bile ducts of animals for the presence of the parasite or visible damage to the organs. There is currently no 'Gold Standard' diagnostic test that can be used to diagnose fascioliasis in live animals. This is a major animal health and welfare issue as accurate, affordable, and readily available diagnostic tests are key to the ability of farmers and veterinarians to administer appropriate treatments to livestock. The lack of accurate diagnosis prior to treatment is seen as a significant contributor to the growing threat of resistance to key therapeutic chemicals (anthelmintics) which threatens the future control of liver fluke. This project will compile a sample bank that will be able to play a significant role in determining the ability of new diagnostic tests to correctly diagnose liver fluke infection in sheep.

What outputs do you think you will see at the end of this project?

The immediate aim is to use the sample-bank to establish the performance of two new liver fluke diagnostic tests. We expect to publish the outputs in peer-reviewed journals which will showcase the performance of these tests in the literature. This will be a key step in allowing the consortiums involved with developing the diagnostic tests to deliver the tests to end users (such as farmers and veterinarians). The long-term aim is to use the samples gathered as part of the project to create a sample-bank that will be a long-term resource for establishing the performance of further liver fluke diagnostic tests.

Who or what will benefit from these outputs, and how?

In the short-term, the project will allow us to establish the performance of two new fluke diagnostic tests with naturally infected sheep (1: the adaptation of the FECPAK G2 faecal egg counting system for use liver fluke; 2: FlukEVal sera based liver fluke ELISA). This approach is considered a necessity as it reflects the situation (naturally infected farm livestock) for which the test will ultimately be used by end users. This is a necessary step in the development of any veterinary diagnostic test and will be a key milestone in bringing these tests to the marketplace and for use by end users (farmers and veterinarians). Making these tests available to end users has numerous potential benefits. Better availability and choice of fluke diagnostic tests will make diagnosing fasciolosis more accessible to livestock keepers. This will bring welfare benefits to livestock as liver fluke has been shown to have notable negative welfare effects. Correct diagnosis is also a key factor in reducing over-use of key flukicide anthelmintics to reduce the development of resistance which risks undermining the long-term control of these parasites. More effective

parasite control can also bring farm business benefits through lower costs and more efficient production as well as potentially reducing farmer mental health strains.

In the longer term, our aim is to create a sample-bank that will allow further liver fluke diagnostic tests to be evaluated on samples from naturally infected sheep without the need for further sheep to be used.

This will establish a legacy for the project and bring 3Rs welfare benefits, by reducing the need for developers of future novel diagnostic tests to undertake regulated procedures on sheep in order to gain samples to validate their tests.

Information on the disease status of the sheep in the project will be fed back to the stock keeper and they will be free to use that information to inform appropriate treatments for their animals.

How will you look to maximise the outputs of this work?

This project will create a sample-bank that will be used beyond the lifetime of this project. For example, the sample-bank will be used to evaluate the performance of further diagnostic tests beyond those identified in this project. We will actively encourage other users to use the sample-bank through formal collaborations and licencing of the sample-bank. This will provide external institutions an opportunity to undertake evaluation of novel diagnostic liver fluke tests without the need to undertake further sampling in sheep which has considerable potential for long-term 3Rs benefits. We aim and expect to gather up to 10 ml of blood which should lead to at least 1 ml of sera per sample. We expect that each 1 ml of blood sera obtained will be able to be used in 100 separate reactions. This will provide a resource that will be available for a considerable amount of further work.

Species and numbers of animals expected to be used

- Sheep: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Liver fluke (Fasciola hepatica) is an internal parasite which infects livestock through grazing infected herbage. Consequently, it only infects sheep which naturally graze infected pasture. This precludes the use of foetal life stages and very young lambs which have not yet started grazing herbage and thus have not had the opportunity to become naturally infected with liver fluke. Juvenile lambs and adult sheep are the most appropriate life stages to use for the project as they will have been given opportunities to be challenged by fluke infections. This will also allow us to quantify performance for animals that will be in their first grazing season and those who may have been infected previously.

Typically, what will be done to an animal used in your project?

Sheep on selected commercial farms with high liver fluke prevalence will be selected for inclusion in the project with the consent of the owners. Suitable sheep from these flocks will be identified via their ear tags and samples of faeces will be collected by rectal grab (or from floor droppings if possible).

Blood will also be collected from the jugular vein of each sheep. The sheep will be held in a holding pen and each farm's vet will be asked to verify that the animals are not in pain, suffering, or distress or likely to have any lasting harm as a result of the procedures undertaken. Sheep will be inspected on the day the procedures are undertaken and they will be released back into the care of their owner after confirmation from the vet. This will end their role in the project.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts and/or adverse effects of the two regulated procedures are expected to be mild and short lived. This may include slight discomfort during the procedures, but discomfort should stop shortly after completing the procedures.

The cumulative effects of two regulated procedures in quick succession is worth noting but undertaking the procedures in a competent manner should still ensure that the expected impacts and/or adverse effects are minimal/very mild.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity level is expected to be 'mild' in all cases and for all animals in the project.

What will happen to animals at the end of this project?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Diagnostic tests that aim to identify whether sheep are infected with parasites such as liver fluke need to be able to demonstrate a suitable ability to differentiate between infected and non-infected animals within flocks in order to fulfil a useful role for farmers and

veterinarians, and in order to aid animal welfare through correct diagnosis that leads to appropriate treatment.

Sheep in commercial flocks that are infected with parasites such as liver fluke are exposed to different naturally occurring parasite populations at different locations on farms and differences in grazing patterns between individuals, which will lead to some sheep becoming heavily infected whilst others are less heavily infected. At the same time, sheep in commercial flocks will also be challenged by other naturally occurring co-infections such as rumen fluke, parasitic nematodes and other diseases and parasites which can affect a sheep's immune system and potentially have a hidden effect on diagnostic tests.

These factors and are main reasons why evaluating diagnostic tests in naturally infected populations that resemble the conditions on commercial farms is considered necessary in order to provide a suitable evaluation of their effectiveness value for farmers and veterinarians and why we need to use animals to achieve the aim of our project.

Which non-animal alternatives did you consider for use in this project?

Possible alternatives to using live animals in this project include the use of samples gathered from sheep slaughtered in commercial slaughterhouses. These could be naturally infected samples that are used directly to evaluate the diagnostic tests or samples that test negative for liver fluke to which we then add a known quantity of suitable parasite life stages prior to use.

Why were they not suitable?

Evaluating the performance of diagnostic tests with samples where a known quantity of suitable parasite life stages is added is an appropriate step in the evaluation process. This is a step we have already undertaken for one of the novel diagnostic tests we wish to evaluate with the sample-bank. However, this does not provide an estimation of the performance of the diagnostic test with naturally infected animals and does not represent the conditions which the test will be used by farmers or veterinarians and therefore is not suitable as a definitive final estimation of the performance of diagnostic tests for liver fluke.

Gathering samples from sheep slaughtered in commercial slaughterhouses does provide an opportunity to gather samples from naturally infected carcasses immediately after slaughter but our previous experience has shown us that the practical limitations of processing samples in a slaughterhouse setting means that it is not possible to obtain a high enough liver fluke prevalence. For example, practical limitations mean samples must be stratified between groups which originate from different farms and which are likely to have very different fluke prevalence levels due to the speed of carcasses moving through the abattoir). This means that it is impossible to devise a practical method to sample intensely from high liver fluke prevalence groups. Furthermore, abattoirs are high risk for SARS- CoV-2 transmission between personnel, and their operation is highly dependent on a large workforce.

This has led to many abattoirs restricting non-staff to enter the premises for the foreseeable future.

Obtaining samples from groups of sheep with both low and high fluke prevalence is a necessity in order to provide an effective estimate of diagnostic test performance in a Bayesian Latent Class statistical framework in the absence of Gold standard comparator tests. We have concluded that the only practical way of obtaining samples from groups of sheep with fluke high prevalence levels is to sample sheep on farms purposely selected for their high fluke prevalence levels.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used an appropriate sample size estimation method that can use expected diagnostic test sensitivity and specificity measures to estimate the numbers of animals needed. The method can make use of initial estimates of test sensitivity and specificity and these are sourced from data already gathered, including pilot data. The data we already hold has been used to reduce the numbers of animals needed through refining our strategy for selecting the commercial farms where we will source the animals. In effect, we already possess enough samples from animals that are not infected with liver fluke. This allows us to optimise animal numbers by using a strategy to increase the proportion of fluke positive sheep in the animals we will use as part of the project (and thus minimising the number of fluke negative sheep we use in the project).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The framework for evaluating diagnostic tests assumes that each sample is independent and this precludes the use of duplicate samples from the same animal. However, we already have 500 samples (~40-50 fluke positive and ~450-460 fluke negative) from a previous abattoir-based study that is part of the sample-bank. This means that the sample-bank already includes enough negative samples to establish the specificity (the ability of the test to correctly identify those without the disease) of the diagnostic tests that the project will evaluate initially and for longer-term use in the sample bank.

Consequently, the project’s efforts can be focused on sampling sheep from farms that are most likely to be infected with liver fluke. As the infection status of individual sheep will not definitively be known prior to sampling, the total number of sheep that will need to sampled will be influenced by the prevalence of the parasites in the overall sheep population used

in the project. We can leverage the fact that the project only needs to gather samples from infected animals to select farms likely to have the highest prevalence and to reduce the total number of sheep to sample.

On-farm prevalence of liver fluke is determined by a range of factors that includes the history of fluke infections and treatments within individual flocks and consequently some farms and groups of sheep within flocks that have been grazing high risk pastures can have very high prevalence levels above 70- 80%. Fluke prevalence is also strongly influenced by the suitability of weather conditions for fluke transmissions in the key period over the summer (May to September). The nationwide prevalence of liver fluke is continuously changing and consequently the project is basing estimates of fluke prevalence in selected high prevalence flocks at a more conservative 50% as using a less conservative estimate risks not returning enough fluke infected sheep from a smaller total number of sheep to be sampled.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have pilot data available for the performance of the two initial diagnostic tests we will assess. This includes data from abattoir samples processed for the new Faecal Egg Counting based diagnostic test and pilot data from another project undertaken in conjunction with external collaborators in the case of the FlukEVal sera-based ELISA. These provide initial estimates of diagnostic performance for the tests which allow us to estimate the number of animals needed more accurately.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

By using sheep from commercial farm’s we reduce the need for transport and farm staff, with whom the animals may have a degree of familiarity, will be able to undertake much of the preparatory work with the animals including initial inspections of the health and welfare of animals before they are used as part of the project. The procedures have also been designed to minimise the amount of time that the regulated procedures will take to complete which includes minimising the time they are held alone or in small numbers and to reduce the time they are physically restrained by the researchers. This will allow us to release the animals into the final holding pen as soon as possible. Our protocol also

ensures that all the animals will be inspected by an independent veterinary surgeon shortly after completion of regulated procedures (within the same working day) where any delayed instances of adverse effects can be identified and any necessary action can swiftly be taken. The use of naturally infected animals negates the need to purposely infect animals in order to meet our objectives. As liver fluke is a parasite that can lead to serious health and welfare, purposely infecting animals does pose long term health risks if treatments are not swift and efficacious. In addition, the feedback on infection status from our regulated procedures will allow the farmers to administer appropriate treatments where necessary, bringing potential health and welfare benefits.

Why can’t you use animals that are less sentient?

We cannot use less sentient animals as the aim of the project is to evaluate diagnostic tests for liver fluke and rumen fluke specifically in sheep.

We cannot use more immature life stages as we require sheep with natural infections of liver fluke and rumen fluke and this only occurs in sheep that graze herbage (juvenile and adult sheep).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures within this project closely resemble standard veterinary procedures that farmers and veterinary surgeons may use to diagnose live fluke infections in commercial livestock settings. We do not consider it appropriate to use refinements such as pain management as administering intramuscular anaesthetics will likely lead to harms equal to, or greater than, the mild procedures to be used in the project. Animals will be monitored for a period of time which can be extended at the discretion of the veterinary surgeon inspecting the animals after the end of the regulated procedures. However, harms to the animals are expected to be mild and transient.

It should also be noted that at least some of these animals will have naturally occurring liver fluke infections and there are potential welfare gains for these animals through correct diagnosis that farmers can use for treatments and therapies where appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The study will be conducted in compliance with the Committee for Medicinal Products for Veterinary Use (CVMP) VICH GL9 “Guideline on Good Clinical Practices”.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project leader will obtain information from qualified and experienced people at the university to obtain the lastest on 3Rs relevant to sheep. In addition, the project leader reviews the NC3Rs website regularly.

198. Analysis of thymus development and function

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Immunology, Thymus, Development, T cells, Tolerance

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to understand the genetic and epigenetic control of the development and function of the thymus throughout life. The thymus is the primary lymphoid organ where T cells are formed and selected.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Different congenital and acquired diseases that affect the thymus result in a loss of regular thymus function or compromise the generation of normal T cells. Insight gained from our studies will provide better diagnostic tools and rational approaches to the treatment of these pathologies.

What outputs do you think you will see at the end of this project?

The proposed work will provide several important outputs: New basic science information will be gained that will inform novel diagnostic approaches and form the basis for new therapeutic strategies to cure thymic diseases. The progress of this work will be regularly

published and presented at conferences, making its conclusions widely accessible to the wider scientific and medical community.

Who or what will benefit from these outputs, and how?

The translation of the proposed work will have several benefits. For developmental biologists and immunologists, the proposed efforts will provide novel information about which genetic and epigenetic controls are essential to form the thymus, an essential primary lymphoid organ. This information will be regularly made available throughout the course of the proposed project. For physician-scientists and clinicians, the generated information will help to decipher the so far unknown molecular causes of several thymus-related pathologies and thus provide the basis for targeted diagnosis and then a rationale for specific treatments. We anticipate that during the time of the project some of the information gained will be translated into direct clinical application. In the long-term, the project will provide invaluable basis for benefits to patients with thymus pathologies as the molecular origin of their diseases can be precisely defined and a rational therapy can be designed.

How will you look to maximise the outputs of this work?

The work is typically carried out as multi-disciplinary effort in collaboration with other scientists. The results are typically and regularly disseminated locally, nationally and internationally by way of conference presentations and publications. Interactions with colleagues that are part of the research network or attend conferences where the data is presented will provide insight into reasons for unexpected findings or unsuccessful approaches. Experimental findings will be shared with clinicians so that specific genes identified to play a role in development or function of the thymus can be investigated in patients to better define their thymus pathology.

Species and numbers of animals expected to be used

- Mice: 28,700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project will use mice as these are the best studied animals for thymus research. To understand the genetic and epigenetic control of thymus formation we will study mouse embryos from day 10 of gestation onwards and newborn mice as thymus formation is only completed during the few days after birth. To judge thymus tissue maintenance and function, which is essential for the life-long formation and selection of T cells, we will analyse mice at different stages of their life trajectory.

Typically, what will be done to an animal used in your project?

The majority of mice will be analysed without having undergone any additional procedures, they will be humanely killed and analysis will be performed on tissue samples.

Irradiation or treatment with antibodies will be used to deplete the immune system in mice, they will then be given cells from the liver or bone marrow of donor mice, which will develop to restore the immune system. Some non-genetically altered mice will have undergone removal of thymus tissue at the breeder/supplier prior to be being supplied to the project. The mice that have undergone surigal removal of thymus tissue and mice with an inborn lack of thymus devlopment or function may have thymus tissues surgically grafted under the covering of the kidney. Animals will be immunised to study their immune responses to known antigens. Animals will be bred with gene mutations that will help us understand the development and function of the thymus. Blood and tissue samples will be taken to probe the cells of the immune system. Substances that induce an immune response in the body (antigens) will be givenby injection to probe the immune system's capacity to respond to antigens. All of the above could, but are not expected to, lead to infections, may transiently be related with pain, and will be associated for a short period with reduced well being as part of the recovery following surgery. Good surgical technique, pain relief, good husbandry, early intervention and treatment will be provided. All animals will be killed at the end of the experiment or as soon as an animal has been judged to have reached a humane end point, so that suffering is reduced. The expected level of severity for the protocols will be mild to moderate.

What are the expected impacts and/or adverse effects for the animals during your project?

Gene-edited mice may be born with a small or no thymus and may therefore experience a higher susceptibility to infections and/or autoimmunity. The former is unlikely to occur under specific pathogen-free conditions while the latter may be accompanied with some weight loss and/or organspecific impairment of functions due to autoimmunity that are typically mild or may not be clinically relevant at all. The injections will result in short term distress of the animal due to handling and will cause minimal pain owing to the needle stick. The surgical procedures will be carried out under anaesthesia but likely cause post-operative pain and discomfort which will be monitored and appropriate analgesia will be administered. Weight loss may occur after irradiation or treatment with an agent, Tamoxifen, which controls the expression of genes, but animals will given moist palatable food to ameliorate weight loss, if no sign of improvement (maintenance or gain weight) is seen within 48 hours the mice will be killed. Mice losing 15% of weight will be humanely killed immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the 24,000 mice in Protocol 1, a mild breeding protocol, approximately 95%, will experience a subthreshold severity with <5% experiencing a mild severity.
Of the 4,000 mice in Protocol 2, a moderate breeding protocol, approximately 75% will experience a sub-threshold or mild severity, with potentially up to 25% experiencing a moderate severity.

100% of the 350 mice in the moderate experimental Protocol 3 will experience a moderate severity.

100% of the 150 mice in the moderate experimental Protocol 4 will experience a moderate severity.

100% of the 200 mice in the moderate experimental Protocol 5 will experience a moderate severity, as all will have undergone surgical removal of thymus tissue at the breeder/supplier prior to be being supplied to the project.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Thymus formation and maintenance are the result of a to date not fully understood complex process that involves many different cell types and their multifaceted interactions. This intricate development cannot be recapitulated in the test tube and thus necessitates studies in mice.

Which non-animal alternatives did you consider for use in this project?

While very few and limited aspects of thymus biology can be modelled in culture flasks using cell lines, the vast majority of biological questions in this project can only be informatively investigated in animals because non-animal alternatives do not exist as model systems to study thymus development, function and maintenance.

Why were they not suitable?

Non-animal alternatives have not been developed for thymus development and very likely will never be generated given the intricacy of the biological system that depends on multiple cell types to interact correctly with each other. Hence model systems do not exist to study a majority of questions related to thymus development, function and maintenance.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have carefully designed the experiments to be performed and subsequently calculated how many animals will be needed to realise in an informative fashion those experiments. Using breeding calculations suggested by the local animal work facility, we then calculated how many animals we need (i) to breed to obtain the numbers of animals required for the experiments planned and (ii) to maintain an animal colony over time.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Wherever possible we will use littermates of appropriate genotype as controls. Based on past experience we will use the smallest possible group sizes that are still informative for thorough statistical analysis. As the effect of specific gain- or loss-of-function gene mutations and cellular manipulations are difficult to predict, power calculations cannot confidently be made ahead of time until results (e.g. phenotype, functions) are available from a small experiment, which will usually study 3-5 mice in the experimental (e.g. gene targeted) and 3-5 mice in the control group (wild type mice). Based on the findings of such studies, power calculations can be made for which advice from a biostatistician will be sought. Given the nature of our experiments, blinding and randomisation are in most cases not part of the experimental design and are therefore not planned.

If the phenotype caused by the mutation is unknown or cannot be predicted with certainty, then more animals will need to be investigated to establish the presence or absence of biological changes resulting from the mutation. But again, all possible efforts are undertaken to minimise the size of the experiment and hence the colony to firmly establish the pathomechanisms operational in these phenotypes.

Where different mouse strains may be required in parallel; strains may be crossed to make double or triple mutants, which will then be analysed in detail for molecular, cellular and organismic changes. We may breed mutants of the strains indicated with two genes mutated, when the single mutant phenotype is mild and in instances where the genetic epistasis needs to be established. In addition, we intend to visualise cells in selected tissues in which specific, targeted genetic changes have been induced using the expression and subsequent detection of distinct fluorescent proteins. Tissue targeting will be achieved by using the recombination of conditional alleles using Cre recombinase. We will set up a small number of breeding colonies to achieve the correct genotypes before expanding breeding for experimental use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use multiple tissue from single mice which will allow not only the analysis of the cells and organs needed for a particular study but will also provide tissue that may be required for other downstream analyses or, for example, the establishment of new methods. These efforts are actively pursued to reduce the number of animals bred for tissue collection. Surplus animals and tissue will be shared with other groups should age, gender and genotype be appropriate. Notifications and requests are sent out by the animal facility via email to other laboratories in the local scientific community.

Our experiments are typically performed on a C57BL/6 genetic background which produces a comparatively large litter size. Consequently, fewer breeding pairs need to be used to have sufficient animals for the planned experiments.

Power calculations cannot confidently be made ahead of time until results are available from a small experiment, which will usually start with a pilot study 3-5 mice in the experimental (e.g. gene targeted) and 3-5 mice in the control group (wild type mice). Based on the findings of such studies, power calculations can then be made, using the Experimental Design Assistant tool or consulting a statistician.

Our molecular studies frequently employ new sensitive methods that require smaller cell numbers to achieve results or are based on single cell analyses that typically require fewer mice to be studied.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Wild type or gene-targeted mice on defined genetic backgrounds (inbred strains) will be used. A small thymus or its complete absence as a consequence of gene targeting does not impact the wellbeing of animals if kept under special pathogen-free conditions. The occurrence of autoimmunity as a consequence of abnormal thymus function is characteristically very mild in the mouse strains used for this project (C57BL/6) and is not expected to result in pain, suffering, distress or harm.

The majority of animals bred on this license will not undergo any additional protocols, but will be humanely killed and tissues will be examined in the laboratory.

Why can't you use animals that are less sentient?

Mice are used for the project as they constitute the genetically best studied experimental animal model for which relevant physiological and pathological data is already available. Moreover, reagents and methods necessary to investigate thymus biology are either only available in mice or best investigated in these animals.
Thymus formation in the mouse is initiated at day 10 of gestation and is only completed a few days after birth. Thereafter, different physiological changes (e.g., puberty, old age) influence the maintenance and function of the thymus tissue. As a consequence, mice at all ages during the life trajectory will need to be studied.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Specific aspects of the project will be continuously reviewed to achieve improved surgical techniques, to adopt alternative approaches, to shorten procedure lengths, and to improve pain management and post operative care (rehydration and feeding).
We will source mice that have had thymus tissue surgically removed (thymectomised) from a commercial company (e.g., Charles River) which performs this type of surgery far more frequently than we would and therefore have greater expertise. This should minimise the harms the animals experience.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The practice will be informed by (i) published procedures of approved protocols; (ii) discussions with colleagues and experts in the field, (iii) newsletters by 3R organisations published in English, German and French

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I subscribe to a 3R newsletters (https://www.nc3rs.org.uk/newsletter-archive and https://www.swiss3rcc.org/en/news-media/newsletters-archive), attend meetings where 3R advances are discussed and consult veterinarians and colleagues regarding new developments in replacement, reduction, and refinement as it pertains to my project.

199. Neuronal mechanisms of appetitive learning

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

appetitive learning and memory, motivation and reward, associative learning and memory, neuronal mechanisms, addiction

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant
Rats	juvenile, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Exposure to signals or ‘cues’ (e.g. sound of ice cream truck) that are linked to rewards including palatable foods (e.g. ice cream) shape our urge and motivation to eat. For example, when we see a fast-food sign, we might be reminded about snacks and experience food cravings. Conversely, we also learn to suppress our responses to such cues when we update these linked cue and reward or ‘appetitive associations’. For instance, if that fast-food shop were to close down and no longer served food, we would react less to that fast-food sign the next time we see it. We do not fully understand how brain cells actually store, retrieve, and update these types of associations. The aim of this project is to investigate in rodents how a tiny minority of brain cells called ‘neuronal ensembles’ stores and retrieves appetitive memories, such as memories about food. We will study the cells in brain regions that are important for motivation to satisfy our basic needs (e.g. drinking and eating). We will also study at a molecular and cellular level, what is special about the brain cells that enables these appetitive memories to be formed, retained, and modified.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

On a fundamental level, revealing how brain cells store, retrieve, and update appetitive memories about is important for understanding basic survival behaviours, such as finding food. Additionally, this work has health-related implications, since desires such as food cravings that promote excessive eating are provoked by cues linked to food and food memory retrieval. Also, therapies that update associations about food and cues show some promise to suppress food cravings. By learning more about the cellular and biochemical properties of brain cells that store and retrieve appetitive memories and control appetitive states, we can better understand why certain individuals may engage in more excessive eating and gain weight compared to others. Also, indirectly and in the long-term (e.g. 15 years), these findings may help create better medicines for people that suffer from conditions such as excessive appetite, overeating, and obesity. This research is timely since, alarmingly, 2 out of 3 UK individuals are now overweight or obese, and are at higher risk of other diseases such as diabetes and cancer.

Moreover, since we are studying learned associations, this research will also provide clues on normal and abnormal mental functioning such as how the brain links and remembers other types of important information that shape our behaviours (e.g. the smell of smoke signalling fire). Such clues may also reveal more about conditions that affect our health such as drug abuse, since the development of drug addiction involves linking information about drugs and the environment where drugs are used (e.g. the sight of smokers creating a cigarette craving).

What outputs do you think you will see at the end of this project?

We envision outputs such as publications in open-access, scientific journals that reach a wide academic audience. Also, during the course of the project, we will present our work at both national and international academic conferences. Furthermore, we plan to reach out to the general public through the lab website, social media, and other local outreach events. Doing so will help disseminate our findings to a much wider audience, and enthuse their interest in learning more about the brain mechanisms of food memory storage and retrieval. Finally, any tools/approaches that are generated from this project will be made freely available to other researchers.

Who or what will benefit from these outputs, and how?

In the short-term (1-5+ years), the beneficiaries will be primarily academic. Since we are investigating mechanisms for appetitive learned associations and related behavioural states, there will be a wide variety of researchers who would benefit from our findings. These researchers may include experimental psychologists who are trying to determine the precise neuronal substrates of memories and aberrant behaviours and neuroscientists who are determining the molecular and physiological factors that control motivational states and shape and store memories. These researchers can use our data to further dissect the neuronal circuits that process memories and advance their research programmes. For instance, they may further characterise the molecular (e.g. neuronal surface receptors, neurotransmitters) alterations and neuronal activity patterns that occur

in response to storing and retrieving memories linked to rewards and any relevant changes in motivational states modulated by internal cues linked with these memories.
As an indirect, long-term (many years) consequence of this proposed research, whether the rewards being considered are food or drugs, this improved knowledge about the underlying neurobiology of appetitive associative learning and motivated behaviours could be used as a building block for further biomedical research that would impact the general public (both clinical and non-clinical populations) in several ways. First, clinical researchers can utilise this data to examine whether the molecular alterations that we observe in the rodent brain following appetitive conditioning are also present in the human brain (e.g. via post-mortem analysis or via PET studies). Subsequently, they can examine whether these factors are implicated in eating disorders, such as overeating and obesity. Second, by showing how learned associations about certain palatable foods (e.g. sugar) and their cues can alter certain rodent neurons, we may better educate people about what foods they should or should not eat. Such information can be valuable for researchers who wish to shape some aspects of public health policy. Third, we will be able to design more efficacious therapeutics that stimulate or inhibit specific neuronal populations that encode appetitive memories and motivation. As such, researchers in drug discovery may benefit from our research. Using such treatments, we may stimulate appetite in those suffering from disorders such as cancer, or decrease appetite for those suffering from overeating.
To provide some perspective about the widespread nature of eating-related disorders, the number of people suffering from eating disorders in the UK alone is estimated to be over 10 million. These disorders are also associated with other illnesses that such as diabetes and heart disease. Also, since our research has implications for other conditions such as age-related memory decline and addiction, those researchers in these areas will benefit as well.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work by finding new local and/or international collaborators who will be able to expand our research programme into a more innovative direction by offering their conceptual and practical expertise. To illustrate an example, our recent work was greatly enriched by establishing a collaboration with a local researcher at our university who provided his expertise on live brain imaging, which revealed novel brain activity patterns that helped establish food memories. Also, such innovative collaborations open new doors to apply for funding schemes that allow for more impactful and ambitious research to be conducted.

Furthermore, we will disseminate our work in open-access journals that have a wide reach and make an active effort to promote our work through social media platforms and blogs. We will also ensure that our research is highly accessible by producing a graphical abstract of our key experiments and findings. Wherever possible, if a story is newsworthy, we will contact the media team out our university to further promote our studies. Finally, we will aim to publish any negative findings from experiments. Doing so will help prevent other scientists considering the same research question from performing those negative finding experiments, preventing unnecessary animal usage (Reduction) as well as time and financial resources.

Species and numbers of animals expected to be used

- Mice: 9000
- Rats: 1900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use primarily use adult male and female mice and rats to examine how appetitive memory mechanisms operate in the brain. We have routinely used these animals previously, which are readily trained and perform robustly on the behavioural tasks described in this application, reducing the number of animals used in line with the 3Rs. Rats and mice are an appropriate choice of species because their neural circuits that process information related to food and their associated cues as well as motivated behaviours to seek food are remarkably similar to those of humans. Hence, findings from these studies which reveal novel cellular and biochemical profiles of these neural circuits have translational applicability. In some cases, rats are preferred to mice, since their brains are bigger and as such specific brain areas are easier to manipulate with intracranial procedures. In many cases, we will use mice since many genetically modified mice are available that allow activated neurons to be further characterised and manipulated. For instance, by using such mice we can monitor the activity of fluorescing neurons in a live broadcast manner and/or characterise the electrical properties of activated neurons. We will use adult mice to better compare the findings obtained from our studies with our previous finding as well as in the literature. However, in some cases we may wish to perform similar studies in adolescent mice to determine whether their brains process food memories differently or similarly to adults.

Typically, what will be done to an animal used in your project?

Our project is divided into 3 main workstreams. In the first two workstreams, animals will typically undergo an appetitive learning procedure under freely moving conditions that will last a few weeks where they have to learn 1) that a cue such as an auditory signal would predict food availability; or 2) to perform an action, such as a lever press, to obtain food. We will probe for their food memories by measuring the responses to the cue in the form of food seeking or by measuring lever presses in the absence of food availability.
During this learning task, animals undergo mild food restriction, so that they become motivated to learn this task. In the first workstream, animals 9-13 weeks old will undergo the appetitive learning procedure. Then at various time points during the learning procedure, we will euthanise the animals and then examine their brains to measure the cellular and biochemical properties of neurons that were activated during learning. In addition, some animals will undergo brain surgery prior to the appetitive learning procedure (or naive state) such that specific neurons can be further characterised and/or controlled using genetic transformation or other biochemical methods. Some animals will simply undergo mild food restriction without undergoing any appetitive learning procedures, in order to examine how the brain encodes an appetitive state (e.g. hunger state). Doing so will help us understand how the brain processes internal hunger cues, that influence the formation of learned associations.

In the second workstream, animals 9-13 weeks old will undergo brain surgery such that the live activity patterns of brain cells can be examined using optic fibres or a cranial window. Following recovery from surgery, they will undergo the above appetitive learning procedure. For some animals, several times during training or in the memory test, we will connect optic fibres to the cannula. Then we will measure activity patterns from labelled

neurons to examine what brain activity may help memory retrieval and/or manipulate the activity of these neurons using optical approaches to see if these neurons are involved in the actual memory retrieval. Some animals will undergo implantation of a cranial window onto its skull. After recovery from surgery, animals will be gradually habituated to being held in position under a microscope on top of a treadmill or cylinder, allowing the mouse to walk or run freely. Over a course of 1-2 months, we will perform around 10 imaging sessions to monitor brain activity, separated usually 2 days apart at various time points in the appetitive learning procedure.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will undergo mild food restriction and will lose a slight amount of weight (10%) for several weeks to motivate them to learn the behavioural task. Their weights and body condition will be monitored daily. However, this weight loss has actually shown to improve the lifespan and health of animals. In the event that there is more weight loss than 15% of their normal weight, we will immediately limit or suspend the food restriction to avoid any suffering.

Animals that undergo surgery might experience pain afterwards. However, these can be managed well with pain medication that humans also respond well to. Initially following surgery, animals are subdued, but they rapidly recover over a period of several days. If necessary, during the recovery period, we can give them soft food to aid their digestion and more pain medication. The health of the animals will be monitored, and if their health deteriorates, then they will be euthanised within 3 days or in severe cases, immediately.

Animals will also receive injections of various substances such as those that turn on certain genes in the brain and/or to control appetite. Discomfort is present during these injections, but only last less than a minute and we use the finest needles possible that minimise pain.

Animals may be initially stressed when connecting an optic fibre cable to the cannula or getting used to being held in a head restraint under the microscope. However, they are slowly accustomed to this process over several days in a gradual manner, resulting in very brief (1 min) periods of stress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice
Total proposed number in project: 9,000
Proportion of severity: 53% mild, 47% moderate

Rats
Total proposed number in project: 1,900
Proportion of severity: 53% mild, 47% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Both rats and mice are ideal model organisms for these types of studies as they have similar brain circuits that generate memories and create motivated actions similar to humans. Our work requires rats and mice because we wish to examine the relationships between the activity patterns and cellular and biochemical profiles of specific groups of brain cells that are implicated in food memories. This requires studies in the intact brain in a behaving organism. However, such experiments cannot be performed in humans due to ethical and methodological considerations. For instance, brain imaging techniques such as fMRI lack the resolution to visualise the activity of specific groups of neurons. Moreover, these studies cannot be performed using cell culture systems because they do not allow us to examine properties of brain cells that are directly relevant to memory retrieval and the diversity of brain cell types is not represented in cell cultures. Also, computer simulations can mimic some aspects of learning, but they will not reveal the unique cellular and biochemical properties implicated in food memories.

Which non-animal alternatives did you consider for use in this project?

We have considered cell culture systems and computer simulations. However, as mentioned above, these systems do not allow for the direct examination of activity patterns and cellular and biochemical profiles of neurons that are relevant for food memory retrieval. As such, they cannot inform us of the properties of specific groups of neurons implicated in behaviours and responses that depend on food memory retrieval such as seeking out food and food cravings.

Why were they not suitable?

The mammalian brain is composed of millions (to billions) of neurons that undergo cellular and biochemical changes during learning and this complex native circuitry cannot be completely mimicked in cell culture systems. Also, unlike the brain, the diversity of brain cell types is missing in cell culture, and for instance we cannot specially examine if excitatory neurons specifically interpret information about food-linked stimuli. Computer simulations could not be used here since they do not reveal the physiological properties of specific neurons implicated in food memories. Additionally, there are no computer simulations to date that completely mimic the reward and motivation brain circuits in an animal. To build better computer simulations, data from animal experiments are necessary. Finally, unlike an animal both cell cultures and computer simulations are not capable of learning the relationships between actual sensory stimuli and food rewards.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on how many mice were used in my last license. We are providing an overestimate here to account for expansion of our any new collaborative research programmes that may form during the course of the project. If necessary, we will adjust the number of animals on the license with amendments if our estimates need further calibration. Our typical sample size per group ranges from n=7-12.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Wherever possible, we use a within-subjects experimental design to collect multiple data points and to increase statistical power and reduce the usage of animals. Such data can be collected for behavioural parameters such as food seeking as well as neuronal activity data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have optimised our breeding strategy such that the minimal number of mice are necessary for efficient generation of transgenic animals. Moreover, the non-transgenic, wild-type littermates will be used for pilot studies or actual experiments since they are similar to normal animals by our laboratory and/or by other laboratories. As mentioned above, wherever possible we will also collect multiple data points from a single animal at the behavioural and neuronal levels to increase data yield. Before a new study is conducted, we will conduct a thorough literature search and use our past data to enable us to conduct pilot experiments with the most optimal parameters for measuring reliable behavioural and neuronal responses. Based on the observed effect sizes, we will determine whether an experiment can be completed with a reasonable sample size. If this is not the case, we will not proceed with that experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In addition, to normal ‘wild-type’ rats and mice, we will use transgenic rats and mice that express special proteins that allow for further characterisation and manipulation of activated brain cells. Although these animals are genetically altered, there is no harmful phenotype and published studies from our lab and others demonstrate that they also behave similarly to normal mice and rats.

This project involves complex behavioural tasks (e.g. learning to make a particular response such as pressing a lever to obtain food) and rodents perform these tasks very accurately. During behavioural training, we carefully observe the animals using a live camera feed, and by examining their training data. These observations are useful for detecting if animals might be unwell. In addition, many aspects of the rodent brain are similar to humans, including those brain areas are important in producing the behaviours that we study. We reduce stress to these animals through use of food rewards in training, rather than punishment. Training using food rewards can be very successful and is widely used to train service animals (e.g. police dogs).

To improve their well-being, animals will be group housed most of the time as rats and mice are social species which naturally choose to live in groups. We also house these animals with enrichment in their home cages and handle them frequently so that they are used to the experimental processes. Also, they will usually undergo behavioural tests in the same familiar location in a dark and quiet room that minimizes stress.

Many of our experiments will involve performing surgery to insert a fine tube called a cannula through the skull or insert a small window in the skull. Animals usually recover well following these procedures, and exhibit behaviours such as grooming, eating, and drinking many minutes after waking up from the anaesthesia. In general, we pay lots of attention to the well-being of the animals (especially after surgeries), including trained and qualified personnel examining a wide variety of behavioural and physical signs. If necessary, animals that are unwell would be humanely euthanised to prevent excessive suffering. These animals are handled frequently so that they are not startled by human contact, and that this also acts as a form of enrichment. Animals are also habituated or get used to the brain activity recording apparatus in a gentle and gradual manner over days, to minimise any stress.

By doing so, any brain activity data obtained is more reliable.

Why can't you use animals that are less sentient?

We need to use mice and rats here as these animals possess brain areas with brain cells that process information related to motivation and reward similar to humans. These animals are necessary to study how brain cells in these brain structures communicate with each other when storing and retrieving food memories. Less sentient, invertebrate organisms such as snails are capable of storing memories about food similar to mice and rats. However, as they are not mammals their brain cells and circuits are rather different to that of humans and lack the richness and complexity. Hence, compared to studies on rats and mice, findings from these studies are not as directly relevant for understanding the human condition for phenomenon such as appetitite control, food cravings, and excessive eating. Moreover, brain cells from lower beings such as invertebrates contain receptors that may not be on brain cells from mammals. As such, they are not informative for developing better therapeutics that potentially modulate human brain function.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As in our previous studies, wherever possible, we will continue to refine our methods to improve the well-being of animals, as soon as we learn of more optimal approaches. For instance, for our behavioural experiments, we may measure additional behavioural parameters that indicate that the animals are learning the task optimally, which will help

guide when to best take the brain activity measurements. Doing so will minimise unnecessary stress that may occur from live brain imaging procedures. Additionally, we will increase habituation to the testing context to decrease the incidences of any non-specific behaviours in order to increase the signal-to-noise ratio of our behavioural parameters of interest. We may also adopt new methods which will help better stabilise our cranial attachments, so they adhere better to the skull. For instance, this year we sought advice from a research group in UCL and managed to obtain a more stable adhesive for cranial attachments which has greatly reduced the chances of these coming off. Also, in the previous years we sought advice from more experienced people regarding how to score the skull better to improve this adherence. Finally, all mice will be removed from cages using tunnel handling to minimise stress of tail handling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to regularly update our knowledge on refinement using peer-reviewed, academic papers that use similar experimental methods and mouse lines. We will also refer to resources, such as webinars and publications from organisations such as LASA and NC3Rs, including the LASA report on avoiding animal mortality, LASA guide to aseptic techniques, and NC3Rs newsletters. Moreover, we regularly subscribe to LabAnimal magazine that will contain relevant articles related to refinement. We will also consult with mousewelfareterms.org so that we can better learn about the terms that describe mouse health for improved assessment and more precise communication of mouse welfare.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As someone who used to teach the ethics of animal research, I am interested in following updates from:

The Universities Federation for Animal Welfare (UFAW), The Laboratory Animal Science Association (LASA) and the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs). We regularly receive updates from these organisations. These organisations often provide educational material on how to improve animal well-being and minimise harm, and currently I encourage my laboratory members to attend webinars hosted by NC3Rs. I will also have regular meetings with my laboratory members to critically examine if any of these good practices can be adapted without altering our experimental outcomes. For instance, in the past we have added additional enrichment into the animals' home cage and determine if this would affect food seeking behaviour. Since a pilot study determined that it did not, we have adopted this refinement. Additionally, my laboratory members regularly search the literature and/or seek help from others to improve experimental protocols to improve data yield. Doing so contributes to the reduction in animal usage.
