1. Defining the role of MYBL2 in Breast Cancer Progression

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Breast cancer, stem cells, patient derived xenografts, metastasis

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aims are (i) to define how MYBL2 levels contributes to stem cell function in vitro and in vivo; (ii) to decipher the mechanism/s by which MYBL2 regulates survival, drug resistance and movement of breast cancer stem cells (BCSCs) between tissue layers, and (iii) to exploit this knowledge to determine if manipulation of MYBL2, and/or downstream pathways, is a way to block BCSC function and hence cancer progression.

To achieve these aims we will:

1. Defining the effect of MYBL2 downregulation in BCSC function in vivo.

2. Evaluate whether altering MYBL2 levels and/or downstream pathways could be a way to eradicate the BCSC compartment thereby reducing metastatic dissemination and disease recurrence.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Breast cancer is the most common cancer in women in the UK. Despite the decline in mortality thanks to both therapy improvements and earlier detection, 90% of deaths in breast cancer patients are a result of cancer metastasis and drug resistance It has become increasingly clear that within the whole tumour, a small population known as breast cancer stem cells (BCSCs), are responsible for tumour initiation, therapy resistance and metastasis. The current clinical management for non-responders is at most palliative, aiming to prolong life and reduce pain in patients, thus, there is a real need for a better mechanistic understanding to facilitate the design of new therapeutic strategies that not only treat, but prevent metastatic, drug resistant disease.

MYBL2 is a transcription factor amplified in breast cancer, with the highest MYBL2 overexpression observed in more aggressive breast cancer types (triple negative basal breast cancer). MYBL2 amplification is associated with worse overall survival, and worse disease-free survival.

Functional validation of MYBL2 within BCSC, and the identification of drug combinations, could lead to the development of novel therapeutic strategies that specifically target this population, helping to prevent disease progression and significantly impacting on the lives of cancer patients.

What outputs do you think you will see at the end of this project?

New information on how cancer originates

New information on mechanisms that govern drug resistance and metastasis

New insight on breast cancer which potentially could facilitate the generation of novel targets for therapeutic intervention.

Potential new treatment strategies (through industry engagement)

The new information obtained through this project will be disseminated via publications and presented at cancer symposiums.

Who or what will benefit from these outputs, and how?

MYBL2 is a protein highly expressed in breast cancer and associated with short overall patient survival and short disease-free survival, and this work will be the first to investigate MYBL2 within the breast stem cell/progenitor population.

By taking a multidisciplinary approach combining in vivo mouse models with the analysis of human tumours and patient derived xenografts (PDXs), data generated will provide significant new knowledge for academics working on DNA-repair, cell-fate plasticity and cancer stem cell biology disciplines.

Long-term: Functional validation of MYBL2 within BCSC, and the identification of drug combinations, could lead to the development of novel therapeutic strategies that specifically target this population (through engagement with industry), helping to prevent disease progression and significantly impacting on the lives of cancer patients.

How will you look to maximise the outputs of this work?

The experimental data generated by this proposal, the final conclusions and supporting graphs/tables/illustrations are useful to the wider research community, which will be shared by timely publication.

Often negative data is useful to prevent others unknowingly repeating unsuccessful experiments. Raw data is also helpful to those wishing to repeat work or use similar approaches as the info can be used for power calculations.

In addition, data will be disseminated by seminar and presentation at national/international conference. Data will be made publicly available within 3 months of a manuscript that uses the data being published.

Species and numbers of animals expected to be used

- Mice: Immunocompromised mice (1000 mice)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We use mice to enable our understanding on how cancer develops and thus identify novel targets for therapeutic intervention. Virtually all the progress that has been made in understanding and treating cancer, including mechanistic understanding of cancer development and how to treat it has been done using mouse models. Mice are the chosen species because they are easy to genetically manipulate, are small and produce large litters, and easy to handle during experimental procedures. Importantly, mice are remarkably similar in genetic make-up to humans, thus mouse models of cancer will help us understand the human disease.

Moreover, the specific strain of mice that will be used under this license (immunocompromised mice) are able to grow human tumours as xenografts without human cell rejection, enabling drug testing and in vitro genetic manipulation before implantation. This enables us to mechanistically interrogate tumour growth, and hence identify new way in which to drug target. We choose to use adult mice of similar age range to minimise variability.

Another reason for using mice in our studies is that the majority of cancer models we will be using have been extensively characterised previously and develop tumours with similar aetiology and molecular profile as that observed in human disease. Published data from others inform and help to design our studies meaning approaches are more refined and use less animals. Tumour growth rate is predictable, thus less mice are required to be used for each experiment.

Typically, what will be done to an animal used in your project?

We will inoculate human cancer cell lines or patient derived tumour material subcutaneously into immune compromised mice to allow tumour growth. If we are using oestrogen receptor expressing breast cancer cells, then mice will require a minor surgical procedure to implant a slow-release hormone pellet/mini-pump enabling cancer cell growth. In some cases, when studying breast cancer stem cells (BCSCs), we will need to conduct IVIS imaging to analyse the fate of BCSCs, involving IP injections of luciferin and general anaesthesia for imaging.

Some of the cells injected will be manipulated in vitro. To be able to switch on inducible genetic elements in cells that have been engrafted into mice, we will need to feed animals doxycycline in their food.

An important part of this project is the assessment of DNA damage chemotherapies and small molecule inhibitors to target proteins related to invasiveness. The specific protein that we would like to study (MYBL2) has been linked to both DNA damage and invasiveness properties. Here, the route of drug administration depends on the specific agent but could include multiple rounds of intravenous or subcutaneous injection, or by oral gavage, or through the addition to the diet or through drinking water. To check that chemotherapies are not adversely affecting mice, we will take blood samples to test for anaemia and leukopenia. In some cases, the course of treatment will be interrupted to see if tumours grow back. Additionally, these cells could be also taken and injected into mice to study their metastatic/invasive potential.

What are the expected impacts and/or adverse effects for the animals during your project?

Immunocompromised mice will be engrafted with human cells that will form tumours as a xenograft, the main adverse effects will be related to this.

Generation of tumours under the skin (subcutaneous model): Implantation of cells will be performed under general anaesthesia. Mice could suffer mild discomfort if not at sufficient levels, overdose- induced non-recovery, or post-operative infection at site of implantation (<1%). During tumour growth, it is possible that some mice will develop tumours that will lead to signs of distress. Although relatively

rare, this may include a 20% weight loss, failure to respond to gentle stimulation, lethargic, abdominal distension, jaundice, piloerection, intermittent hunched posture, diarrhoea, or continuous laboured respiration. At first signs of any of these the mouse will be humanely killed.

Generation of tumours in the lung (Metastatic model): Tail vein injected animals could suffer from breathing difficulties. Typically, this could occur between 5-8 weeks after injection depending on the number of cells used and the type of cell line. Animals will be culled up to 12 weeks after transplantation or immediately if they display humane endpoints such as >15-20% weight loss, body condition score <3/5, failure to drink or eat over 24 hours etc.

It is possible that delivery of chemotherapeutic drugs will cause adverse effects. As the drugs we will use are well reported in the literature, we will be able to pay close attention to the development of any signs of distress. For example, anaemia and leukopenia are common side effects of chemotherapy, and we will be able to monitor the extent of this by blood analysis.

Other small drugs do not seem to have any toxicity as reported by previous groups.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that 100 % of the mice will develop tumours for which the maximum severity is moderate. However, 50% of these animals will receive potential therapies which, depending on success, would reduce the severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vitro cell culture-based models fail to recapitulate the complex interplay between cancer cells and the tumour microenvironment. New emerging approaches such as 3D cultures have emerged, but still, they are in vitro approximations that cannot reproduce the complexity of a disease. Studies using mouse models have been and still are fundamental and enlighten our understanding of the processes that lead to cancer progression and metastasis that could not be achieved otherwise. Thanks to the use of animal models of cancer, new drug targets and insights into the molecular mechanism of disease are coming to light.

Which non-animal alternatives did you consider for use in this project?

All our in vivo work will be preceded by extensive in vitro work. This system includes culturing human breast cancer cells in monolayer as a homogeneous population on plastic, and in 3D cultures (mammospheres). However, to validate our in vitro experiments, it will be necessary to extrapolate our findings to an in vivo setting, where microenvironment plays a big part on cancer cell behaviour.

Why were they not suitable?

As explained above, in vitro systems (both, normal cultures, and 3D cultures) can give a good approximation about the activity of specific drugs on cancer cells. Nonetheless, the

in vitro cultures are far from representing the true environment of the cancer cells. The cross-talk between environmental factors and cancer cells is lost in these in vitro cultures, representing a big limitation if results are to be used for therapy. Thus, modelling cancer in mice is necessary to fully understand disease progression and identify novel therapeutic approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g., pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers will be determined by pilot studies and estimations based on previous data either from the group, or published data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

NC3R's Experimental Design Assistant online tool and a sample size calculator online tool, as well as our local biostatistician will help with experimental design to reduce animal numbers, methods to reduce subjective bias, and appropriate statistical analysis without compromising the scientific objectives. Non-invasive in vivo imaging and quantification techniques of transplantations will enable multiple measurements on the same animal over a period (longitudinal sampling), reducing the number of animals, maximizing the information obtained per animal, reducing variation, and improving quality of data produced.

Where possible, transplantation experiments will be performed by the injecting two contralateral flanks of the mouse, thereby reducing the number of animals being used by a half. This will be done in particular when expanding tumour tissue for further use, or if putting experimental (+ shMYBL2) and control (-shMYBL2) into the same animal if both tumour cell types are to be exposed to the drug.

To calculate frequencies of stem cells in cancer cell populations, the L-Calc program is used. The minimum numbers required to obtain estimates of stem cell numbers with this program are data from three different cell dilutions, each of which was transplanted into five different animals. However, five dilutions into five animals are required for robust data with smaller 95% confidence intervals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding of animals will be done responsibly and with careful colony management, ensuring breeding produces cohorts of mice suitable for experimental use.

Pilot experiments with small number of animals (n=3) will be performed in those cases where effect size cannot be estimated based on our in vitro data, the literature, or previous data from co-applicants or collaborators.

All tissue surplus to requirement will be deposited into SEARCHBreast (https://searchbreast.org), a resource to facilitate sharing of archived material derived from in vivo breast cancer models.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Immunocompromised mice will be used, as they will allow for the engraftment of human cells without human cells being rejected by the immune system of the mouse. We will monitor tumour growth during time through the use of non-invasive techniques, reducing the number of animals required for the experiment. The tumour volume as determined by non-invasive calliper measurements or bioluminescence imaging will be plotted against time. This design offers the advantage of determining significant differences between tumorigenic growth potential of cell lines before the limited tumour volume is reached.

Why can’t you use animals that are less sentient?
The nature of the project requires that mice are in good health and alive so tumour cells can engraft and tumour can develop, thus mimicking what happens in humans. Because tumours require time to engraft, we cannot use immature Life stages or terminally anaesthetised animals/

Compared to other less sentient species such as Zebra fish or Drosophila melanogaster, which show a 60% homology with the human genome, mice and humans shared 97.5% homology of their coding DNA sequences. Like humans, mice naturally develop diseases, including cancer.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

When conducting a surgical procedure, we ensure that analgesia is administered before the start of the procedure. Mice are allowed to recovery from the surgery by being housed in a warm cage and observed until animal has fully recovered and is mobile. Mice are checked again for wellbeing and wound closure 4hrs later. Based on experience, it has been found that by placing the wound towards the bottom third of the spine with a combination of suturing and glue, mice are less likely to bite the wound and cause reopening. Thus, we will follow this procedure on our work.
Once mice start to develop tumours, they are monitored at least twice a week by non-invasive methods, and more so if tumour growth develops rapidly.

When administrating drugs, we will use refined techniques where possible: use of flexible gavage needles, giving doxycycline in diet rather than via injectable route etc

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines for the welfare and use of animals in cancer research. Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

Jones HRP, Oates J, Trussel l BA (1999) An applied approach to assessment of severity. In: Humane End points in Animal Experiments for Biomedical Research (Hendriksen CFM, Morton DB, eds).

London: Royal Society of Medicine Press, pp 40±7.
In publications, we will report our animal research according to the ARRIVE guidelines and conduct our experiments with advice from the PREPARE publication (PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research. ARRIVE has now been endorsed by more than 400 journals including the Nature group, PLoS, and Cell, as well as funders, universities, and learned societies.
I will sign up for the NC3Rs newsletter, so will be made aware of any notification.
I will attend seminars organized by our animal facility aimed to keep PPL holders informed on new advances in the 3Rs.

Any new advancements will be made clear to members of my team through our weekly lab meetings.

2. Comparative Cardiovascular Homeostasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

blood pressure control mechanisms, salt sensitivity, kidney function, podocyte function, kidney response to disease

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Zebra fish	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to further our basic understanding of blood pressure control and the development of hypertension through our studies on genes related to blood pressure maintenance. We wish to explore three key areas of kidney function - changing function of cells in response to blood pressure increases, injury-response of specialized filtration cells called podocytes and diseaseresponse of specialized cells of the kidney tubule.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The development and underlying causes of hypertension are not fully understood. High blood pressure is affected by genes and by factors like dietary salt and calorie intake, both of which are high in most developed countries. Often there is little clue to the underlying cause(s) of the high blood pressure – why are some people more affected by salt than others; how does diet during pregnancy affect blood pressure in newborn babies and adults; what key changes at the gene or cell level lead to gross changes of blood pressure at the whole body level?

This project covers rodent and fish models designed to increase our basic understanding of the complex interactions between genetic and environmental factors, which contribute to normal blood pressure control, and how imbalance leads to hypertension. The kidney is a critical organ for salt handling and will be a key focus of this project. Novel data and insights will be obtained regarding blood pressure regulation, salt balance, and the mechanisms underlying kidney damage and repair.

What outputs do you think you will see at the end of this project?

We will make our results available to the wider scientific community, through publication in peerreviewed journals and at conferences.

We will generate animal models and in vitro models, which will be made available to the wider scientific community.

We expect to identify mechanisms underlying reversible changes in cell function, and podocyte injury, which will be important moving forward to develop organoids in vitro.

Who or what will benefit from these outputs, and how?

The scientific community will gain immediate and long-term benefit from new mechanistic insights through publications in peer-reviewed journals, dissemination at International

meetings, direct collaboration and sharing of models generated. Animal models, generated through our previous work, continue to be used worldwide for essential research.

Mechanistic insights will ultimately inform clinical practice beyond the life of this project. We work closely with medical colleagues and where necessary, have access to patient materials in order to assess application to the bedside (e.g. current studies of reversible renal cell function). Pharma is increasingly engaging with universities as strategic research partners, with reciprocal benefit. We encourage links with industrial colleagues, in order to assess the action of experimental drugs in our animal and in vitro models.

Dissemination of the research, through public engagement, drives greater public understanding both of our group/projects and of the wider health issues.

How will you look to maximise the outputs of this work?

We will maximize the output of any new knowledge, through publications in peer-reviewed journals, dissemination at International meetings, direct collaboration and sharing of models generated.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 6000 (5000 larvae, 1000 adults)
- Mice: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use mouse and fish models designed to increase our basic understanding of the complex interactions between genetic and environmental factors, which contribute to normal blood pressure control, and how imbalance leads to hypertension and/or kidney damage and repair.

Rodent models allow us to investigate the development of salt-sensitive hypertension by addressing the effects of dietary manipulation, and identifying key changes at gene, cell, tissue, organ and whole body level, throughout development. This requires tissue sampling at embryo, neonate, juvenile and adult stages, and dietary manipulation post weaning.

Zebrafish share gene, cell, tissue, organ and system functions with higher vertebrates. Because larvae are transparent, we are able to study early pronephric development before free-feeding is established. From two weeks of age, the mesonephric kidney develops, giving us access to additional comparative materials. Zebrafish also have the ability to repair injury, allowing us to investigate injury and repair mechanisms, both in unprotected and free-feeding stages of development.

Typically, what will be done to an animal used in your project?

Initially, we will validate our novel mouse model, by feeding a high salt diet to mice with surgically implanted telemetry devices, which record real-time blood pressure in conscious, freely moving animals. We will then collect tissue samples at key time points during which salt-sensitive hypertension develops, for further analyses, including primary cell culture and single cell RNA sequence analysis, which will provide us with large amounts of information regarding the sequelae of salt-induced changes in our cells of interest.

We have used state-of-the-art genetic techniques to manipulate gene function in a key gene involved in blood pressure control in zebrafish. Gene knockout, in a zebrafish line expressing appropriate cell reporters, allows us to analyze the consequences of gene knockout, through tissue analysis, cell culture and single cell RNA sequence analysis, which will provide us with large amounts of information regarding the sequelae of loss-of-function in our cells of interest, without the need for drug treatment. Only a small number of fish will be treated with drugs to compare the effect of drug response to loss of gene function.

We have generated zebrafish lines expressing fluorescent reporters in podocytes - key cells in the kidney, which are adversely affected in kidney injury. We induce injury or cell ablation in the podocytes of unprotected larvae, using drug treatments or optogenetic approaches, and follow the immediate response to injury/ablation in unprotected larvae.

What are the expected impacts and/or adverse effects for the animals during your project?

Most GA rodents covered by this PPL will be bred for tissue isolation, FAC sorting, primary cell culture and/or scRNAseq analyses (sub-threshold).

Mice that undergo surgery (under deep anaesthesia), may experience pain post-operatively, but this is managed by the administration of pain-killers. Mice generally recover quickly from surgery, regaining any weight-loss within 5 days. Any weight loss observed in metabolic studies usually resolves within 4 days.

Drug treatments e.g. BrdU will be short term exposure only.

Most GA zebrafish covered by this PPL will be bred for tissue isolation, FAC sorting, primary cell culture and/or scRNAseq analyses (sub-threshold).

Zebrafish that undergo drug treatment (e.g. captopril for tissue challenge) or injection of drugs (e.g. puromycin for cell ablation) may suffer from oedema to a level that will not affect survival.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice undergoing surgery, dietary manipulation or drug challenge are likely to experience moderate severity of experience. Only 10% of all animals are likely to experience this level of severity.

The vast majority of zebrafish that undergo injection of drugs for tissue injury or cell ablation will be less than 5 days old (unprotected) and are unlikely to suffer because of immature sensory perception.

Captopril will be administered to adult fish at a dose level that does not cause adverse effects.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Hypertension is a highly complex disorder that cannot be replicated in a culture dish. It involves multiple organs, hormones, genetic, neuronal and environmental factors. By undertaking basic research into specific aspects of gene function, metaplastic differentiation, cell plasticity, injury and repair, we can understand the complexity of the kidney structure and function. By developing in vitro models of these processes, we aim to work towards the development of functioning kidney organoids.

Which non-animal alternatives did you consider for use in this project?

We have considered primary cell isolation, characterisation and culture in all aspects of our current research. Inconsistencies between presently available cell lines, such as the $mCCD_{cl1}$ cell line, and their equivalent cells in vivo, mean that observations may have limited application in the clinical setting. For example, mCCD cells do not appear to replicate the full degree of plasticity between PC, ICalpha and ICbeta cells. This project will enable the study of more appropriate cells ex-vivo.

Why were they not suitable?

Presently available immortalized cell lines may not be as suitable or informative as primary cells. We are therefore planning to isolate primary cells, wherever possible, to use for in vitro analyses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate the minimum number of animals required to achieve 80% statistical power in each experiment. This is judged using data from closely related experiments in the Centre or in recent scientific literature. We routinely monitor variance during experiments allowing us to adjust numbers pro-actively and use the minimum required for robust statistical outcome.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, factorial designs are used to maximize the information obtained from the experiment. For example, next generation sequencing analyses maximize the information attained from a small number of animals.

Longitudinal rather than cross-sectional studies considerably reduce the number of animals needed for time-point evaluation in, e.g. disease progression and remission; in vivo studies (metabolic cages) and telemetry recording of blood pressure. Repeated in vivo imaging reduces the need for time course experiments in which multiple animals are culled at different time points and the tissues examined histologically. These procedures provide a statistically powerful (repeated measures) approach to integrative phenotyping and importantly direct other studies to informative time points.

Collaboration with experts in relevant specific techniques, ensures success and reduces animal numbers. We will import relevant rodent and zebrafish lines from collaborators or commercial breeders where appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will maintain the minimum numbers of rodents and fish in each line to allow propagation in order to supply sufficient animals for the experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodent transgenic strains are required to model clinical conditions, and are critical for comparative purposes regarding cardiovascular, metabolic and renal function. Since genetic manipulation is advanced for these species, we constantly refine strategies for gene targeting, such as CRISPR technology, (using targets identified by microarray analyses) to maximise information obtained from transgenic models.

By inducing gene expression through, for example, time-limited exposure to pro-drugs, any adverse effects are minimised. Surgeries will be combined where possible. Animals undergoing any surgical procedures are monitored closely by a technician/researcher familiar with the model. Analgesia is administered post surgery as advised by the NVS or NACWO.

Tailored monitoring, and the implementation of strict humane endpoints represent significant refinements.

We increasingly use zebrafish larvae to understand the role of genes such as podocin in early kidney development. Most observations are made before larvae are free-feeding. The short generation time and optical clarity make the zebrafish an attractive organism for these studies, and this will significantly reduce the number of rodents, which would otherwise be used under this PPL.

Why can’t you use animals that are less sentient?

Where possible, we routinely use the less sentient zebrafish models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will strive to use the minimum number of animals in protocols of moderate severity, while achieving statistically significant results. We constantly strive to improve surgical and post-operative care and monitoring schemes. We will routinely introduce nesting materials and stimulae to home cages.

Similarly, for zebrafish, we strive to reduce startle responses and stress while netting the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will observe best practice guidance as specified by the NC3Rs and the latest FELASA guidelines for rodent and zebrafish use.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will, throughout the project, follow the latest guidance given by our local NVS, the NC3R newsletter, discussions with colleagues and literature review. We will also follow the latest FELASA guidelines on rodent and zebrafish use.

3. Cortical and subcortical networks for rodent cognition

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cognition, cortex, memory, rodent, thalamus

Animal types	Life stages
Mice	juvenile, adult
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to identify how specific interactions within the rodent brain support different aspects of cognition. A particular focus concerns two brain regions (the anterior thalamus and hippocampus), which are connected to each other and are both associated with neurological conditions causing memory problems.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Numerous common neurological conditions permanently impair cognition, including

memory. Notable examples include strokes and dementia. The conventional focus for the study of memory has been the status of medial temporal brain sites (the hippocampal formation and parahippocampal region). Our programme of research has repeatedly highlighted how this focus is detrimental as it ignores a network of cortical and subcortical sites upon which the hippocampus depends, while also showing how these same sites have additional cognitive functions. The planned level of analysis (at the neuronal level) and the lack of selective neuropsychological data for some of the key sites (e.g., the anterior thalamic nuclei) has meant that animal-based research provides unique insights. While neuroimaging findings from humans complement the animal data, they lack anatomical resolution, resulting in an absence of findings at the neuronal level.

What outputs do you think you will see at the end of this project?

The principal scientific benefits come from new information leading to a clearer understanding of cognitive mechanisms. The principal outputs will be communicated in scientific publications and presentations (including those to non-specialist audiences). Over the past five years we have published over 40 papers from research under by my last PPL, reflecting our effectiveness at disseminating new information. Additional outputs include open access to our experimental data from the time of publication.

Who or what will benefit from these outputs, and how?

In the short-term, our studies will generate a better understanding of distributed neural systems for learning, memory, and attention. The main beneficiaries will be academic researchers in closely related fields. This outcome will principally be delivered by the papers published across the timescale of the PPL. Evidence of the current impact of my research can be seen in my overall scientific citations (>10,000 since 2015, i.e., from the date of the start of my previous Project Licence).

Over the longer term I will continue my collaboration with human imagers to examine some of the basic tenets of the models we are developing and to maintain the two-way flow of information from animals to humans and back again. This approach reflects my determination to ensure that our discoveries in animals can help recast and refine questions about human memory and the causes of memory loss in conditions such as dementia. Past examples include the discovery that recall and recognition can operate using different brain circuits, with implications for both animal models of dementia and amnesia, and for the testing of initial signs of dementia, e.g., in Mild Cognitive Impairment.

How will you look to maximise the outputs of this work?

I will continue my collaborative approach to neuroscience, both within the UK and beyond. Other collaborations involve human imaging, where findings from my animal research help guide the collaboration.

I have a strong track-record of academic publications (250+ papers, >30,000 citations) and conference presentations. Our group will continue to publish papers in open-access form to enable the widest readership.

We will, also use forums such as BioRxiv to make pre-prints accessible, so alerting other researchers to our findings and, thereby, stopping duplication, while also providing access to our research data.

I have confidence in the value of published null results (subject to appropriate methodology and power). One valuable vehicle is the new, open-access journal Brain and Neuroscience Advances (launched 2016). One feature of this journal is its willingness to publish well-executed research with null results and/or failures to replicate.

I am registered to ORCID to increase the availability of my research output.

Species and numbers of animals expected to be used

- Mice: 250
- Rats: 1450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rats and mice are the preferred choice. They are used because they are mammalian species that afford translation to humans, allow the implementation of targeted genetic manipulations, and display high levels of behavioural flexibility needed for the experimental procedures to be implemented. A further criterion is that the key brain sites retain the same basic structure and connectivity between rodents and primates.

Further benefits of studying rats and mice stem from the wealth of past neuroscientific findings concerning these species, ensuring that there is no need for additional studies to test basic aspects of structure and function.

Typically, what will be done to an animal used in your project?

A total of 1700 animals (1450 rats, 250 mice) will be used across the life of the project. The purpose is to understand the properties of a set of interconnected brain regions that form a network in the rodent brain to support cognition. The principal objective has three components.

To understand the anatomical properties of the network, adult mice or rats (approximately 10% of animals) will typically receive a general anaesthetic (gas) to initiate a surgical procedure. After creating a small hole in the skull, it is possible to inject very small volumes of one or more tracers into target brain sites. Following wound repair and recovery the animal is cared for until the tracer has moved along neurons (days or weeks depending on the tracer).

To map the location of the tracer the animal is anaesthetised and then a fixing solution is injected into the blood stream via the heart (‘perfusion’), and the brain removed after death. To understand the functional properties of the network, some studies (approximately 75% of animals) will manipulate a specific target site or its connections and determine how that affects cognition, as measured by behavioural analysis. Adult mice or rats initially receive a general anaesthetic (gas) as part of a surgical procedure (or pair of procedures) that involve making small holes in the skull, allowing the injection of viruses that travel within neurons, without harmful effects. Following recovery, injections of a drug to activate the virus makes it possible to temporarily moderate specific pathways

('chemogenetics'). These drugs might be injected systemically (into the body) or intracerebrally (into target sites in the brain). Alternatively, we will inject a viral construct that is light sensitive, so that it can be switched on and off by local light sources placed on or within the brain, thereby, switching neurons on and off ('optogenetics'). The effects on cognition are measured by behavioural tests of learning.

Some of these behavioural tasks assess spontaneous patterns of activity, e.g., object recognition, while others may involve the use of food (rats) or liquid (mice) rewards. For these studies, food or water (but never both) may be restricted under carefully monitored regimens with well-defined criteria. On completion, the brain is studied following perfusion and removal. Such studies typically last for 3-6 months.

To understand the neuronal signalling properties of the network, studies will record the electrical activity of multiple sites. Adult mice or rats (approximately 15% of animals) initially receive a general anaesthetic (gas) as part of a surgical procedure that involves making small holes in the skull, allowing microelectrodes to be fixed and retained in target sites. Following recovery from surgery, neuronal recordings are made in awake behaving rodents performing tasks known to tax specific aspects of cognition. In a further refinement, these recordings may be combined with either 'chemogenetic' or 'optogenetic' manipulations (see above), in order to detect how pairs of sites interact. On completion, the brain is studied following perfusion. Such studies typically last for 3-6 months.

What are the expected impacts and/or adverse effects for the animals during your project?

For studies understanding the anatomical properties of the network, full recovery from the surgery is expected and the injected tracers themselves have no painful actions or effects on behaviour.

Consequently, the transient adverse effects (pain) arise from the immediate effects of the surgery (skin incisions and sutures).

For studies designed to understand the functional and neural signalling properties of the network, the adverse effects of any surgeries are very similar to those described above, recognising that the brain itself has no pain detectors and any injected substances have no direct aversive actions. One additional factor is that some animals have cannulae or electrodes permanently fixed to their skulls so that infusions or recordings can be made over periods of weeks or months. Nevertheless, animals display little sign of discomfort and continue to show normal patterns of eating and drinking.

As the purpose of the experiments is to understand cognition it is vital that the animal can show a full repertoire of normal behaviour and have intact sensory-motor abilities.

For some behavioural tests, animals may be encouraged to seek food reward. For this reason, they may be food restricted to ~85% of free-feeding weight, a level that serves to counter obesity and has no negative health effects. In a very limited set of circumstances animals might be trained for a liquid reward, during periods of very carefully controlled and monitored water restriction. Excessive changes in behaviour or loss of body weight would, however, lead to the immediate discontinuation of experimental work and either termination of the animal or appropriate treatment under veterinary advice.

Expected severity categories and the proportion of animals in each category, per

species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats - 1450 overall. Expected to be 1250 moderate, 200 mild. Mice - 250 overall. Expected to be 150 moderate, 100 mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research concerns the neural basis of cognition. This poses a challenge as any manipulation ultimately requires assessment or verification against some aspect of cognition, typically learning and memory, but also attention. The sheer complexity of mammalian neural networks and the need for a behavioural output measure has, so far, meant that there are no viable non-animal alternatives.

Computational modelling, while of much interest for the study of plasticity and signalling, involves networks that lack sufficient biological complexity and lack the required verifiable endpoint, cognition. While cross-referencing to the human brain is invaluable, the level of analysis that is the focus of our research simply cannot be addressed by the study of human brains.

Which non-animal alternatives did you consider for use in this project?

Two options would be to switch to computational simulations or to conduct the research with humans through neuropsychological methods and/or using non-invasive neuroimaging.

Why were they not suitable?
Simulations: The challenge of understanding cognition in the context of real biological systems means that while computational modelling can test general principles of information transfer it cannot place these in an environment that captures the complexity of the mammalian brain. Nevertheless, we are in discussions with mathematicians to look for underlying principles governing patterns of connectivity.

But this research still demands accurate biological data.

Human studies: It is, alas, not possible to switch to human studies if we wish to understand the detailed mechanisms of thalamic – cortical interactions for cognition. Neuropsychology often relies on the analysis of patients with selective pathologies. There are, for example, no known syndromes that selectively affect the anterior thalamic nuclei. Despite the occurrence of thalamic strokes, the pattern of arteries within this brain area means that circumscribed loss of the anterior thalamic nuclei never seems to occur. (There are,

however, conditions where anterior thalamic pathology or disconnection is associated with cognitive changes – consistent with our predictions from animal research - but these conditions never affect individual brain sites.)

Neuroimaging, even at the highest resolution, struggles to identify the individual anterior thalamic nuclei and cannot isolate the functional interactions of these nuclei with fMRI. Meanwhile, diffusion MRI cannot reveal the direction of any given nerve pathway (i.e., distinguish outputs from inputs) nor can it reveal diffuse pathways. Furthermore, neuroimaging studies are very often correlational in nature, making it very hard to identify causality.

Despite, the many limitations of in vivo imaging of the human brain, I will continue to collaborate with experts in these techniques as my expertise in neuroanatomy and cognitive networks has made it possible for me to guide and interpret collaborations using these non-invasive approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g., pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Behavioural studies: The research involves both conventional permanent lesions as well more-recently introduced viral-based methods (chemogenetics and optogenetics). The latter have the potential to induce transient disruptions that are more targeted (both spatially and temporally) than conventional lesions. Using these viral-based methods over recent years has resulted in reduced overall animal numbers. The reasons include the more detailed analysis of individual animals combined with the potential for a given experimental animal to be used as its own control, by switching the manipulation on and off. It is, however, still vital to have separate control groups for any nonspecific actions of the virus/activating stimulus and its surgical delivery.

Anatomical studies: We will continue to examine the fine nature of the connections to and from anterior thalamic nuclei and draw comparisons with other brain sites by tracking tracer injections. Animal numbers depend on the complexity of the sites of interest and how they might differ. The axonal transport of fluorophores tagged to viruses, e.g., for chemogenetics, does, however, mean that tissue from behavioural studies can also contribute to anatomical investigations. We are guided by the twin challenges of obtaining minimum confirmatory cases with the value of confirming any differences between brain sites. Power calculations are rarely feasible at the outset of a study. We do, however, carefully monitor the accumulation of data in order to stop as soon as is scientifically acceptable.

Electrophysiological studies: A very similar situation arises to that just described for anatomical studies. The data from individual animals can vary enormously in quantity and quality. There is a balance to be made between generating sufficient data in repeat animals in order to draw valid (reproducible) conclusions while, at the same time, not using any more than required. One consequence is the need for data analysis to proceed in

parallel with the experiments, so that an end point can be determined as it is reached.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Choice of species: The studies use rats and mice. One of the many benefits is that we can limit ancillary studies as there is a large literature on which we can build. For example, many of the major anatomical links have already been described and detailed using the in vivo transport of tracers injected into brain sites.

Choice of behavioural tasks: Priorities involve validity, ease of acquisition, and whether studies can be 'within' or 'between' subjects. 'Within subject' tasks (typically where the animal can act as its own control) include 'working memory' tasks in which the same problem can be given repeatedly to the same animal, with overall performance remaining stable. This approach reduces variance, so increasing statistical power and, thereby, reducing animal numbers. Over recent years we have devoted time to refining both spatial (e.g. T-maze alternation) and nonspatial (e.g., object recognition) tests of working memory.

By switching to procedures that have multiple trials in a single session for tests of object recognition and recency we can reduce data variance, so requiring fewer animals. The introduction of transient interventions, e.g., optogenetics, makes this 'working memory' approach all the more powerful, aiding the re-testing of the same animal as its own control.

Some key tests (e.g., attention-shift) cannot, however, be run as 'working memory' tasks as an individual animal cannot be re-tested on the same class of problems (as the repeat would substantially alter levels of performance). Here, the priority is for a task that can be readily acquired by all animals (to reduce variance and training duration). Digging tasks provide an excellent example as they use a natural behaviour (foraging to find buried food) where rodents are naturally biased to associate attributes of the digging material with the food. This combination promotes rapid, reliable learning.

The incorporation of complementary connectivity data: The neuronal transport of signals tagged to viruses, e.g., for chemogenetics, means that tissue from behavioural studies can also contribute to anatomical investigations. A further resource is the Allen Brain Atlas https://mouse.brain-map.org/. This on-line site contains details of hundreds of anatomical tracing experiments in mice (all involving anterograde tracers). Data from this resource complements and extends that from our rat experiments, so helping to limit the numbers of rats required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animals come from accredited sources where we are confident of their health status and homogeneity.

Trying to determine the optimal number of animals required in advance of an experiment is not straightforward. Power calculations are a valuable first step but also have limitations as they are derived from other, albeit similar, studies, i.e., effect sizes may differ between studies. Pilot studies, therefore, have an important, additional role in setting group numbers, or in determining whether any potential effect size is so small that the numbers of animals required would be ethically unacceptable. Bayesian analyses of data acquired incrementally provide a valuable check on the status of a study, i.e., whether to proceed

further.

I am an advocate of tissue sharing, e.g., for anatomical projects. We are currently collaborating with other research groups in the UK and beyond to share rat anatomical data, so avoiding duplication. As described above, we have extended this practice to use publicly available databases, where possible, e.g., Allen Mouse Brain Atlas, https://mouse.brain-map.org/.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In the past we have been very reliant on studying the impact of permanent lesions (e.g. by neurotoxins) in selective brain targets and measuring their effect on behavioural tests of cognition (along with sham lesion controls). We will largely replace this traditional approach by the use of 'chemogenetic' and 'optogenetic' methods to transiently modify targeted pathways in rodents. In chemogenetics, a chemical ligand is injected which temporarily activates specific nerve sites that have previously been made sensitive to that chemical. In optogenetics, light is shone onto a specific brain area that has been modified so that light pulses alter neuronal activity. In some of these preparations there is an indwelling chemical injector/light source to target cortical or subcortical sites. Any such preparation must be fully compatible with the animal performing complex behavioural tasks in an unencumbered manner.

These newer methods are a refinement over the previous standard methodology (the making of permanent brain lesions) from both a scientific and welfare perspective. One advance is their ability to isolate specific, site-to-site interactions. The previous way to test site-to-site interactions ('crossed lesion disconnection') required a minimum of four separate surgical groups (now typically replaced by two or even one, with these new methodologies). The previous surgical groupings included animals with multiple, crossed lesions in different brain sites. That disconnection approach also had important theoretical and practical limitations, e.g., the direction of effect between the two sites could often not be inferred, while fibres that cross hemispheres can suppress any disconnection effects, causing misleading null results. Consequently, these newer methods (chemogenetic and optogenetic) require fewer groups (i.e., fewer animals) and create less ambiguous data, so limiting the need for follow-up studies.

Perhaps the largest change from a welfare perspective is the emphasis on transient, highly-localised neuronal dysfunctions. Consequently, we can ensure that for the large majority of the post-surgical period the animal has a functionally intact CNS (in contrast to conventional, permanent lesions). This transient intervention approach minimises any overt or hidden negative consequences of the 'lesion'. For the same reason, the new techniques do not cause lasting harm, e.g. to sensorimotor, emotion, or motivation states, as any impact is brief. The more targeted nature of the interventions further reduce the

likelihood of unintended consequences. These techniques also create new opportunities for within- subject statistical comparisons, which rely on comparing the same animal in two different states (brain site inactivation versus unaffected state). Statistically this is more powerful than comparing between groups, meaning that some behavioural tests can be reduced in duration. For chemogenetics the drug used to activate the injected construct has been carefully selected so that at the dose levels used it should have no nonspecific overt affects - this is critical both for wellbeing and to ensure unambiguous behavioural data. For optogenetics a 'cold', restricted light source is used.

Our goal is to understand the neural basis of cognition. Consequently, sensorimotor regions are avoided, ensuring minimal nonspecific adverse effects when the transient 'lesion' is applied. Moreover, our target sites are not thought to regulate basic levels of motivation, such as eating or drinking. Cage enrichment (chewing blocks and tubes) is typically standard, while group housing is adopted whenever possible.
Finally, the greater scientific investment in each animal has meant a shift towards greater pre-training, with extensive handling, habituation, and initial training, prior to any surgical intervention. In this way we can ensure that all animals receiving interventions can readily acquire the behavioural demands when in the control state. This practice is beneficial in reducing animal stress and aiding recovery.

Why can’t you use animals that are less sentient?

Our research is designed to relate to the adult and aging human brain. Rats and mice remain the choice of species as the structure and connectivity of key brain sites are strikingly similar to ours. To study cognition, it is vital to examine learning tasks that are analogous to those that humans encounter. Rats are unusually versatile at problem solving, partially reflecting their omnivorous nature. They show a wide repertoire of stratagems helping us, for example, to discover and analyse the brain’s multiple spatial location and navigation systems. (The Nobel Prize in Physiology or Medicine, 2014 was awarded to O’Keefe, Moser, & Moser: "for their discoveries of cells that constitute a positioning system in the brain" – discoveries initially made in rats.) We are unaware of any demonstrably, less sentient species that has the required cognitive skill-set.

Nonrecoverable studies under terminal anaesthesia are of value as an initial first step in determining the consequences of a manipulation (e.g., chemogenetic or optogenetic) at the level of individual neurons, e.g., through electrophysiology. This will, however, only provide preliminary data as, if the full behavioural experiment is later initiated, it will be necessary to assess neural activity in awake, behaving animals. We are, however, able to use the expression of immediate-early genes in post- mortem tissue as a proxy for neural activity in some studies, so avoiding additional in vivo electrophysiological verification.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The Animal Health checklist (see Action Plan) provides an invaluable means to monitor and standardise the monitoring of animals. In consultation, we look for any further checks that might usefully be added to the section 'Expected Adverse Effects specific to your research, in order to reflect the novel techniques that we are increasingly using. One example concerns the status of any indwelling cannula.

A different area of anticipated refinement concerns the ligands (currently clozapine) we use to activate DREADDs (both systemically and intracranially). Recent studies suggest

alternatives with better binding properties, resulting in less spread within the brain, i.e., less potential for ‘off target’ unwanted effects that might potentially cause distress to the animal.

We also anticipate the emergence of reliable DREADDs virusest h.t travel retrogradely in nerve axons (we currently only use anterograde viruses). Retrograde transport will allow more precise targeting of subregions within sites of interest, e.g., specific thalamic nuclei. This advance should result in more selective cognitive dysfunctions, with less risk of any distress or unintended consequences to the animal.
We increasingly pre-train animals on behavioural tasks prior to surgery. This has multiple benefits. Occasional animals are unable to acquire task rules, and so it would be inappropriate for them to receive surgical interventions. Pre-training speeds up the required days of training post-surgery, so reducing time spent following intervention. It is also likely that this practice reduces stress at the time of surgery and aids recovery. We also increasingly rely on behavioural tasks that match the animals' innate predispositions, e.g., tasks based around natural foraging, while ininnatecreasingly eliminating the use of aversive stimuli.

Further routes for refinement arise from discussions with the NACWO, aided by the recent presentation of our research programme to the animal support staff. NC3Rs provides a vital source of new ideas and welfare practices, e.g., rat 'tickling', available to all our researchers.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs provide a repository of information, including updates concerning Refinement. We will regularly access this information, e.g. webinars, along with receiving notifications as subscribers. The ARRIVE guidelines provide a self-checklist to ensure experimental rigour. Other relevant information is published by UFAW, FRAME, RSPCA, and LASA.

ARRIVE 2.0 (2020) has been updated and reorganised into two sets, the “ARRIVE Essential 10,” which constitutes the minimum requirement, and the “Recommended Set,” which describes the research context. Prior planning and adherence to these requirements will enable both research rigour and refinement.

Refinement also arises from awareness of current research developments (from web resources, e.g., Pub Med, Web of Knowledge, Google Scholar) and having sufficient flexibility to adapt to new, improved methods.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

A vital method is via the NC3Rs website https://nc3rs.org.uk/ I and all my research team are registered subscribers, so we receive regular news updates and reminders of resources. Topical examples include information on the new ARRIVE guidelines (2.0, 18th August 2020). These resources are further promoted NC3Rs Regional Programme Managers.

Other relevant information comes from the Laboratory Animal Sciences Association (The Forum), UFAW (University Federation for Animal Welfare), the RSPCA, and the NVS.

Implementation arises from discussion with the research team, the NACWO and their support team, along with the NVS. To enable this process, I recently gave a seminar to the NACWO and support staff regarding the goals and nature of my research, so they are best placed to assist.

4. Investigating disorders of sex development in the mouse

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

disorders of sex development (DSD), sex determination, mouse models of human genetic disease, gonad development, cell fate determination

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

There are two broad aims: i) to create and study mouse models of human disorders/differences of sex development (DSD); and ii) use these models and other approaches to identify molecular and cellular mechanisms by which cells in the developing fetal gonad commit to becoming a building block of either a testis or an ovary.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sex development (or sex determination) describes the process by which the fetus develops male gonads (testes) or female gonads (ovaries) during gestation in the womb. Usually, a chromosomally XY fetus develops testes and an XX develops ovaries. Disorders/differences of sex development

(DSD) in the human population are relatively common and can affect development of the gonads (testis and ovary), the reproductive tracts (such as the vas deferens or oviduct) and the external genitalia. Whilst sometimes DSDs can be relatively mild, as in the occurrence of undescended testes, they can sometimes, although rarely, have a more dramatic and distressing impact, as in cases of XY female presentation or ambiguous genitalia. The majority of cases of DSD that disrupt the development of the gonads (gonadal dysgenesis) still do not have an explanation at the genetic level and therefore do not benefit from a genetic diagnosis and associated clinical management.

The creation of mouse models of DSD has two major impacts: i) it allows clear roles in gonad development (sex determination) to be established for genes (and changes to those genes) implicated in human DSD by clinical and human genetics investigations - these can then be used for novel diagnostic tests for specific DSDs; ii) it reveals the genetic principles by which genes act to build mouse and human gonads, shedding light on similarities and differences and revealing mechanisms by which cells adopt a particular fate (testicular or ovarian) during fetal development. The latter component forms part of the bigger project, happening in labs all around the world, of understanding how a single-cell embryo develops into a multi-cellular organism and exploiting this knowledge in regenerative medicine (such as stem cell therapies, and so on).

What outputs do you think you will see at the end of this project?

The primary output will be knowledge: understanding the role of genes in mouse gonad development and thereby shedding light on the origins of disorders/differences of sex development (DSD) in humans, with a view to improving diagnosis. This knowledge will be the product of collaborative interactions, ongoing for a number of years, of human geneticists, clinicians and mouse geneticists, in the UK and elsewhere in the world. The knowledge will include understanding molecular mechanisms of gene function but also how genes interact. We now routinely study mice that have alterations to more than one gene and on different genetic backgrounds. The idea here is to model the more complex genetics that characterises human diseases, where evidence for digenic (involving two genes) and oligogenic (involving several genes) inheritance is becoming clearer. Therefore, one additional output here are the mouse lines that we generate (3-6), which will be of interest to other researchers nationally and internationally, both in the sex determination field and beyond. They may allow the identification of new biomarkers of disease and possible therapeutic targets.

One focus of our phenotypic work at the moment is the use of single-cell approaches. This means we can examine the impacts of deleting a gene on the expression of all other genes, one cell at a time. This approach is already revealing the complexity of the sex determining pathway and pervasive disruption to or loss of sex identity at the cellular level in genetically altered mice. The approaches we are taking will be of use to others in the field and beyond and we will advertise the computational approaches we take, and associated protocols, and make them available to others, through scientific meetings and publications.

We have a track record of publishing in high profile journals and will continue to do so. We will also disseminate novel data and methodologies through involvement at meetings and in collaborative networks in which we operate, and through publication.

Who or what will benefit from these outputs, and how?

Our immediate collaborators, especially those studying the genetics of human sex determination, will benefit from the insights that our research creates. They will be able to tailor their genetic screens and molecular analyses to reflect the knowledge we produce in the mouse. This might include investigating in humans genes related to the mouse genes we study, or genes in the same 'pathway' of activity. It will also allow them to perform functional studies on human cell lines or with human fetal tissue, using hypotheses arising from the mouse data we provide. The interaction here is synergistic and iterative: we benefit from their studies of human genetics in identifying genes to study further in the mouse, and the mouse genetics and phenotyping data allow them to further refine and extend their studies in humans, and so on.

Our mouse genetics collaborators and the wider mouse community will benefit, because we make available all of the genetically altered lines that we generate. Some of these lines will be of interest to researchers studying other systems (cardiovascular, neural etc), because many of the genes we study impact systems beyond the reproductive organs and related phenotypes may be observed.

Another group to benefit will be clinicians who are looking to close the existing diagnostic gap, such that individuals with DSD can be confidently given a diagnosis for their condition. Additionally, patients and their families may benefit from such diagnoses and the improved clinical management they permit.

Finally, the wider scientific community will benefit from the approaches that we take and novel methodologies we use, including computational methods for examining single cell gene expression in developing tissues.

How will you look to maximise the outputs of this work?

All of our experimentation is collaborative. We only study genes that our human genetics/clinical colleagues consider interesting and worthy of further study. If initial investigations in the mouse suggest that it will not be profitable to proceed, the experiments will be terminated. We have, however, previously published data showing that a particular gene does *not* function in mouse sex determination: this is because some

genes are associated with a wealth of supporting evidence, from humans and other sources, *suggesting* a potential role, and it is important that we publish negative data (showing that such a role does not exist) to prevent others from repeating our studies. We will continue to publish such negative data.

Species and numbers of animals expected to be used

- Mice: 9850

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The aim of this project is to model aspects of human disorders of sex development (DSD) in mice and study the genetic control of gonad development. As a mammal, the mouse has reproductive organs that are similar to those of humans, in contrast to other non-mammalian vertebrates, like fish and birds, that differ significantly in the ways in which they use genes to build gonads in a fetus. More generally, the mouse model is known for its utility in reproductive biology, its contribution to reproductive medicine, and medicine more generally, as a model of human biology. Moreover, research into mouse gonad development by my laboratory and others over the last 30 years has revealed that many genes functioning in mouse sexual development also function in human sexual development. Examples of these include the key pro-testis genes SRY, SOX9 and DMRT1, and the pro-ovary genes WNT4 and RSPO1 – and this commonality strongly suggests that pathways of gene activity are highly conserved between mouse and human sex determination.

Typically, what will be done to an animal used in your project?

Typically, mice will be bred for maintenance of a genetically altered strain. Some females will be mated and killed when pregnant in order to allow the study of fetal reproductive organs. Occasionally, but rarely, pregnant mice will have a chemical agent administered to them in order to allow control of timing of gene inactivation in a fetus, activation of transgene expression or mark dividing cells.

What are the expected impacts and/or adverse effects for the animals during your project?

Occasionally, but very rarely, adult mice may experience some lasting harm because of the novel genetic alterations that they have. Suffering here will be minimised by using refined methodologies and finding ways of targeting the impacts of the genetic alteration to the gonad: gonadal abnormalities alone are very unlikely to result in suffering.

The vast majority of the research proposed here focuses on the fetal mouse gonad, between 10.5 and 14.5 days after fertilisation. There will be very few adult mice that

experience anything other than transient discomfort, since most will only be carrying (heterozygous) mutations.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of animals bred under this licence will experience suffering sub-threshold: they will experience no suffering other than transient discomfort. Around 10% will experience up to a mild limit and a small minority (5-10%) will suffer up to a moderate limit.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The adult gonad is a complex organ comprising many different cell types, such as germ cells, which contribute genetic material to the next generation, and gonadal supporting cells, which support germ cells through their developmental journey, from embryonic primordial germ cells through to mature gametes just prior to fertilisation. Hormones are produced by steroidogenic cells. These cell types are already in place during the fetal period. Fetal gonad development is a complex, dynamic process, involving migration of cells from sites outside the gonad, and a complex choreography that is very time-sensitive, by which different cells types communicate and come into close proximity over time. Only the examination of this process in the context of the whole developing fetus can allow a reliable examination of the process of gonad development as it occurs during pregnancy. This process cannot yet be studied in individual cells in isolation or in groups of cells cultured together.

The study of gonadal function requires the use of a whole animal because it is subject to control by a complex hormonal system, involving the pituitary gland and hypothalamus of the brain. This system cannot yet be adequately modelled in a dish.

Which non-animal alternatives did you consider for use in this project?

We have used cell lines to perform various functional tests and such lines will still be useful to us in future. In particular, we have used cell line assays to assess the impact of mutations and

'reprogramming' methods to turn stem cells into cells that mimic cells of the fetal gonad. But this latter method only works so far to produce one of the gonadal cell-types, and the cells are only *similar* to endogenous fetal cells *in vivo*: they do not faithfully recapitulate the features of cells isolated directly from a fetus. But they can still be useful.

In addition, we have used 'organ culture' methods to study particular processes - such as cell migration into the gonad - but this still requires an early fetus to provide an early stage gonad, which is then developed further in a dish in culture media.

Why were they not suitable?

The cell models discussed above allow certain processes, particularly biochemical processes, to be studied and we have done so and will continue to do so. But the aim here is to study the impact in the mouse of genetic alterations that model those found in humans. Studying the impact of those genetic alterations in individual cells will not allow a complete understanding of how they impact the complex, multi-cellular choreography of mouse (and human) gonad development in the fetus. The intricate ways in which cells communicate with each other over time is vital, and this cannot yet be modelled in a dish, outside of the normal environment of the developing fetus in the womb. But we continue to be vigilant about the development of 'gonad organoid' approaches i.e. 'artificial' gonad-like organs made by mixing different cell-types together. Nobody has yet made such an organoid, but some laboratories, with whom we are in contact, are trying. The development of *in vitro*-derived gametes is one reason for generating gonads in a dish, but better understanding gonad *development* is almost certainly a condition of future success.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers estimated here are based on over 25 years of studying and publishing on the process of sexual development in the mouse and the statistical methods that have underlain this. We have extensive experience in performing experiments and publishing data from them; we know how to design controls and how many repeat experiments we need to perform, in order to generate statistically significant data that will pass the peer review process prior to publication. Such publication is vital for maximising the impact of our data on the community of researchers.

As an example, 5-6 independent fetal gonads will be required to reliably examine the impact of a genetic alteration on gene expression, using a variety of techniques. The number of such experiments has been estimated based on the number of different genes whose expression we need to analyse. On average, a pregnant female mouse will provide around 8 embryos/fetuses. Only 1-2 of these might have the desired genetic alterations,

although others can act as important controls. On some occasions, the number of desired embryos may be less, such as when mice with more complex genotypes are crossed together. These sorts of consideration account for the number of adult mice that need to be bred.

Lower numbers are required for the moderate breeding licence since the vast majority of mice bred under this licence with be sub-threshold or mild.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have access to, and make regular use of, a trained statistician to assist in experimental design.

We mostly use a particular strain of mouse, C57BL/6J, which is ideal for investigating impacts on male gonad development. We have enormous amounts of experience in what to expect from this strain in normal gonad development, and therefore deviations from that norm are easy for us to spot if we repeat experiments on a handful of occasions to verify the outcome. The outcome is often quite tightly constrained by using the same mouse strain, in which every individual has a near identical genetic constitution (genome). This also helps to keep numbers of animals to a minimum. Single-cell approaches have also meant that we do not have to collect large numbers of fetal gonads to purify enough RNA for bulk RNAseq approaches or protein for Western blotting.

Females intended for tamoxifen dosing will be palpated at 9.5 dpc and if not pregnant can be used for timed mating again rather than dosed and wasted.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continually monitor and revise the amount of breeding we perform. Breeding is designed to ensure that we have sufficient number of female mice to support the generation of fetal gonads for use in various types of experimentation. The minimal number of phenotypic tests on fetal gonads will be performed, consistent with being able to establish convincingly that a phenotype exists and, if possible, its molecular and cellular basis. Regular meetings with the breeding team ensures breeding is matched to the number of females required for timed matings.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our focus is on using similarities between mouse and human reproductive biology to shed light on the causes of human disorders/differences of sex development (DSD). We mostly intend to isolate and examine tissue from the fetal gonad - most animals bred under this licence will experience no lasting harm and will be killed following breeding. We will attempt, when possible, to target genetic alteration to the developing gonad: a very small minority of mice will be allowed to exhibit abnormalities in the juvenile/adult period caused by genetic alteration. Conditional approaches allow us to overcome lethality and welfare-related issues.

Why can’t you use animals that are less sentient?

The mouse sex determination pathway is highly conserved with humans, in contrast to that of flies, fish or birds. These latter three, for example, lack a sex-determining Y chromosome. We have previously collaborated with a laboratory that uses zebrafish. However, such work is useful only for certain aspects of our research, such as examining whether a mutated gene malfunctions in the context of another species. The use of non-mammalian animals is not sufficient to model human gonad development or biology: this because there are differences in the sex chromosome systems, the organisation of the sex-determination genetic networks and the underlying biology of the gonad, including the role of hormones. However, if there was an opportunity to study a gene with a highly conserved gonadal role in a less sentient animal, we would take it.

The majority of embryos/fetuses studied here will be before 14.5 dpc and therefore before they are protected under ASPA.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any adult mice being administered substances will be handled using best practice techniques. We will strive to restrict harm to the fetal period by, in the vast majority of cases, generating adult animals only carrying a single copy of a defective gene or transgene. Adult animals lacking a functional gene in every body cell will be minimised by the use of conditional gene deletion techniques. No surgery will be performed on this licence.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from LASA guidelines.

The animal house has full AAALAC and ISO9001-2015 accreditation. To conform to these standards we must ensure a high level of quality control on all fronts including husbandry, phenotyping and administrative processes. The ARRIVE guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have attended and presented at a variety of 3Rs-related events in the UK, including AWERB Hub events. I have a network of contacts due to my previous participation in bioethics events, my chairing of the local AWERB for 10 years and my membership of an NC3Rs working group. I will implement reduction and refinement through close contact with my colleagues who are striving to do the same in their own model systems, and through regular discussions with NACWOs and animal technicians on site. I also visit the NC3Rs, FRAME and ARRIVE guidelines websites for news updates. Advances that we can implement will be implemented.

5. Identifying genetic and cellular mechanisms of alveolar development and repair

Project duration:

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

lung, alveoli, tissue repair, regeneration, development

Animal types	Life stages
Mice	adult, pregnant, neonate, embryo, juvenile

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Growing evidence indicates that reactivating or manipulating factors that are important for lung growth during development can be used to repair/regenerate damaged lung alveoli following injury and/or to generate additional alveolar surface area where development has been disrupted. This project will identify potential pro-repair factors that are required for lung development and determine whether they can be manipulated to treat alveolar injury

in adult lungs and/or generate additional alveoli in developing lungs where there is insufficient surface area for normal respiratory function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The clinical burden of both adult and congenital lung disease (including disease affecting premature babies) worldwide is substantial; in the UK alone, respiratory disease kills one in four people. The lungs have an innate ability to repair themselves, however in many lung diseases, the normal process of tissue repair is disrupted. Examples include Chronic Obstructive Pulmonary Disease (COPD), where alveolar tissue is destroyed and Bronchopulmonary dysplasia (BPD) where insufficient alveoli form in infants born prematurely. There are currently no curative treatments for these diseases, patients are only provided with symptom relief such as oxygen support. Therefore, we will identify factors that are required to generate lung alveoli and investigate whether these factors can be used to help repair or grow additional alveoli and treat these diseases.

What outputs do you think you will see at the end of this project?

Outputs from this project will include new information about factors required for lung development and whether these factors can be manipulated to repair lung damage. We may also identify potential treatments to enhance lung repair (which may involve the combination of pro-repair factors with novel delivery techniques designed to optimise pro-repair function). Development of these treatments to clinical trials will be suitable for diseases affecting the alveoli including COPD, Idiopathic Pulmonary Fibrosis (IPF) and BPD and will be outside the scope of this programme of work. Other outputs will involve scientific publications of our findings including methodological papers to enable other groups to adopt novel techniques we have developed.

There will be 3 main outputs from this programme of work:

Comprehensive evaluation of whether at least three mouse models with developmental lung defects also have a role in lung repair and make this data available to scientific community.

Evaluation of whether modification of signalling pathways that affect lung development can modify lung repair using mouse and human models.

Publication of 2 methods papers describing novel models to image and track lung repair that are established during this research.

Who or what will benefit from these outputs, and how?

In the short-term (5 years), the outputs will benefit the research community by identifying novel genes required for lung development and/or to repair damaged lung tissue that could be suitable targets for drugs to treat various lung diseases.

In the longer-term, the models, delivery techniques and/or pro-repair molecules that we discover during this programme of work maybe suitable to investigate, as potential treatments for lung diseases. This will be in partnership with pharmaceutical or bioscience companies.

How will you look to maximise the outputs of this work?

We have a network of key collaborators who use similar approaches to us but in different organs including kidney, heart and liver. We regularly share resources and information with these groups.

We publish methodological papers on new techniques and models that we develop to inform the wider scientific community.

We will continue to hold workshops to highlight the uses of precision-cut lung slices to the International scientific community.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures. Explain why you are using these types of animals and your choice of Life stages.

In this project, embryonic, juvenile and adult mice will be used. This is because we need to investigate the growth of lungs and lung disease after birth and in adults.

We will also use some genetically modified mouse strains so that we can determine the role of a particular gene at different stages of life e.g. by inactivating the gene in embryos that will then mature into adults or inactivating only once mice reach adulthood.

Typically, what will be done to an animal used in your project?

Most typically an animal under this licence will be bred and then killed using a schedule 1 method to obtain tissues (4500 out of 5000 =approximately 90% of all animals).

The remaining 10% of all mice (500 out of 5000) in this licence may be used in protocol 3 to test potential therapeutic interventions for lung injury.

Of the 10 percent of mice that may be used in Protocol 3, the typical type of experiment will be as follows:

To test pro-repair factors for treatment or prevention of lung disease- wild type and mutant mice are administered intranasally (i.n.) with a single substance to induce lung disease or

injury e.g. Influenza or LPS. This is unlikely to cause more than a minimal clinical effect. Following induction of lung disease, a putative pro repair treatment is administered i.n. on up to three separate occasions over a maximum of 14 days, with a minimum of 24 hours in between doses. Some mice will receive a pro- repair treatment without prior induction of lung injury. Mice will be killed by anaesthetic overdose followed by harvesting of blood, tissues and other bodily fluids for further analysis.

Example of the most extreme type of experiment likely in P3- approximately 10% of mice

To test pro-repair factors for treatment or prevention of lung disease- wild type and mutant mice are administered i.n. with a single substance to induce lung disease or injury e.g. Influenza or LPS. This is unlikely to cause more than a minimal clinical effect. Following induction of lung disease, a putative pro repair treatment is administered i.n. on up to three separate occasions over a maximum of 14 days, with a minimum of 24 hours in between doses. Some mice will receive a pro-repair treatment without prior induction of lung injury.

A blood sample may be taken on one occasion and/or in vivo imaging on a maximum of 2 occasions. Urine may also be collected. Under terminal anaesthesia mice may then undergo lung function analysis followed by blood sampling followed by post-mortem harvesting of tissues.

What are the expected impacts and/or adverse effects for the animals during your project?

None of the procedures used should cause lasting harm. Anaesthetics are used where appropriate to reduce stress for example during administration of substances to the nose. Some of the substances we administer may cause flu-like illness with some loss of appetite and weight however, these symptoms are transient. We will closely monitor mice for signs of ill health such as piloerection, hunched posture, inactivity or inappetence. If any such symptoms are observed, mice will be monitored more frequently and additional measures such as warming or wet mash will be provided. Should the signs persist for a period of 24 hours the animal will be humanely killed. In addition, mice will be weighed daily and any animal that loses 15% or more of its starting body weight will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around 80% of animals will experience mild severity or sub-threshold severity, where animals are bred, genotyped and then killed to obtain tissues and body fluids. Of the 20% of mice remaining 10% used in P3 could reach moderate severity. A further 10% of mice will be used in protocol 2 however, only one quarter of these mice could reach a moderate severity limit i.e. only those where the gene of interest has been completely removed (homozygotes) therefore the total percent of mice that may reach moderate severity is 10% plus 2.5% = 12.5%.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the lung is a complex organ and the essential respiratory organ of the body, it is not possible to undertake certain comprehensive physiological studies outside the context of an intact organism where all native cell and tissue types are present in their normal numbers and arrangements (e.g. epithelium, mesenchyme, vasculature, lymphatics and nerves). In addition to all these components being present in their normal arrangements (morphology) constituting an entire organ, the lungs must be connected to an active circulatory system and be maintained within a restricted space (thoracic cavity) that is subjected to mechanical cyclic strain as occurs during normal breathing. There is currently no alternative to a whole animal that can reproduce all these factors together.

Another key reason why we cannot currently entirely replace animal use for this project is that this study focuses on how developmental pathways and their disruption have a long-lasting effect on adult health and disease suffered in the postnatal animal. It is therefore necessary to perform these studies on mice with developmental disorders maturing into effected adults. Moreover, we wish to identify genes that are required to establish normal structure of the whole lungs, e.g., for the lungs to form their full complement of airways, alveoli etc.

We do this by analysing the whole lungs both during development and post- natally, if embryonic development is affected, in the context of a mouse carrying a genetic modification in a gene(s) of interest. This type of analysis must be undertaken in whole intact lungs that have developed in a genetically modified in vivo environment and cannot be undertaken in a system such as a lung slice or one that models one compartment of a whole lung e.g. an airway (ALI cultures) or lung on a chip (an alveolus).

Which non-animal alternatives did you consider for use in this project?

Whenever possible we make use of non-animal alternatives. Some of our experiments will be carried out using mouse or human cell lines and other experiments are conducted using human lung tissue slices. We also make use of various biobanks of human material e.g. UK Biobank, Northern Finnish

Birth cohort and information for our studies to understand the genetics of lung development and disease. Throughout the project, where possible, non-animal experiments will be employed and we will consult various databases of existing human and mouse information.

Why were they not suitable?

As outlined, it is necessary for us to use animals for some of our experiments so that we can obtain information about how a particular gene or signalling pathway affects an animal at different life stages and how the lungs are affected in the context of a whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is estimated based on previous experience of the number and type of experiments we will do over the duration of the project. Where we had previous data from similar experiments available, online power equation calculators were used to determine animal group sizes required to obtain statistically meaningful data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where we had previous data from similar experiments available, online power equation calculators were used to determine animal group sizes required to obtain statistically meaningful data. We also employed the NC3R's experimental design assistant where possible to ensure that animal numbers are the minimum required to obtain meaningful data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to make use of databases of human and mouse information e.g. UK Biobank and Mousephenotype.org to obtain information which will reduce the number of animals we need to use.

Using our experience and that of the animal technicians, we will employ efficient breeding strategies for example, Mouse lines will only be maintained whilst there is a justified use for their continued breeding. Any line with no predicted usage will be cryopreserved and removed from the shelf. Prior to establishment of a colony of GA mice under this licence, any available breeding data will be sought.

Well established breeding calculations will be used to predict output.

Breeding numbers are calculated taking into account average litter size for that stock as well as known neonate mortality. Breeds are set up in a controlled, time restricted manner, to ensure that all mice born are the correct age for the study.

Where breeding information is not known (i.e. for new lines) a small pilot breed will be carried out first to assess viability. These mice, if viable, can be used for the first cohort of

the study, and remaining larger breeds will be set up taking into account information gathered from the pilot breed.

Where possible, we will maximise the data obtained from each cohort of mice. For example, when mice are sacrificed blood, BALF and any relevant tissues will be extracted from the same animals. Where relevant this may include tissues from other organs such as heart, kidney, liver which we will share with our existing collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The severity of the breeding stock will be held to a minimum by the following strategies: Information gathering- Information on any expected adverse effects will be gathered prior to establishment of a line. Welfare assessment - Systems of comprehensive welfare assessment are in place. These will be used to define the least severe humane endpoints for every GA line. Least severe genotype - Where possible the lines will be maintained as the least severe genotype possible (e.g. heterozygotes will be used for stock maintenance where the homozygous state has undesirable adverse effects).

Sampling techniques - The least severe technique will be used to obtain a biopsy for genotyping i.e. from the ear pinnae phenotyping tests - Lung function analysis will be either in an unrestrained plethysmograph where mice are not anaesthetised and can move freely or under terminal anaesthesia.

Where substances are administered to mice e.g. pathogens, or LPS, we will use the minimum amount of agent, by the least invasive route (typically intranasal administration) which has previously been shown to cause the desired effect.

In many experiments, we will use ex vivo models that we have developed using precision-cut lung slices to address our research questions. For these experiments mice are killed using a schedule 1 method and the lungs are extracted to obtain tissue slices.

Why can’t you use animals that are less sentient?

The mouse is the lowest mammalian species in which the full range of genetic and physiological manipulations necessary for the investigation of lung development and disease can be achieved. It is critical to perform these studies in mammals since there are significant differences between the respiratory systems of frogs and fish to that of humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Daily monitoring of animals will take place where substances have been administered, this will include monitoring of body weight allows us to define more humane endpoints. Pain management will be provided on the advice of the Veterinary Surgeon for any procedure or situation that requires it. Training is continual making use of new developments and technologies as they become available.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The establishment where work under this licence will be undertaken is AAALAC accredited. We will follow published ARRIVE guidelines and as well as information issued by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), and the RSPCA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The scientific literature and conferences are sources of information on new developments and technologies, as are workshops run at our establishment on the Replacement, Refinement and Reduction of animal use.

6. Batch Potency and Safety Testing of Foot and Mouth Disease (FMD) vaccine

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

FMD vaccine, Potency, Safety, Antisera

Animal types	Life stages
Cattle	adult

Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To ensure that each batch of FMD vaccine is produced is safe and effective for field use.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished

Why is it important to undertake this work?

To ensure the ongoing protection of the global animal population from Foot and Mouth Disease (FMD) by vaccination. FMD is a highly contagious viral disease of cloven-hooved animals with significant economic impact in cattle, pigs, sheep and goats. In wildlife, all cloven-hooved species are susceptible to FMD with some of them such as African buffalo, acting as a reservoir of the virus without showing clinical signs meaning that eradication of FMD by slaughter is not possible. In susceptible, non- vaccinated domestic farm animal populations, morbidity could be as high as 100% and is an OIE (World Animal Health organisation) notifiable disease.

What outputs do you think you will see at the end of this project?

The availability of an effective FMD vaccine is the cornerstone of many national government strategies to prevent FMD outbreaks with their associated animal welfare problems and social and economic and environmental costs.

Who or what will benefit from these outputs, and how?

Routine vaccination is used in any countries or zones where the disease is endemic or where there is a risk from circulating virus spreading from neighbouring countries or zones which are infected.

How will you look to maximise the outputs of this work?

N/A

Species and numbers of animals expected to be used

- Cattle: 2350

- Pigs: 2010

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Protocols 1 and 2. The species, numbers and ages of the animals used is specified in the European Pharmacopoeia. Any deviation from these specifications will lead to rejection of the results by the regulatory authorities.

Protocol 3. The species and number of animals used for this test are determined by the volume and specificity of antiserum required.

Typically, what will be done to an animal used in your project?

Protocol 1: Animals will be vaccinated and have their rectal temperature taken for two days prior to vaccination and then for up to fourteen days post vaccination. Animals will be euthanised by a Schedule 1 method.

Protocol 2: Animals will be vaccinated and a blood sample will be taken from superficial blood vessels no more than twice in a 28 day period. Animals will be euthanised by a Schedule 1 method.

Protocol 3: Animals will be vaccinated and a blood sample will be taken from superficial blood vessels (no more than 15% circulating blood volume in a 28 day period or no more than 10% on any one occasion). Animals will be euthanised by a Schedule 1 method.

On the rare occasion for protocol 2 and 3, an additional blood sample may be taken but this will remain within the permitted volumes (no more than 15% circulating blood volume in a 28 day period or no more than 10% on any one occasion)

What are the expected impacts and/or adverse effects for the animals during your project?

Protocol 1, 2 and 3 - Some animals may experience mild swelling around the injection site. Some animals may experience slight swelling (hematoma) around the blood sampling site.

Animals in protocol 1, may experience a high temperature reading which is outside of the sponsors limits. If this is seen for two successive recordings, the findings are reported to the NVS, who will examine the animal (s) to diagnose if it is the vaccine or an incidental intercurrent disease that is at fault. Treatment or Schedule 1 is dictated by the NVS.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1: Mild – All animals Protocol 2: Mild – All animals Protocol 3: Mild – All animals

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field,

which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The procedures detailed in this licence application are governed by European and British regulatory requirements which stipulate the methods of testing to be employed.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is based on the expected number of vaccines to be tested throughout the life of the project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Protocol 1 and 2 – The number of animals used for each test is the minimum number required by the European Pharmacopoeia. Any deviation from these numbers will lead to rejection of the results by the regulators.

Protocol 3 – These numbers would be dictated by the demand from the sponsor.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As the number of animals to be used is dictated by the legislative requirements, the only other area of optimisation is to reduce wastage by reusing animals that have completed other projects and where the re-use criteria are fulfilled.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For the safety test, the European pharmacopeia specifies the most sensitive category of animal to measure any adverse effects of the vaccines on each target species (this usually means the youngest age indicated). The safety test involves the injection of a double dose of the commercial formulation of the vaccine with temperature monitoring.

The original method of assessing vaccine potency was a challenge test with live FMD virus

The European Directive 2001/82/EC indicates that methods other than the challenge method stated in the Pharmacopoeia for determining the potency of FMD vaccine may be used provided that statistical evaluation has established a satisfactory correlation between the two methods. The correlation between the level of circulating neutralising antibodies in animals vaccinated with the batch under test and the level of protection against infection has been well established and all the major FMD institutes and vaccine producers now use the in-vitro assay of neutralising antibody levels as a direct measurement of vaccine potency. This means the test has reduced to usually one injection with commercial formulation of the vaccine and then a blood sample. The European Pharmacopeia specifies cattle, or any other species for which immunogenicity has been shown. There is now an increasing requirement of national governments for the tests to be carried out in at least one of the target species the vaccine is intended for.

Why can’t you use animals that are less sentient?

The pharmacopoeia dictates the species and age of animal required for this regulatory testing based to ensure efficacy and safety of product.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

All injections and blood sampling are carried out by trained and competent staff and to recognised veterinary standards.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance and information is obtained from NC3Rs, IAT, LASA and the RSPCA, particularly. LASA guidelines on administration of substances and taking of blood sample, NC3Rs guidelines on blood sampling. Where specialist training is required, inter-institutional exchanges and training visits are organised.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

In addition to staying involved via stakeholders such as LASA, LAVA, NC3Rs, every six months the organisation's 'Species Use and 3R group' meets to discuss all animal work performed at the establishment. A summary of the work performed on this PPL will be presented to the Animal Welfare and Ethical Review Body (AWERB) committee after 18 and 48 months of the PPL. This will include discussions on how improvements on the work can be made.

7. Maternal and neonatal immunity to virus infections

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

virus, antibody, infant, vaccine, drug

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to characterise maternal and infant immune responses to virus infection in order to develop novel approaches for control of virus infection in both mothers and offspring.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Childhood virus infections are a major cause of infant mortality. For example, worldwide an estimated 215,000 children under 5 years old die annually from diarrhoea caused by rotavirus infection (Tate et al, 2015), and up to 111,500 children under 5 die from respiratory disease caused by influenza infection (Nair et al, 2011). In addition, the extent of disease in children caused by newly emerging viruses such as COVID-19 is not yet fully known.

In order to protect children from virus infections it is essential we develop highly effective vaccines and anti-viral drugs. We therefore need to understand how the immune system of infants responds to virus infection so that the most effective control strategies can be designed. It is known that the maternal immune response can significantly affect the immune response of offspring, so both groups of individuals must be carefully evaluated together. Using a breeding mouse model of virus infection will enable detailed study of this complicated system.

What outputs do you think you will see at the end of this project?

By the end of this project we will have greater understanding of the immune responses of mother and infants to virus infections. We will use this knowledge to develop a new approach to protect babies from one or more of the viral infections of childhood. This may be in the form of a new vaccine strategy, or a new anti-viral drug. These findings will be published in peer-reviewed journals following the ARRIVE 2.0 guidelines (a checklist of recommendations to improve the reporting of research involving animals), and we plan to put forward any promising new products for clinical trials.

Who or what will benefit from these outputs, and how?

Improved knowledge of mother and infant immune responses to viruses will be of considerable value to the wider viral immunology research community within the time-frame of this five year project. Development of new vaccines or anti-viral therapies has the potential to reduce childhood disease and deaths from virus infections, although delivery to patients will require lengthy clinical trials which will occur beyond the duration of this project.

How will you look to maximise the outputs of this work?

Partnerships are already established with a collaborator who plans to study new vaccine approaches to virus infection in adult mice. This project will therefore complement ongoing work.

Knowledge gleaned from this project will be published open access in a timely manner in order to disseminate findings as widely as possible. Both successful and unsuccessful approaches will be published and discussed at scientific conferences.

Species and numbers of animals expected to be used

- Mice: 8880

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To study antibodies that are transferred from mother to infant across the placenta and in breast milk ('maternal antibodies'), a mammalian model is required. For this reason, we

have chosen to use the mouse as this is a good and widely accepted mammalian model for this research. This model will enable us to gain understanding of virus infections and maternal antibodies in humans.

Typically, what will be done to an animal used in your project?

Female mice will be infected with different viruses to induce protective immune responses. Mice will then be mated in order to study how maternal immunity is transferred to their offspring. Immune responses in both mothers and pups will be assessed by collecting small volumes of blood from the animals during life, as well as extensive study of their organs after the animals are killed at the end of each experiment.

Pups may be infected with virus within the first week of life, or later as adults. Virus infection levels will be measured either by studying stool/blood samples, imaging mice under anaesthesia, or from organ analysis after death.

New vaccine approaches will be tested by either vaccinating the mother before/during pregnancy, or by vaccinating young pups. To test how effective vaccines are, pups will be infected with the viruses when adults.

New anti-viral drugs will also be tested in mouse mothers and pups to see if new ways of treating virus infections can be identified.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the viruses studied may cause mice to lose weight in the first two days after infection, but weight normally returns back to normal within approximately 7 days. Some of the viruses used may also cause signs such as ruffled fur and rapid breathing during the same period. All mice that show these signs will either be killed if signs reach predetermined humane endpoints such as weight loss of 15% plus clinical signs of disease, or if the mice have not returned to full weight within 2 weeks.

Although mice infected with some viruses may develop signs of disease at high doses of virus, this project aims to identify improved vaccination and treatment options. It is therefore anticipated that only the control mice which don't receive the vaccine or treatment in each experiment are at risk of experiencing disease. Furthermore, careful calculation of virus doses will be performed in preliminary experiments to ensure that disease is kept to a minimum.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: mild severity 90%

Mice: moderate severity 10%

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals is essential to study the overall immune responses to virus infections. This is because the immune response to viruses is very complex and cannot be replicated in cells in a laboratory. Furthermore, to determine how effective new vaccine approaches are, experimental infections in mice are required.

Which non-animal alternatives did you consider for use in this project?

We have considered, and will initially use cells in the laboratory for all preliminary experiments. This is because different cells can readily be infected with the viruses we are studying, and this will allow us to study the effects of viruses and antibodies on a single cell level.

Why were they not suitable?

Experiments in the laboratory will be suitable for first testing whether virus replication can be blocked by specific antibodies or drugs. However, to study complex immune responses that involve many different types of cell working together, infections and vaccinations of live animals are essential.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have extensive previous experience of infecting mice with viruses, which enables us to make good estimates of how many animals will be required for each experiment. In addition, we have used a specialised programme called the NC3Rs Experimental Design Assistant to help us calculate the number of mice needed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Extensive review of the scientific literature has been conducted to enable predictions for likely outcomes of experiments planned (e.g. suitable virus doses, efficacy of maternal antibody transfer), so the minimum number of mice can be used. I have also sought the advice of more experienced colleagues to ensure animal numbers are at a minimum and welfare is maximised.

We will test all new medicines for treating virus infection in cells in the laboratory first, and only progress to animal experiments if positive results are obtained.

Where possible, we will infect mice with viruses that can be tracked using specialised imaging equipment. This will allow us to monitor how much virus is present in each animal by imaging, instead of having to kill the mice to measure the amount of virus in each organ.

The PREPARE guidelines have also been consulted for formulation of this project, and these will be followed to ensure continued communication between the animal facility and our team.

We have used the NC3Rs Experimental Design Assistant to help us calculate the number of mice needed, and will continue to use this throughout the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding programmes of genetically altered mice will be optimised to ensure as little over-breeding as possible. This project will aim to keep “surplus” animals to a minimum. In order to reduce the numbers of breeding pairs the mice will be kept as purebred lines (when appropriate), provided that they do not show any signs of disease.

Samples collected from any mice as part of experiments planned will be stored long term at -20C. This will make the samples available for future analysis by scientists working on this project, and also for any collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project uses mice that will be infected with different viruses, then their immune responses will be studied by collection of blood samples, and analysis of different organs after death.

The mouse has been selected for this project as it is the best way to study human anti-viral immune responses. The mouse also benefits from well-established and robust technologies for modifying their genes. Where possible we will use experiments of the shortest duration so long as to do so will yield satisfactory data.

In order to understand how maternal immunity impacts on infant immunity to virus infections, we must work with viruses that can replicate in mice. These can cause clinical signs at high doses, but is essential that we follow the outcome of infection to fully investigate immune responses that can lead to viral clearance. If we kill animals at the first sign of infection we cannot investigate what responses are required that allow them to clear the infection naturally. Previous experience has shown that weight loss can correlate closely with the amount of virus in a mouse. Monitoring weight loss is therefore an effective way of determining infection, and is a widely used and accepted measure. However, weight loss is not the only measure of infection and we will use a comprehensive monitoring and scoring system to assess the animals throughout experiments.

Finally, this project aims to use non-surgical embryo transfer as a new approach for breeding genetically modified mice. This method will be explored and optimised over the course of this licence as a refinement to the existing surgical method of embryo transfer.

Why can’t you use animals that are less sentient?

Study of how maternal immune responses impact on the immunity of infants requires use of animals that transfer antibodies to their offspring via the placenta or in milk. This specialised method of antibody transfer therefore means species such as fish, flies or nematodes cannot be used for this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All mice that are infected with viruses will be monitored twice daily for any clinical signs of illness (e.g. ruffled fur and weight loss in adult mice, or rejection by the mother in pups). The results of these will be recorded in a spreadsheet for each experiment. Additional mash will be provided for sick animals unable to access the food hopper, and extra nesting material will be given to improve the comfort and warmth of virally infected mice.

Weights for all animals over 3 weeks of age will be recorded once daily after infection until weights have returned to normal. Mice will thereafter be weighed once weekly. Again, a record of weights will be kept.

To assess levels of virus we will use minimally invasive sampling, such as sampling from faeces, or imaging where possible.

For any procedures requiring anaesthesia, mice will be monitored closely for the duration of their recovery.

For viruses given by mouth, a drop of sugar solution will be placed on the end of the delivery tube in order to encourage swallowing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use guidelines from the Laboratory Animal Science Association (LASA) to make sure all experiments are conducted appropriately. In particular we will follow the 'Guiding principles on good practice for Animal Welfare and Ethical Review Bodies'.

To ensure refined experimental design we will follow the PREPARE guidelines for planning experiments, and for thorough, responsible reporting of results we will follow the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to be informed about the 3Rs during the duration of this project by regularly checking our institute's 3R's search page, and being registered for the regular NC3Rs e-mails and newsletter updates. Regular reference to guidance documents provided by Laboratory Animal Science Association (LASA) and the RSPCA will be made.

We will also ensure continued contact with the organisational teams in the facilities in which our mouse work is conducted. Any new recommendations will be incorporated into our experimental plan wherever possible.

8. Regulation and development of adaptive immune responses

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Immunology, Antibodies, Infection, Vaccines, B cells

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project to understand the cellular and molecular mechanisms that control adaptive immune responses, with a focus on how antibody-mediated immunity develops.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit – these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines are among the most important medical interventions available, saving millions of lives each year.

Vaccines work by “educating” the immune system about what potential pathogens “look like”, i.e. by inducing immunological memory against them. An important way that this is achieved is by stimulating the generation of pathogen-specific antibodies. Antibodies are soluble proteins that are found in blood and in tissue fluids and are made by terminally differentiated B cells, a type of white blood cell. The most potent antibodies usually have “neutralizing” capacity, that is they can tightly bind (i.e. with high affinity) key sites (epitopes) that invading microbes use during the infection process. For example, effective influenza vaccines stimulate the production of antibodies that recognize and block the function of hemagglutinin, a glycoprotein that the virus uses to enter lung cells.

The goal of our research is to understand how B cells “decide” which antibodies to make during immune responses. B cells face an enormous challenge, because they need to be able to recognize an almost infinite number of target epitopes. Furthermore, microbes commonly change (or disguise) the proteins that they express to avoid and escape immune recognition. Fortunately, antibody responses are also highly plastic: B cells can edit their antibody encoding genes and therefore engineer bespoke reagents for each pathogen that they encounter. This remarkable feat is achieved in specialized structures known as germinal centres, where B cells mutate their antibody genes and then select the best variants. Our research is focused on understanding the development and regulation of adaptive immunity in general, but we have a major focus on determining how particular antibodies are selected in germinal centres.

Despite effective and safe vaccines existing for many important diseases, there are several common and devastating diseases against which it is still not possible to immunise. Among these are HIV/AIDS (caused by human immunodeficiency virus, HIV) and malaria (caused by Plasmodium spp), which still kill many hundreds of thousands of people each year. The development of vaccines that induce long- term immunity against Covid-19 will also benefit from a better understanding of how antibody responses are orchestrated. Consequently, there is an urgent need to learn more about how immunological memory is established and regulated, and then to use this knowledge for informing vaccine development strategies. By learning what determines antibody specificity during immune responses, we hope to gain a better understanding of what is needed to drive protective immunity.

What outputs do you think you will see at the end of this project?

This is a basic science project that is expected to lead to the generation of new fundamental knowledge regarding how antibody dependent immune responses develop and are regulated. We hope to identify new mechanisms that can be exploited in the development of vaccines.

We aim to identify biochemical pathways that can be targeted in diseases that involve dysfunctional B cell responses, e.g. lymphomas and autoimmunity. We anticipate contributing to a generally improved understanding of how adaptive immunity is established. The discoveries made through this research will be reported in peer reviewed publications.

Who or what will benefit from these outputs, and how?

We aim to decipher the mechanisms determining the magnitude, quality and nature of antibody- dependent immune responses in settings of infection and after immunisations. Antibodies are soluble proteins that are made by the immune system that specifically bind to particular foreign antigens (sites on pathogens), and by doing this they either neutralize the pathogen by inhibiting its normal functions or induce its destruction. Almost all currently approved vaccines, as well as many of those in development, are thought to rely upon antibodies for their efficacy.

The first beneficiaries of our research will be other immunologists in academia and in private industry (benefits expected to be evident within 2-5 years). Our aim is to decipher some of the key principles underpinning the regulation of antibody responses, therefore the findings are likely to be of interest to broader audiences beyond those in our immediate field. Some of our earlier findings are reported in popular textbooks used to educate medical and science students around the world, and we anticipate a similar impact again (a second beneficiary, expected in 4-10 years). Science is a highly iterative process, therefore major findings help inform the next research steps to be taken by multiple groups (impact over longer periods of 5-10 years). Beyond the findings themselves, the development of new approaches and techniques is also likely impact other fields such as T cell biology and developmental biology (second beneficiary, benefits in 2-5 years).

Inappropriately targeted antibody responses are responsible for a range of autoimmune diseases. As such, the third beneficiary will be scientists and clinicians involved in researching or treating autoimmune diseases (third beneficiary, 2-5 years). By determining the mechanisms controlling normal antibody-mediated immune responses, we anticipate identifying pathways that might be dysregulated in disease. Similar principles are true for some cancers also; dysregulated germinal centre responses can cause lymphomagenesis (fourth beneficiary, 3-6 years). The indirect impact on understanding disease pathogenesis is likely to take a further 3-7 years.

Vaccine development involves making reagents that initiate antibody responses against targets of interest, i.e. particular sites on pathogens. For example, the most promising approaches currently under development for vaccination against human immunodeficiency virus (HIV) involve trying to very carefully shepherd antibodies down defined developmental pathways in germinal centres.

While such pathways only occur occasionally in the course of natural infections, it is thought we should be able to manipulate immune responses using vaccines in such a way as to induce them.

Effective vaccines will also depend upon stimulating the generation of sufficient antibody titres (i.e. high concentrations of antibodies in the blood). Our research is aimed at understanding how antibody maturation pathway trajectories are determined, and what controls the generation of antibody secreting plasma cells, therefore our findings will benefit researchers working in this area (fifth beneficiary, 2-5 years).

In summary, our results will directly benefit basic science in the short and long-term and expect to indirectly contribute to the understanding of various diseases/treatments.

How will you look to maximise the outputs of this work?

Output will principally be in the form of peer review publications. We always publish our findings in well-respected international journals, thereby ensuring optimal distribution. Our institute has a dedicated public engagement officer who will help draw attention to studies as and when they are released (e.g. through social media and traditional press platforms). Beyond publications, we will present our findings at conferences at the earliest appropriate times, to ensure quick dissemination of newly gained knowledge. Where appropriate, we will collaborate with other research groups in related disease areas so that they can quickly make use of our discoveries, tools and approaches.

Species and numbers of animals expected to be used

- Mice: 34250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures…

Explain why you are using these types of animals and your choice of Life stages.

Adult mice will be used to research the biology of adaptive immune responses. Adult mice are used because they have fully formed immune systems that are similar to that of humans.

Typically, what will be done to an animal used in your project?

Genetically altered or wild-type mice may receive immunisations to induce immune responses. In some cases, they may also have immune cells from other mice transferred into them using injections.

Alternatively, mice may receive bone marrow transplants following whole body irradiation. At certain stages of immune responses, mice may receive injections of certain drugs, such as those used in people, to block certain molecular pathways. By subsequently comparing treated and control mice, we will learn how certain molecular pathways impact immune responses. The measurements made may include asking whether mice are better or worse protected from a certain viral infection (e.g. Influenza A virus), or we may harvest lymph nodes from euthanised mice and examine the quality of the immune response.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts will be similar to those experienced by humans receiving similar treatments. Where mice receive whole body irradiation and bone marrow transplantation, they are likely to feel unwell for some period and will be susceptible to opportunistic infections. Such mice will be

housed in appropriate controlled conditions to limit the chances of infections and may receive prophylactic antibiotic treatments. Immunisations may cause some local

irritation/inflammation and can be associated with a fever-like response. The side effects of drug treatments will depend upon the specific compound but like in humans they can range from no undesirable effects to moderate levels of systemic or local discomfort. Influenza and malaria infections are usually self-resolving but do cause general periods of feeling unwell that can last multiple days and cause mice to reduce their food and/or water intake.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice (>80%) will suffer subthreshold or mild severities of suffering. Some mice (<20%) are expected to suffer moderate severities of suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We aim to understand how protective antibodies develop in germinal centres. Germinal centre responses are a complex multi-cellular and multi-lineage process that cannot be recapitulated in vitro. Germinal centre B cells cannot be isolated from human blood samples. Germinal centre B cells are programmed to die or differentiate outside their native environment, further limiting the types of ex vivo experiments that can be performed. For these reasons, it will not be possible to determine the mechanisms controlling antibody development without the use of animal experimentation.

Which non-animal alternatives did you consider for use in this project?

- We have considered using human blood samples.
- We have considered using human tissue samples (e.g. tonsils).
- We have tried using in vitro differentiated “induced germinal centre B cells” (iGCB cells). In silico modelling.

Why were they not suitable?

Human blood samples do not contain germinal centre B cells or any of the other cell types found in germinal centres. Antibodies do not undergo affinity maturation in the blood.

Human tissue samples. These are useful for descriptive and comparative purposes, however it is not possible to probe specific mechanisms this way.

In vitro differentiated “induced germinal centre B cells”. iGCB cells share some properties with real germinal centre B cells, but in reality they are more different than similar.

We collaborate with in silico modellers, however while such approaches are useful for prediction, they cannot test real biological mechanisms or functions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of mice have been estimated based upon typical numbers of experiments required to test specific hypotheses. These estimates have taken into account our experience from the last 16 years as well and projected changes in project scope during the next five years. Average animal group sizes take into account POWER calculations for reaching statistical robustness and prior experience of levels of variability within groups.

Numbers of animals required for breeding protocols take into account animals generated with the wrong genotype as well as animals that are required for colony maintenance but will not be moved to other protocols. Animal numbers listed in experimental protocols include those transferred from breeding protocols as well as those purchased from the core facility and outside vendors.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of excess mice generated through breeding will be minimised by constant and careful monitoring of breeding programmes. We will endeavour to repurpose mice that are identified as having the wrong genotype for their initial purpose (e.g. using them in place of wildtype animals in experiments where appropriate, or for parasite production).

Careful experimental design, including efforts to increase uniformity and reduce random variation, will be used to detect significant differences with low numbers of animals. Blinding is introduced where possible, for example in scoring histology. Therefore, our approach is to use factorial designs and blocking to remove nuisance variables, if numbers allow. The majority of our experiments produce quantitative data that can be analysed by parametric methods such as ANOVA or t-test (STATA, www.stata.com). Experimental procedures are reviewed within our group and at institutional inter-group meetings. The university biomedical services unit and training support officer provide statistical support.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of animals used will be reduced by careful animal breeding strategies. Examples of careful breeding employed will include advanced experimental planning so that animals are bred in greater numbers for specific experiments where they are needed, and care will be taken to ensure that required animal numbers are generated concurrently so as to allow good experimental group sizes. In cases where single mice are required to carry multiple genetically altered alleles, breeding strategies will be carefully designed to ensure efficient inheritance of the desired genotype; for example by breeding 69omozygous mice together rather than heterozygous mice (potentially reducing animal use two-fold relative to heterozygous breeding strategies).

We have an active collaboration with a computer modelling group and, where appropriate, in silico predictions will be used to target experimental approaches more efficiently.

We will share malaria parasite stocks with our collaborators to reduce the number of animals required for their generation. When using new experimental approaches, small pilot experiments will be used initially to assess feasibility and their appropriateness.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project involves the breeding, maintenance and use of genetically altered animals. In the majority of cases, the genetic alteration itself will not cause the animal any harm. In a minority of cases, animals harbouring gene alterations that cause them to be immunosuppressed are required. Such modifications include the interruption of genes that are required for the development of certain immune cell types. We will always use models that are the least harmful while achieving the required effect; this will often involve using genetic alterations that are least likely to cause mice to suffer infections from opportunistic pathogens.

Our research is aimed at understanding how immune responses are regulated. For this, we commonly need to infect or immunise mice with pathogens or vaccines, respectively. Vaccines usually cause less harm than infections, therefore these will always be our preferred choice. Vaccines usually include adjuvants that boost their immunogenicity and promote longer-lived immune responses. A wide variety of adjuvants exist and each differs in terms of their inflammatory properties, and therefore how likely they are to cause undesired effects (such as local inflammation, transient fever). Where possible, we will use the least harmful adjuvant type (e.g. alum) to minimise the harm caused, and we will also always chose the least harmful appropriate route of administration (e.g. often using subcutaneous administration rather than intraperitoneal).

We will avoid the use of Complete Freund's adjuvant wherever possible – we expect using in very rarely (in <1% of immunization experiments). These experiments sometimes require us to also transfer immune cells from one mouse to another, however the use of best practice techniques means that this rarely causes more than transient mild discomfort to the mouse.

Immune responses to vaccines and infections are not identical, and therefore we will sometimes need to use pathogen challenge models (e.g. influenza A virus, malaria causing plasmodium parasites, vaccinia virus). For such experiments, we will use the least harmful strains possible, and use appropriate inoculum doses that are less likely to cause significant disease. This will minimise the severity of symptoms caused by the infections. Following infection, mice will be carefully monitored for signs of suffering and experiments will be terminated if animals approach the severity limits outlined herein.

To decipher the molecular and cellular events controlling immune responses, we will sometimes treat mice with defined drugs or pathway altering substances. To minimise harm, we will carefully determine, based upon the scientific literature, an appropriate dose regime. Where the expected effects of any drugs on the animal's welfare are not known, or where harmful effects are likely, animals will be carefully monitored for signs of suffering. If repeated injections are required, we will consider whether the installation of osmotic pumps for continual slow-release administration.

Bone marrow chimeric mice are generated by treating animals with a dose of irradiation that ablates their existing immune system, followed by reconstitution the irradiated mice with donor bone marrow. This experimental approach allows us to assess whether certain genes are required in certain cell types. To minimise the harm of the whole-body irradiation, mice will usually be treated with a course of antibiotics for approximately 4 weeks following the treatment, thereby minimising the likelihood of them suffering opportunistic infections. The minimal irradiation dose possible will be used, and irradiation doses will be split to limit harmful effects to other tissues and organs. We will sometimes use approaches that involve adoptive transfer of mature immune cells into non-irradiated hosts to avoid using irradiation-based approaches.

Why can't you use animals that are less sentient?

Mice are the least sentient animals that have immune systems similar to that of humans. We need to use adult mice in order to mimic closely the adult human immune response, and similar experiments cannot be performed in less sentient animals due to them lacking a similarly complex immune system. Immune responses take days to fully develop and can continue evolving for several weeks or even months. For this reason, terminally anaesthetised animals cannot be used in most experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will continue discussions with vets and animal technicians regarding how our protocols can be refined further. We continue to monitor the scientific literature for approaches that are more efficient and less harmful, for example new adjuvants for immunisation. One

example where this has already proved useful is in identifying technological advances that permit in situ photoconversion through the skin (where previously surgery was required). Another example is the use of hock injections in place of foot- pad injections. We also will utilize techniques for silencing/expressing (e.g. Crispr) gene that involve retroviral/lentiviral delivery platforms as an alternative to generating new genetically altered mouse lines.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the 3R resources (https://www.nc3rs.org.uk/3rs-resources).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All lab members will regularly attend the animal facility users meetings to learn about the latest developments in the 3Rs.

We will continue discussing our experimental approaches with facility NACWOs and NVSs so that protocols can be constantly improved. We will regularly visit the 3R website (https://www.nc3rs.org.uk/the-3rs) to obtain the latest updates.

9. Molecular basis of meiotic recombination and its impact on fertility

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

fertility, chromosome pairing, cell division, egg, sperm

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand how maternal and paternal chromosomes - the DNA structures that carry the genetic information in every cell of the body - pair and exchange material (recombine) during the cell division that produces eggs and sperm in mammals (meiosis), and to determine the impact of this process on fertility.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The cell division that produces eggs and sperm (called meiosis) is fundamental for healthy sexual reproduction in mammals. In sex cells, maternal and paternal chromosomes must pair and exchange genetic material (recombine) to maintain a correct number while dividing, which ensures successful meiosis and normal fertility. However the mechanisms

that control this process remain poorly understood. This project will characterise in detail existing and novel regulators of each of these steps to understand how they impact meiosis and fertility levels in the mouse.

Errors in meiosis result in miscarriage, birth defects, and infertility in humans. Infertility affects 1 in 6 couples worldwide. Despite recent advances in the treatment of male infertility in particular, the exacts defects involved remain largely unknown. The results from this project in mice will be directly relevant to human fertility, and indeed infertility. Findings may therefore assist diagnosis and counselling in patients with fertility issues, and open new treatment options.

What outputs do you think you will see at the end of this project?

This project will greatly advance our knowledge and understanding of the molecules involved in meiosis (the cell division that generates sperm and eggs), and how they impact fertility in mammals. These experiments conducted in the mouse will provide a detailed characterisation of the role of both known (but poorly understood), and novel (yet to be discovered) protein factors that regulate this fundamental process.

We expect the findings will be published in high ranking scientific journals, and will support successful applications for further funding. All new computer-based methodologies developed, as well as the data generated from the animals used during the course of this project will be extremely valuable and become available to the wider scientific community for use in other types of analysis that may advance further research in this field.

Who or what will benefit from these outputs, and how?

As meiosis (the cell division that produces eggs and sperm) is highly conserved across mammals, we anticipate the findings will have an immediate impact and advance both scientific and medical research into human fertility.

In the long term, the molecules identified and characterised in these studies in mice will provide new fertility candidate genes for screening which may help diagnosis and counselling in couples with fertility issues, and open new treatment options for patients with infertility.

How will you look to maximise the outputs of this work?

This project is established in close collaboration with three other groups locally, each bringing specific skills and expertise. This enables an efficient and coordinated analysis of the mice studied, and the integration of the findings into a highly informative view not otherwise possible. The experimental strategies will be continually reviewed, and revised if necessary against the objectives, as a collaborative discussion. The findings from this work will be published (including all data generated made publicly available), and regularly presented at relevant conferences in the field, providing additional collaborative opportunities that may advance further the progress of the scientific discoveries.

Species and numbers of animals expected to be used

- Mice: 8000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Meiosis, the specialised cell division that produces sperm and eggs, occurs exclusively in cells of the male and female reproductive tissues, respectively. To characterise the protein factors involved, and study their role in maintaining normal fertility in mammals, we chose the mouse as our experimental animal model.

The laboratory mouse is the most widely used animal model in research to study key biological processes in human health and disease. Due to similar genetics and biology between mice and humans, genetic manipulation in the mouse can be used to identify disease mechanisms and develop treatments for humans. Importantly, infertility naturally occurs in the male offspring of crosses between certain mouse species; these represent natural (non genetically modified) fertility models to study. In addition, sites where genetic material was swapped between maternal and paternal chromosomes (the structures that carry the genetic information in all cells of the body) are easy to detect in these crosses. Finally, a number of mouse mutants already exist for key molecules involved in meiosis; this provides a great resource for this project. For all these reasons combined, the mouse represents the most appropriate model for this research and its relevance to infertility in humans.

Meiosis occurs at specific times in males and females during their lives. In females it begins in the mother's womb, in the ovary of the foetus, and pauses at birth, resuming later at puberty to complete at the time of sperm fertilisation; in males it starts in the testis around 10 days of age, and carries on into adulthood. We will therefore use mice ranging from foetal to adult stages.

Typically, what will be done to an animal used in your project?

The animals will only be used for breeding and maintenance of the lines of interest to:

assess fertility in live animals (through breeding) provide reproductive tissues for downstream analysis of meiosis

What are the expected impacts and/or adverse effects for the animals during your project?

The genetic modifications engineered during this project are not expected to cause any harm to the animals besides a reduction in fertility (ranging from a partial to a complete loss).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity: 100% of all mice

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Meiosis is a cell division that occurs exclusively in sex cells of the male and female reproductive systems. While we will be using non animal, easy to expand, cancer cells to study certain properties of the molecules involved in this process, these systems lack the specialised cell environment only present in sex cells. It is extremely difficult, however, to maintain sex cells alive and functional outside the animal to carry out experiments. At present, meiosis can therefore only be studied in the whole organism by analysing reproductive tissues of animals from relevant strains. In addition, this project requires live animals to investigate the impact on fertility of certain genetic modifications, by monitoring breeding performance to quantify fertility levels.

Which non-animal alternatives did you consider for use in this project?

Cancer cell systems: before moving to animal studies, if appropriate, we will first test the relevance of molecules of interest in cancer cell systems where they can be artificially expressed and some aspects of their function studied. In addition, such system has the advantage of high expression (in contrast to typically very low levels in the living animal), and more complex, quicker gene manipulation than possible in the mouse. The findings from these studies can then guide and complement experiments in animals, directly impacting animal numbers down. In some instances, they may even preclude animal strain development if the function of the molecules tested do not prove to be relevant.

Sex cell systems: a number of studies have demonstrated the benefit of using mouse embryonic (stem) cells to characterise some aspects of meiosis, and we are keen to try and implement these more relevant cell systems for functional studies in the future. Recently, this cell type was successfully turned into sex cells using a specialised cocktail of factors. If feasible, we would consider implementing this methodology in the future to replace some of the animal-based studies. This alternative, however, is likely to be technically challenging with limited success. This would have to be weighed against the level of replacement and reduction in animal use this approach would potentially enable so as not to compromise the progress of the research. Trials would first be required to determine the feasibility of this methodology in our hands.

Why were they not suitable?

We have successfully used in the past and intend to continue to use as much as possible non animal cancer cell systems where key molecules can be artificially expressed and some aspects of their function studied. However, as mentioned earlier, these systems lack the specialised factors only expressed in the male and female reproductive tissues, and cannot fully replace (only contribute to a reduction in animal numbers) the studies in the whole body where the correct cell environment is present.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates are primarily based on the actual number of animals used on 2 previous Licences with similar animal experiments, taking into consideration:

established mouse lines of interest already breeding on the current Licence

new genetically altered mouse lines for genes of interest that will be generated during the course of the project

On average, we used 1000 mice per year over 5 years for maintenance of mouse colonies and experimental animals, all lines combined (average of 5 lines being studied). Based on an average of 8 lines in breeding, we estimate we will use a total of 8000 mice over 5 years to complete this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Wherever possible, if appropriate, the molecules of interest will be tested first in cancer cell systems before moving to animal studies. We have successfully used and will continue to use cancer cell lines wherever possible to help inform and refine the animal studies, therefore working towards a reduction of the number of animals needed for experimentation. However, these cell systems lack the specialised environment only present in sex cells, and therefore remain limited for functional studies.

During the experimental design, we searched and will continually review available cryobanks and databases, including MGI (http://www.informatics.jax.org), the international mouse knockout consortium (http://www.knockoutmouse.org), and the DNA Archive for ENU chemical mutagenesis screens (http://www.har.mrc.ac.uk/services/archiving-distribution/enu-dna-archive) for existing mouse lines of relevant gene mutants and fertility models. Every care will be taken to avoid duplicating animal resources.

All new analysis downstream of animal tissue collection will be first trialled and optimised in pilot experiments on a small group of animals to estimate the minimum number to be used to achieve the results.

Once determined, we will carefully control the breeding to avoid excessive and unnecessary production of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding: breeding of all colonies will be reviewed every 2 weeks with the animal care staff to produce the numbers required and, if possible, only the genetic modification desired, avoiding excessive and unnecessary production of animals.

Sharing of tissues: we will aim to share the tissues from the same animal between multiple analyses. When new opportunities arise, pilot experiments will be conducted to assess the feasibility of these approaches.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most widely used animal model in research to study key processes in human health and disease. Due to similar genetics and biology between mice and humans, genetic manipulation in the mouse can be used to identify disease mechanisms and develop treatments for humans.

Based on these principles, we have chosen to use the mouse as our experimental model to study meiosis (the cell division that produces eggs and sperm), and its role in fertility in mammals.

Importantly, infertility naturally occurs in the male offspring between very distinct mouse species, providing natural models of infertility. In these, and in other fertile crosses between distinct mouse strains, sites where some genetic material was swapped between maternal and paternal chromosomes (the structures that carry the genetic information in all cells of the body) are easy to detect. These mice are therefore very informative strains in which to introduce genetic modifications of interest to test their impact on meiosis and fertility.

During this project, we will characterise existing and newly generated mouse mutants for key genes of interest expressed in reproductive tissues. No harmful consequence is

expected from the genetic modifications studied in these animals besides an impact on fertility (ranging from a partial to a complete loss). This project only requires breeding and maintenance of these mouse models to assess fertility in live animals, and provide reproductive tissues for analysis of:

fertility levels by measuring the weight of testes and ovaries, and counting eggs and sperm

pairing of chromosomes by antibody staining of sex cells

binding of key molecules on chromosomes

changes in expression of key genes during meiosis

Why can't you use animals that are less sentient?

The mouse is the most appropriate animal model to study the cell division that generates eggs and sperm, and characterise the key molecules involved in this process for the reasons outlined above. Dictated by the biology of the process we are studying, we will use mice ranging from foetal to adult age. Like in humans, this cell division occurs at specific times during the development of male and female mice: in females it begins in the foetal ovary and arrests at birth, resuming later at puberty to complete during egg fertilisation by sperm; in males it starts in the testis around 10 days of age, and carries on into adulthood.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

No harmful consequence is expected from the genetic modifications introduced in these animals besides an impact on fertility (ranging from partial to complete loss).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the published guidelines for best practice "Refinement and reduction in the production of genetically modified mice, Laboratory Animals Vol 37, Supp 1, July 2003".

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The licence holder and all animal users involved in the project are regularly updated on advances in the 3Rs via the following routes:

termly 3Rs newsletters published by the 3Rs sub-committee of the ACER (Animal Care and Ethical Review) Committee at the University are circulated to all animal users: they provide an update on the 3Rs advances in many areas of research and give specific examples of good practice and successful implementation in specific areas of research across the University. Useful links to other 3Rs resources and upcoming 3Rs workshop events (both internal and external) are also advertised here.

Animal Welfare Meetings for animal facility users (3 times/year): the Regional Programme

Manager for the NC3Rs (National Centre for the Replacement, Refinement and Reduction of Animals in Research) and NACWO (Named Animal Care and Welfare Officer), are presenting examples of successful trials and new implementations of the 3Rs from projects within the University (also published in the 3Rs newsletter). Useful links to 3Rs resources and upcoming 3Rs workshop events (both internal and external) are also circulated during these meetings.

discussion with the Regional Programme Manager for the NC3Rs: opportunities for the implementation of a recent advance in the 3Rs within or outside the University, or the development of a novel approach can be explored in more detail.

N3CR website: www.nc3rs.org.uk.

10. Understanding the Mechanisms of Healthy and Unhealthy Ageing in the Central Nervous System

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Ageing, Neurodegeneration, Synapse, Calcium homeostasis, Memory

Animal types	Life stages
Mice	juvenile, adult, aged, neonate, pregnant
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand the mechanisms that lead to changes in synaptic and network properties of excitable cells within the brain that accompany natural ageing processes and neurodegenerative conditions such as Alzheimer's disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The average age of the general population is increasing but a lengthened life expectancy is often accompanied by a lengthened period of poor health. Understanding how we can age naturally but well will help us to improve the quality of life of the ageing population and help to reduce the societal impact that ageing has. Whilst many people age naturally relatively well, others suffer from neurodegenerative diseases that not only reduce life expectancy but seriously affect the quality of life. Alzheimer's disease is the most common neurodegenerative disease in the western world. It not only shortens life span and it has a debilitating effect on the sufferer, it has a huge impact on the families and carers of the victim as well as on society. Understanding how the brain ages naturally compared to the effects of agerelated neurodegenerative diseases will help us to improve the quality of life of older people as they age and help to establish therapeutic approaches to reversing both healthy and unhealthy affects of ageing.

What outputs do you think you will see at the end of this project?

Information

Our overall objective is to establish how age-related changes in synaptic properties affect neuronal activity and the way in which animals learn. By understanding this, we will provide the scientific community with knowledge that will enable us to develop therapeutic strategies to slow down and possibly reverse the cognitive effects of ageing. Alongside this, we will use similar approaches to better understand what changes occur during the early phases of neurodegeneration at a point where neuronal damage may be limited providing some opportunity for treatment. We expect that the work that derives from this project will help us and others gain an insight into these natural and unnatural effects of ageing.

Publications

We hope that each of the 4 objectives of this project will bring one or more publications. Publications will be based around first the synaptic effects that we discovery. For example, we will plan a paper that examines the effects of endocannabinoids on pre- and post-synaptic properties in the hippocampus and a second paper examining their roles in the cerebellum. We will then establish how neuronal activity is affected during learning and then complete the circle by testing whether chronic treatment with endocannabinoids reverses the cogntitive decine associated with aging. In parallel, we will test to see how

beta amyloid deposition in APP knock in mice affects synaptic signalling and then neuronal activity and behaviour.

Products

My laboratory has a track record of developing new technologies. We have 3 patents for microscope development and we were awarded a grant recently to develop a super-resolution miniature microscope. We will use this microscope as part of this project to visualise neuronal activity at high spatial and temporal resolution. There is the possibility that this may become a commercial product that we can provide to other researchers.

Who or what will benefit from these outputs, and how?

We expect that the work that derives from this project will help us and others gain an insight into the natural and unnatural effects of ageing. We will publish as much of this work as promptly as we can but the timescale will depend upon securing appropriate funding, completing the work and writing it up. We expect that much of it will be published during the lifetime of the project but it is very likely that publication will continue beyond the project duration.

The neuroscience community will benefit from this work because the results will add to the overall knowledge that we currently have on the processes of ageing. Despite age-related illness being a major societal problem, relatively little is known about the ageing mechanism. In particular it is important for us to understand how we can improve the quality of life in a society where life span is increasing but the last few years of life are often difficult for both the elderly person and for their carers. Whilst it is optimistic to think that we will find a 'cure' for ageing over the lifetime of this project, we certainly expect to establish potential approaches to slow down the effects of ageing.

Beneficiaries will also include the undergraduate and post-graduate students and post-doctoral researchers who will participate in this project. They will obtain training in in vitro and in vivo techniques, learn new methods and gain an understanding of the physiology of ageing and neurodegenerative diseases.

How will you look to maximise the outputs of this work?

We will publish as much of this work as promptly as we can. Two approaches will be made. The first will be based on the scientific outcomes of the research and will follow the usual approaches. Since we are involved in technological development, we will also be able to combine some of the results with more technical papers that describe the methodology of the work. This will encourage others to adopt similar strategies. Alongside standard publications, we will continue to attend conferences and liaise with colleagues to help share and adopt best practice.

Our transgenic mice are used by several other groups as a tool to better understand the role of presynaptic processes. We have started collaborations with groups who work on tinnitus and hearing and overseas groups working on mechanisms of Alzheimer's disease. I hope to deposit mice into a suitable repository so that others will be able to use them.

As we develop new technologies to help complete this work, we will endeavour to make these technologies available to others. This may be through an open technology model but could also include a commercial approach.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 120

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice represent the lowest species of sentient animals suitable for this work. They are widely used for this type of work and so the results we produce will build upon a substantial body of existing information both from our laboratory and others. We wish to examine how the signalling properties of excitable cells in the brain change with age and how these changes impact on the ability of the brain to learn behaviours that are known to decline with age. We wish to compare these effects to those that take place in examples of unhealthy aging such as the neurodegenerative condition Alzheimers disease. We therefore need to use young adult animals and those that have aged naturally, as well as genetically modified animals that have been developed to mimic forms of neurodegenerative disease.

Typically, what will be done to an animal used in your project?

Two main types of experiments will be carried out. In the first, animals will be deeply anaesthetised using a gaseous anaesthetic and then killed rapidly to allow removal of brain tissue so that we can then use this tissue in experiments carried out in vitro. In a small number of experiments, recordings will be made from these anaesthetised animals to examine neuronal function in the complete brain. In the second key part of this project, we will take a different approach which is to record neuronal activity using optical techniques with a miniature head-mounted microscope. This will allow us to test the behaviour of these animals during the learning of tasks which require parts of the brain that are affected during normal aging and the onset of Alzheimers disease. For these experiments, mice will undergo one or more surgical procedures under anaesthesia that allow the injection of material that causes a genetically encoded sensor to be expressed in the brain. A small glass lens will be implanted

into the brain at the injection site and a miniature baseplate fixed to the skull to allow a small lightweight microscope to be temporarily clipped onto the animal. These are small enough for the animals to behave freely without the need for anaesthesia. The preparations for these recordings can be done with up to 4 short surgeries that may also involve the implantation of a miniature device for the supply of pharmacological agents designed to reverse the effects of aging or neurodegeneration. Individual surgeries take

approximately 1 hour to complete and animals are allowed 1 week to recover between surgeries with prophylactic pain control provided. Behavioural experiments take up to 30 minutes but may be repeated several times to establish whether animals learn. During these experiments, the microscope is placed onto the animal and it is held secure with magnets. Video streams of data are recorded during the animals' behaviour and analysed offline later. We are able to correlate the activity of neurones in the brain with behavioural performance and hence gather an understanding of how neuronal activity changes during aging and neurodegeneration and how this impacts on learning.

What are the expected impacts and/or adverse effects for the animals during your project?

Some experiments are performed on animals that are deeply anaesthetised and they do not wake up after the experiment. Apart from the induction of anaesthesia, there are no expected adverse effects for these animals. For experiments where the purpose is to observe neuronal activity during learning, the mice need to undergo one or more surgical procedure. Animals are provided with prophylactic pain control during and after the procedure to minimise pain. Animals recover within hours of the procedures and generally start to behave normally very quickly. Animals that do not show normal behaviour are scrutinised by professionally trained staff including veterinary surgeons and if they cannot be made comfortable, they are humanely killed.

Part of our project involves the use of aged mice. Most mice age normally but as animals get older, they are more susceptible to conditions that are associated with old age. This might include the appearance of tumours or a general deterioration of the condition of the animal. Animals are monitored closely and parameters such as appearance and weight and checked. Humane endpoints are defined such that if an animal exceeds these defined stages, they are humanely killed if it is not possible to treat the situation.

We will also use mice that have been genetically altered to contain mutations that occur in humans that give rise to early onset forms of Alzheimers disease. These animals display cognitive decline at an age approximately 3 times earlier than normal mice. These mice will therefore be used to study the effects of Alzheimers disease but at an age where the neuropathological signs are present (> 4 months) but the behavioural events are evident but the harmful/adverse effects are minimal. These animals will be observed in much the same way as aged mice to ensure that they do not suffer adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Surgery has some risk but from experience, approximately 5% of mice are likely not to recover from a single surgical procedure. Additional surgeries will add further risk but we will minimise this by limiting, where possible, the number of surgeries per mouse to a goal of no more than two. This is a feasible goal as our surgical and experimental techniques become more refined. Post-surgery, all animals are likely to experience some discomfort

but this will be ameliorated with analgesic treatment. Each individual surgery is likely to reach a mild severity but it is the need to carry out repeat surgeries that means that mice that undergo multiple surgeries are more likely to reach the maximum allowed severity level of moderate. This will be countered by careful peri-operative analgesia and a move towards reducing the number of surgeries to a minimum which we hope will be two. Nevertheless, it is likely that most of the animals undergoing two or more surgeries will reach the moderate severity limit which is the maximum for this procedure.

Mice will be aged up to 24 months but the majority (approx 75%) will be used for experiments at ages up to 18 months. At this time point, most mice do not display adverse effects or only experience mild effects. A small number of animals (< 25% of those animals that fall into the aged category) may be aged up to 24 months because the effects of ageing continue to increase with age and it may be necessary to examine this very old age group. Our group ranges for these ageing studies are <6 months, 12 months, 18 months and <24 months. Animals under 12 months are not considered aged and so would not expect to meet the maximum severity level for this protocol which is mild. By 18 months of age, the proportion of animals that might experience age-related symptoms will increase but from past experience, the numbers that are likely to experience the maximum severity rate of this protocol (moderate) are <10% of this particular age group. Where possible, we will use 18 month old mice as our maximum age group but as already indicated, age-dependent effects on cognition increase with age. Of the upper limit of 25% of all animals that might be aged up to 25%, we expect that 25% of these mice (also estimated from past studies) might experience symptoms that place them into the maximum severity rate for this protocol (moderate).

In studies using genetically altered mice that exhibit high levels of amyloid plaque deposition, we expect < 10% of the mice to display behaviours that approach the maximum severity level of this protocol (moderate) since the majority of mice will be used at an age where the pathology is present but the adverse effects remain minimal.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We wish to understand how the excitable cells within the brain communicate under normal circumstances and how their transmission properties change with learning. Using novel optical and electrical methods to assess activity in key areas of the brain associated with particular forms of learning, we will then examine how the properties of these cells change during the process of normal ageing and the onset of neurodegenerative conditions such as Alzheimer’s disease.

To achieve these goals, we need to be able to examine neuronal function in a realistic and preserved network in animals and tissues that have been aged and in clinically relevant models that display signs that are as similar as possible to those observed in Alzheimers disease in humans. Immortalised cell lines are not suitable for most of this work because they do not form realistic neural networks. Brain slices represent an important model for us because the networks are largely preserved and the slices afford access to single cell recordings, population recordings, easy drug access and modern imaging methods that provide more information than electrophysiology alone. However, it is not possible to link changes in behaviour to changes in single cells or networks of cells. For this, it is necessary to transition experiments into in vivo work where we can associate changes in cell and network properties with changes in behaviour. The use of genetically altered animals that display signs and symptoms of diseases, allied to in vivo work, provides us with the models necessary to understand and hopefully combat these diseases. Our approach to this is to use the most relevant model to achieve each aim whilst taking all steps possible to adhere to the principles of the 3Rs.

Which non-animal alternatives did you consider for use in this project?

We have made extensive use of immortalised cell lines in the past and we continue to do so where possible. We also use mathematical modelling approaches to inform and thereby minimise the use of animals. However, there are not yet available models that can realistically model neuronal activity during behaviour.

Why were they not suitable?

Non-animal models are not yet sophisticate enough to replace the experiments detailed in this project. They are very useful for helping to predict the actions of drugs, for example, on relatively simple systems and this information informs further work using animals. However, models are limited by the information available and animal experimentation helps to provide that information.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice used is higher than the number of experiments that we will conduct because it includes the process of breeding the mice. In some cases, the breeding approaches we use mean that mice are heterozygous such that a mouse containing the genetic alteration is bred with a wild-type animal. With this method, half of the animals will be positive and half wild-type. Some of the wild-type mice will be used as controls but the majority of the experiments included in this project will be using positive GA mice. We will also breed these animals with transgenic mice that are positive for a mutation of the

amyloid precursor protein. This will be a complex process involving multiple crosses to develop a stable line that expresses both SyG37 and APP knock in mutations.

Many of these mice will be used for the collection of brain tissue and the numbers over 5 years is based upon the numbers of experiments we know we can carry out per week to meet the objectives of the project.

A relatively small proportion of animals will undergo surgical procedures prior to behavioural testing and some transgenic animals will only undergo behavioural testing. Numbers are based upon the numbers required to ensure that statistical results can be relied upon.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have set our objectives and experiments to work in a way that enables us to define the nature of experiments using methods that do not require either the use of animals of techniques that are not covered by this project licence. This first stage ensures that we only carry out work on animals that we are already sure there is a good scientific reason to indicate they will be successful. We have also, over the last few years, refined out experimental approaches to microscope development which means that our success rate is increasing so that we are more likely to achieve a successful outcome.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We regularly share tissue and several colleagues in our department use parts of the brain that we do not require. A single brain can yield at least 10 hippocampal slices, 5 cerebellar slices and 3 slices of brain stem, for example. We have developed a computer model based on our work looking at presynaptic calcium to test in silico the effects of drugs that alter, for example, ion channel properties. These results can provide an insight as to which drugs might be useful in our tests, We can then try these drugs in vitro and if successful, use them in vivo. This approach allows us to eliminate unnecessary experiments early on in the scientific process and only perform experiments on awake animals that are very likely to yield useful results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Over the last few years, we have developed a transgenic mouse that expresses a calcium sensor selectively at presynaptic terminals in the brain. We have used this mouse model to examine the nature of synaptic transmission in the hippocampus and cerebellum and most recently to show that during the ageing process, calcium levels in the presynaptic terminals becomes disrupted leading to changes in the release properties of synapses and consequently changes in transmission strength and in the ability of synapses to change their strength. Concurrently, we have shown that these aged mice have a reduced ability to learn in behavioural tasks associated particularly with spatial navigation that involves and requires hippocampal integrity. By expressing this sensor in mice, it is possible to prepare brain slices from these animals and record, using optical techniques, directly from the tissue without the need for complex electrophysiology or injection of dyes or other agents to measure neuronal activity. This greatly increases the success rate of experiments and allows more experiments to be performed from a single animal, thereby addressing the 3Rs directly. The use of in vitro tissue allows animals to be used with minimal suffering.

These mice also pave the way for more sophisticated in vivo experiments. It is possible to measure calcium signals in these behaving animals using miniaturised microscopes to examine the contributions of presynaptic calcium to neuronal activity during behaviour. These can be combined with the application of other sensors, such as GCaMPs which are designed to be expressed in postsynaptic structures so that pre- and post-synaptic activity can be compared.

We have developed a miniature microscope that weighs less than 1.5 grammes and clips onto a small baseplate fixed to the skull of mice. The mice appear to behave normally after a short period of acclimatisation. This method allows us to record from a field of neurones in real time during behaviours that require learning. Compared to some electrical recording methods, this optical approach provides information from tens of cells simultaneously so we can understand how networks of cells interact rather than just one cell at a time. The animals become rapidly acclimatised to the experimenter. If the animals are distressed, they will not perform.

Ageing is a natural phenomenon. If animals start to show adverse effects, then they are treated and if that is not successful, then they are humanely killed so they do not suffer. Whilst animals age, they are well cared for by the staff at the facility, observed regularly and provided with food and water and in cage 'enrichment.

To understand how the brain changes during unhealthy ageing as, for example, during the development of Alzheimer's disease, we will use a transgenic mouse model that over-expresses amyloid leading to amyloid plaque formation. By combining this mouse strain with our own SyG37 presynaptic calcium model, we will be able to examine the contributions that presynaptic calcium make to changes associated with the development of this neurodegenerative disease. This new model will assimilate the advantages of our mouse model in recording presynaptic calcium with a disease model that mimics the pathophysiology of Alzheimer's disease and combined will advance our understanding of the process of 'unhealthy' aging.

Why can’t you use animals that are less sentient?

Rats and mice are mammals. Their brain structure is similar to that of humans and they undergo and perform behaviours that are reminiscent of those that humans carry out. It is possible to use less sentient species for some experiments involving behaviour but the availability of transgenic mouse models and the similarity of their brains to humans make them a realistic model for aging and agerelated diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals receive very careful and thorough post-operative care. They are observed immediately after surgery and treated immediately if they do not show appropriate signs of recovery or if they show signs of pain or distress. Peri-and post-operative analgesia is provided. Our miniscopes have been adapted recently to reduce the size of the implanted lens to minimise the damage to the brain caused during implantation and to increase the success rates of experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to experimentation, we will conduct a systematic review of the literature to ensure that the experimentation is necessary and then to ensure that the approach we use is likely to yield the expected results.

In experiments involving surgery, we will use best practice in all aspects of the work including aseptic surgical techniques and the use of peri-operative analgesia to minimise pain and suffering. We will, where possible, use implantable minipumps to standardise chronic drug administration. Although these pumps require a surgical procedure for implantation, their use prevents the need for daily injections and provides a constant, controllable level of drug administration.

We are constantly refining the design of our miniature microscopes to reduce the size, weight and to improve their ease of use for the experimenter. With practice, they can be clipped into place easily as they are held in place with magnets producing a stable recording that lasts for many weeks/months. By adapting the miniature lenses that we use, we can now avoid having to remove large areas of tissue above our recording site and thereby improve the repeatability of our experiments and reduce the influence of the experimental method themselves on the experimental outcome.

The use of transgenic mouse strains allows us to use the most realistic models of human diseases available and by combining these models of neurodegeneration with our SyG37 strain, we can assess neuronal presynaptic function easily without the need for more complex methodologies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We undergo regular professional development which includes ensuring that we remain aware of the principles of the 3Rs. We will discuss our work with the named persons, keep abreast of developments through NC3Rs and take advantage of advances in technology that will reduce the numbers of animals used and enhance the success rate and amount of data obtained.

11. Cryopreservation, Breeding and maintenance of genetically altered mice as a service

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cryopreservation, Re-derivation, Breeding, Rodents, Health status

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Maintain a high-health status of rodent colonies as required by many ongoing scientific projects, using the practice of embryo re-derivation.

Preserve and archive important genetically altered rodent lines by cryopreservation to ensure prevention against loss as well as to avoid unnecessary breeding.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that acc**rue after the project has finished.**

Why is it important to undertake this work?

Animal models remain indispensable tools for studying disease biology and physiological processes. One of the reasons the mouse remains a valuable model for such study is the ability to manipulate its genome. Therefore, transgenic and gene targeted mice will continue to be required.

Where possible, we would import genetically altered (GA) lines into our facility from sources that provide high health status animals devoid of pathogens. However, this is not always possible as many academic Institutions both national and internationally do not maintain high health status animals compared with those housed in our facilities. Such animals before entering our main experimental facility are cleaned by embryo re-derivation. Once the health status of imported animals becomes comparable with existing animals, breeding and experimental work can start. In addition, rather than import live animals from other sources that cause travel stress to animals, we will have the ability to import frozen genetic material (sperm or embryos) and produce a line of interest by using non- conventional breeding practices, such as surgical embryo transfer in suitable female mice.

Value of cryopreservation of sperm and embryos. Generation of a bank of frozen embryos and/or sperm from all modified lines would reduce breeding of mice and ensure a repository is available for future use. Cryopreservation of GA animal lines contribute significantly towards implementing 3Rs, but especially Reduction.

The present project license that provides the above services to the scientific community is held by a senior academic and will expire in January 2021. Specifically, these services include provision of breeding high health status genetically altered (GA) mice by conventional breeding or by embryo transfer and cryopreservation of genetic material from the lines that need to archived or are still needed by the research community.

Several research groups who are familiar with my work in the field have indicated that Animal Facility management should continue to provide these services through a dedicated project licence for a further 5 years.

What outputs do you think you will see at the end of this project?

Maintain a high-health status of rodent colonies as required by many ongoing scientific projects by the practice of embryo re-derivation

Preserve and archive important genetically altered rodent lines by cryopreservation to ensure prevention against loss as well as to avoid unnecessary breeding

Who or what will benefit from these outputs, and how?

We can provide the skills, knowledge and equipment required to efficiently produce transgenic mice with the minimum of animal wastage.

Cryopreservation service. Archiving frozen embryos and/or sperm from all GA lines would reduce breeding, and therefore the number of excess animals being produced. It will also ensure a repository is available for future use to guard against the potential loss of a line which would be difficult to replace.

Maintaining a high animal-health status. Required for many scientific projects by preventing any import of pathogens into the animal facility by the practice of embryo re-derivation.

How will you look to maximise the outputs of this work?

The staff members providing the Transgenic Service are familiar with the mouse lines we commonly use and are highly experienced in the techniques involved in transgenic mice production and the breeding of GA mice. The skills and methods are continually being improved and optimized. No individual lab would be able to devote an equivalent amount of time to increasing efficiency and troubleshooting.

Species and numbers of animals expected to be used

- Mice: No more than 14,300 rodents will be used over the 5 year project time frame. This is broken down into 13,000 (max) undergoing mild severity and 1,300 (max) undergoing moderate severity procedures.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures**..**.

Explain why you are using these types of animals and your choice of Life stages.

The production of GA mice is technically difficult. We can provide the skills, knowledge and equipment required to efficiently produce transgenic mice with the minimum of animal wastage. 1.

Cryopreservation service. Archiving frozen embryos and/or sperm from all modified lines would reduce breeding, and therefore the number of excess animals being produced. It will also ensure a repository is available for future use to guard against the potential loss of a line which would be difficult to replace. 2. Breeding and maintenance of GA lines. 3. Maintaining a high animal-health status.

Required for many scientific projects by preventing any import of pathogens into the animal facility by the practice of embryo re-derivation.

Typically, what will be done to an animal used in your project?

- Vasectomy
- Under general anaesthetic the vas deferens will be exposed via the scrotal approach. Each duct will be severed, resected, sutured and/or cauterised, the wound closed, and the animal allowed to recover
- Embryo recipients
- Surgical or non-surgical Implantation of genetically modified embryos into the oviduct or uterus of pseudo pregnant female, the animal allowed to recover, give birth, the litter is kept but the female is killed by a Schedule 1 method
- Superovulation
- Administration of substances by intraperitoneal injection (e.g. gonadotrophin followed about 48 hours later by luteinizing hormone. Maximum volumes 0.5 ml of each) All mice are killed by a Schedule 1 method within 7 days of the initial injection and oocytes/embryos are harvested post-mortem

What are the expected impacts and/or adverse effects for the animals during your project?

All surgical procedures will be carried out using sterile techniques to minimise the potential risks of infection to the animal. All animals will be given pain relief before any surgery to avoid pain or potential discomfort. Animals will be either transferred onto other PPL’s to be used in further projects, or humanely killed once they reach their set end point.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of the work will be under a mild severity limit with very little likelihood of any adverse effects to the animals. Any procedures that are carried out under moderate rated protocols have very little chance of adverse effects.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In some scientific projects it is not possible to replace the use of rodents. When investigating disease and developmental processes, the complexity of a whole organism cannot always be recapitulated using alternative in vitro systems. The tissue, cell and molecular interactions involved in such complex processes cannot be examined in their entirety in vitro.

The genetically altered mice generated and bred under this PPL will be investigated for phenotypes and processes that cannot be examined in any other way. All animals bred on this PPL are destined for use in another PPL and the case for that particular model will have been made, and approved, separately in that PPL and by that institute's Animal Welfare and Ethical Review Body.

Which non-animal alternatives did you consider for use in this project?

It is not possible to replace the use of rodents

Why were they not suitable?

As we need to freeze sperm or embryo to archive lines, this is only possible using live rodents.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Using estimates from numbers used under the previous licence and in discussion with users of the facility, data from cryopreservation and embryo transfers that is stored on our database.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Looking at breeding data provided by our database, HO returns and data from cryopreservation and embryo transfers that is stored on our database.

The breeding data is used to work out breeding calculation which uses litter size, litter interval and how much stock that needs to be produced, which will give an idea of how many breeders need to be set up.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers proposed in this programme of work are based on reasonable estimates of generating the required GA mouse lines for the facility over the next 5 years. The advantage of using a centralised transgenic service is that it will decrease the overall number of mice used to generate GA lines. The reasons for this are:

- The availability of highly skilled workers will ensure the lowest number of animals possible will be used.
- Central coordination of animal stock production allows the most efficient use of breeding stock. Excess mice or embryos generated for one project can be used in other transgenic projects.
- Sharing of sterile male mice between projects requiring generation of pseudo pregnant females.
- Making use of our expertise in the areas of sperm and embryo freezing to archive all mutant lines, such that a stock of live mice for each line are not required to ensure lines are not lost.
- The strains that are being used in the facility have been chosen because they are the most efficient for production of transgenic mice.
- New techniques are continually tested and adopted to reduce animal usage significantly.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of the work will be under a mild severity limit with very little likelihood of any adverse effects to the animals. Any procedures that are carried out under moderate rated protocols have very little chance of adverse effects. However, all surgical procedures will be carried out using sterile techniques to minimise the potential risks of infection to the animal.

All animals will be given pain relief immediately after any surgery to avoid pain or potential discomfort. Animals will be either transferred onto other PPL's to be used in further projects, or humanely killed once they reach their set end point.

Why can't you use animals that are less sentient?

Most of the rodents being used have to be at breeding age (6-8 weeks) to carry out this work, with the exception of the superovulated females which are 4 weeks+.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The availability of highly skilled workers will ensure the lowest number of animals possible will be used.

Equipment is being used that will maximise the efficiency of transgenic production. Such equipment is costly and could only be purchased by a central service unit.

Central coordination of animal stock production allows the most efficient use of breeding stock. Excess mice or embryos generated for one project can be used in other transgenic projects. Sharing of sterile male mice between projects requiring generation of pseudo pregnant females.

Making use of our expertise in the areas of sperm and embryo freezing to archive all mutant lines, such that a stock of live mice for each line are not required to ensure lines are not lost. The strains that are being used in the facility have been chosen because they are the most efficient for production of transgenic mice.

New techniques are continually tested and adopted to reduce animal usage significantly. we are hoping to do further training on the Subcuticular Stitch and Wound Glue method shown on training course, which would replace the need for autoclips on the embryo transfer females and further training on nonsurgical transfers at the moment it would need to be a mixture of both surgical and non-surgical methods so we could compare the data.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Mertens C, Rulicke T (1999) Score sheets for the monitoring of transgenic mice. Animal Welfare 8: 433. Mertens C, Rulicke T (2000) Phenotype characterization and welfare

assessment of transgenic rodents (mice). Journal of Applied Animal Welfare Science 3:127.

Jackson, I.J. and Abbott, C.M. (2000) Mouse genetics and transgenics: A practical approach. Oxford University Press.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The NC3R's information is sent out in a monthly newsletter, looking out for training sessions which would help implement and improve my work and practices.

12. Using zebrafish to understand neurodegenerative disease and develop therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

zebrafish, development, disability, therapy, mechanism

Animal types	Life stages
Zebra fish	embryo, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to increase our understanding of diseases and the functions of the mutated proteins that cause those diseases, as well as providing disease models for therapeutic discovery and development

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The project focuses on rare inherited diseases, which together affect about one in every 10 people, even though each disease has an incidence of less than 1 in 2000 people. They frequently cause premature death in childhood and the vast majority have no approved treatments. We will also study diseases that have a more complex origin, in which the same genetic factors interact with environmental factors. There is a huge need to find treatments for both inherited and complex diseases.

What outputs do you think you will see at the end of this project?

We expect to have increased our understanding of the function of three or more proteins involved in childhood neurodegeneration and epilepsy, including understanding how those proteins interact with other processes within the cell and how disease arises. We plan to generate several disease models, and by studying them we will better understand the disease process. One or more chemicals will be tested to see if they treat any of the childhood neurodegenerative diseases that we are studying. We will publish our findings.

Who or what will benefit from these outputs, and how?

In the short-term scientists will benefit from increased understanding of childhood neurodegenerative diseases including the normal function of the protein that is mutated in the disease, and the effect of the disease on processes occurring within cells and a whole organism. This will lead to better treatments for patients in the long term.

The availability of additional disease models will enable treatments to be tested on more models so that the research community can be more confident that the treatment will work on patients, who will benefit in the medium term.

The availability of zebrafish disease models that can be used to test thousands of chemicals in a relatively short amount of time means they can be exploited to find novel chemicals with potential to treat the disease. This will benefit scientists in the short-term and patients in the long-term.

We found a chemical that appears to treat seizures in CLN2 disease. Knowing how this chemical has its positive effect will support efforts to bring the chemical to the clinic as a drug in the medium term, and provide researchers with new knowledge in the short-term.

How will you look to maximise the outputs of this work?

We will publish our work as open access. We plan to publish both positive and negative results. We will present our research at international conferences.

We collaborate with others to increase the impact of our research.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 21400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

Data from zebrafish can be extrapolated to other vertebrates due to a high level of similarity. This means that it is valid to use the zebrafish to model disease, investigate what is going wrong in the disease and search for and test novel treatments. The rapid, external development of zebrafish enables the vast majority of experiments to be performed on developing zebrafish that do not feel harm, and without harming the mother. Of the available vertebrate models, zebrafish have the lowest brain function.

Typically, what will be done to an animal used in your project?

We will study existing and new disease models, which we will create. To create new models, we inject the one cell embryo with agents to specifically alter a targeted gene. We select healthy embryos and grow these to adulthood. We then select adult fish carrying this genetic alteration in their sperm and eggs, and breed from those fish to generate subsequent generations.

During these breeding programs, we need to be able to identify fish carrying the genetic alteration from wildtype fish, so we take a small number of cells (either from their fin which regenerates, or from their mucus on their skin) and analyse the gene for the alteration. Once we have identified the genetically altered fish, we incross them to make fish that have two genetically-altered copies of the gene, which we expect to show signs of the disease at some point during their life. We then assess those potential disease models to see if they do actually show signs of the disease, and if so, we study them further, and set a humane endpoint.

To understand what is going wrong in the disease, we sometimes need to manipulate other processes as well, either using chemicals or by altering other genes. We then examine the fish to see if this has made a difference. We can examine their movement or behaviour, or an invisible process happening within, which we visualise with a specific label, most often on fish that have been sacrificed for their tissue.

To search for treatments, we use disease models at the embryo stage to screen large numbers of chemicals, and check to see if the signs of the disease are reduced by adding the chemical to the water the fish are in. If we already have good reason to believe that a chemical might make a good treatment, we might use adult disease models but we will use embryonic and larval models first if possible. In this case we might bathe the fish in the chemical, or inject it. If our results are similar to those of our collaborators using other

species or patient cells, we can be more confident that the treatment will be beneficial for patients.

As a practical way to reduce the numbers of fish kept alive, we take sperm from adult males and freeze it. We can then use this to re-derive the strain several years later using in vitro fertilisation (where eggs are taken from a female adult and mixed with the sperm to generate embryos that will grow into adult fish).

What are the expected impacts and/or adverse effects for the animals during your project?

Most adverse effects are expected to be transitory eg when taking mucus or fin samples there may be slight discomfort, which we treat with pain killers. Sometimes we will need to anaesthetise the animals eg when taking mucus or fin samples, and there is a small chance of an adverse reaction, in which case we will euthanise the fish straight away. It is possible that some experiments could result in infection, in which case we will treat with antibiotics or euthanise the fish. Massaging the belly to release eggs or sperm could also result in damage to internal organs if not gentle enough, in which case we will euthanise the fish as soon as this is noticed.

The disease models are likely to show one or more of the following signs: obviously small eyes; obvious weight loss; discolouration; abnormal swimming, behaviour, posture or balance; abnormal gill movement; unusual interactions such as aggression. We will euthanise all fish which have shown these symptoms for 4 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 50% of fish will experience mild severity and 50% will experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To model a disease, investigate what is going wrong, search for therapies and test those therapies, you need all the relevant tissues present. The diseases we work on predominantly affect the nervous system but there is increasing evidence that they affect the heart, so we expect problems to arise in other tissues if we manage to treat the brain and improve survival. Furthermore, in some of these diseases, it is known that patients

generate antibodies in their blood that bind proteins in their brain. Hence, a full understanding or the disease and treatments will only come from studying intact animals.

Which non-animal alternatives did you consider for use in this project?

We employ non-animal alternatives and non-sentient animals where possible. These include performing experiments in cell models (traditionally used mammalian cells, patient cells, human stem cells, the social amoeba), invertebrates such as the fruit fly and the nematode worm, frog oocytes and/or embryonic zebrafish depending on their suitability for the experiment. We also take tissue from euthanised zebrafish and grow the cells in a dish.

Why were they not suitable?

These methods do not replicate the complex environment seen in a vertebrate but they do give us some information so we do these experiments to inform what experiments should be performed in zebrafish.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We expect to use up to 8000 of these fish for breeding purposes to supply embryos for experiments. This is based on 40 different strains (some are combinations of several strains) with no harms caused by the genetic manipulation. Zebrafish are healthier when in groups of 20 or more, and new generations are needed about every 6 months - the old generations are not euthanised until the new generations are genotyped (usually as adults). For some complex strains, only a small proportion of the fish are the correct ones but this is not known until adulthood when we can check their genes. Over a 5 year period, this adds up to 8000 fish.

We expect to use 8000 (over a 5 year period) genetically-altered strains for simple experiments where we document the harmful effects of the genetic alteration. Each experiment requires a pilot study to calculate the number of animals required for a full study, and then each study should be replicated three times to ensure reproducibility. Assuming 75 animals (25 animals in each of three groups) per replicate, this allows for about 35 experiments over 5 years.

We expect to use 4000 (over a 5 year period) genetically-altered strains for complex experiments where we document the potentially harmful effects of the genetic alteration in combination with a drug or chemical treatment, for example. Each experiment requires a pilot study to calculate the number of animals required for a full study, and then each study should be replicated three times to ensure reproducibility. Assuming 150 animals (25

animals in each of six groups) per replicate, this allows for about 9 experiments over 5 years.

We will need to generate new strains of zebrafish and estimate 1000 animals will be needed. This is assuming 5% of animals will be able to transmit the new genetic alteration to their progeny and that we may make up to 50 strains.

In order to preserve newly created strains, we expect to use 400 animals, which is approximately 10 animals for 40 new strains or combinations of strains.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the Experimental Design Assistant to design experiments using zebrafish embryos and will continue to use it for all zebrafish experiments. This has led to us reducing bias. For each experiment we also write 1) the objective, 2) a detailed description of the method and reagents needed (and ensure they are available) to minimise variance between researchers, 3) a calculation of the numbers of animals needed based on small (pilot) studies, and 4) a description of the analysis method and the statistical test to be used.

We preserve sperm to reduce live animals, negating the need to recreate strains or combinations of strains, and reduce genetic drift. We use live animals for egg and sperm production to reduce numbers of animals euthanized for this.

We aim to try new, less harmful methods at earlier stages in zebrafish development for detecting the genetic alterations. Fish are not harmed and can be raised to adulthood without having any harm. Significantly, only fish of the required genetic alteration need to be raised to adulthood, reducing numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot experiments will be used to generate data to determine a suitable number of animals for a full experiment. For experiments using embryos, we usually find that 10 per group is acceptable. Simple experiments comparing wildtype to a disease model tend to require less animals than an experiment where there is also a drug or chemical treatment, so in these cases, more animals are usually needed. For experiments new to us, we discuss animal numbers and data analysis with statisticians in advance.

We estimate the number of animals needed and breed what is required plus 20% to account for deaths during larval stages. Once zebrafish are checked for their genetic alterations, those not required for experiments or breeding are euthanised. We aim to determine the genetic alterations using the least harmful method possible.

We offer to share spare animals and tissue at our institution.

We do not keep animals beyond 18 months old and frequently euthanise them when we can.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use zebrafish as there is now a great deal of evidence that data from this vertebrate is relevant to humans. This is true for models we have generated to date for CLN3 disease, CLN2 disease and EAST syndrome are no exception. We also have evidence that a novel drug first tested in cells works similarly in mouse and zebrafish to reduce CLN3 disease symptoms. The fast, external development of zebrafish means that many disease models can have clinical signs during embryo and larval stages, and these can be viewed easily without harming the mother. Embryonic and larval zebrafish are not sentient and do not feel harm so are not classified as animals when used for experiments and therefore their use is not regulated.

The CLN2 disease model will be used at the unregulated age. The CLN3 disease mutant model causes only mild symptoms (thinner retina and yellow colour) in adults. We do not yet know when the new disease models will display symptoms, but we aim to make models that replicate the genetic change in humans as best we can so that the model is as relevant to the disease as it can be.

The majority of animals will not experience more than mild issues due to experiments, minimising suffering. Some animals will experience moderate harm, because they are used for experiments that require us to observe the harmful consequences of the genetic alteration, though we aim to limit the harm caused as much as possible by choosing to study the earliest symptoms. Occasionally, we only have one animal for a particular strain. To avoid single housing, we will house them with animals of another genotype that have a visible difference such as fin length, pattern or coloration.

Some of the animals that will experience harm from the genetic manipulation will be further manipulated with genetic material, chemicals or drugs, or by transplantation of tissue from one animal to another. Such experiments are required to show a drug treats the disease, or that a disease process really has negative consequences and should be targeted in treatments, or which cells need to be corrected by gene therapy. Transplantations will be performed during unregulated stages to minimise harm and because the tissue integrates better into the host at this stage. Drug, chemical or gene therapy treatments will be first tested on unregulated zebrafish. The least invasive methods of delivery will be used where possible (bathing, in the food, through the mouth, then injection). In these experiments we also aim to limit harm by choosing to measure the earliest harmful effects. We will create

new disease models and genetically-altered strains. Only healthy fish are raised to minimise harm.

Fish will be examined for the effects of their genetic alteration or treatment. The majority of these investigations will be observations of normal behaviour and locomotion or tests on the tissue after euthanasia. We will perform some brain function tests that require anaesthesia or restraint but are otherwise not harmful. The dose of anaesthesia is carefully checked for the first fish (ensuring a quick and healthy recovery after the procedure) and then tested on the next two fish to confirm the dose is correct, before continuing with the remaining fish.

The fish in all the genetically-altered strains will need their genetic alteration identified. We will use the least harmful method and the earliest stage possible. When tissue samples are required, we will preferentially use skin swabs over fin clippings. Both of these methods use anaesthesia with recovery, but skin swabs are thought to be less harmful. We have recently begun using skin swabs and will need to show that the results using this method is as good as with fin clips for each strain before we can use skin swabs exclusively.

The dose of anaesthesia is carefully checked for the first fish (ensuring a quick and healthy recovery) and then tested on the next two fish to confirm the dose is correct, before continuing with the remaining fish. Pain killer is used prior to, during and after fin clipping.

We will need to preserve sperm, which allows us to freeze these strains and maintain less fish alive. These strains can later be resurrected using in vitro fertilisation. Again, the dose of anaesthesia is carefully checked when taking sperm or eggs. Fish recover and can be used to provide sperm or eggs once more, meaning less fish are required. Currently, experts at another university preserve sperm for us. We aim for them to train us in this method.

Why can’t you use animals that are less sentient?

Where possible, we will use animals at more immature life stages which are less sentient. This will depend on the stage when the genetic alteration causes symptoms or clincal signs that are measurably different from wild type zebrafish. When we do not need to measure a clinical sign, we will measure changes that are observed in tissue from animals euthanised prior to the age when the clinical sign is evident. When we do need to measure a clinical sign, we will design experiments to assess as many changes as possible (both live and under terminal anaesthesia) to gain maximum data from each animal.

We favour the use of zebrafish over invertebrates as the zebrafish brain is considerably more similar to the mammalian brain. As zebrafish are the genetic vertebrate model with lowest sentience, they are also our preferred vertebrate for experiments at regulated stages. We feel that the zebrafish is the most refined model for the research questions we are addressing.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

When studying adverse effects, we aim to limit the harm caused as much as possible by choosing to study the earliest relevant consequences.

Occasionally, we only have one animal for a particular strain. To avoid single housing, we will house them with an animals that have a visible difference such as fin length, pattern or coloration.

Transplantations will be performed during unregulated stages to minimise harm and because the tissue integrates better into the host at this stage.

Drug, chemical or gene therapy treatments will be first tested on unregulated zebrafish. The least invasive methods of delivery will be used where possible (bathing, in the food, through the mouth, then injection.

We will create new disease models and genetically-altered strains. In this method, only healthy fish are raised, to minimise harm.

Once we have created a new genetically-altered strain, we will develop a score sheet for that strain so expected clinical signs and symptoms are known and specifically looked for.

The dose of anaesthesia is carefully checked for the first fish and then tested on the next two fish to confirm the dose is correct, before continuing with the remaining fish.

To detect the genetic alteration, we will use the least harmful method and the earliest stage possible. When tissue samples are required, we will preferentially use skin swabs over fin clippings. Both of these methods use anaesthesia with recovery, but skin swabs are thought to be less harmful.

We have recently begun using skin swabs and will need to show that the results using this method is as good as with fin clips for each strain before we can use skin swabs exclusively. We use pain killers when we take fin samples.

We aim to try new, less harmful methods at earlier stages in zebrafish development for detecting the genetic alterations. Fish are not harmed and can be raised to adulthood without having any harm. Significantly, only fish of the required genetic alteration need to be raised to adulthood, reducing numbers.

The protocols state the minimum amount of monitoring of zebrafish that should be provided. Monitoring will be increased if any fish respond differently than normal to the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office guidance. For published methods, to ensure best practice and least harm, we will discuss new methods with the Named Animal Care and Welfare Officer and possibly the Named Veterinary Surgeon.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We seek advice from large zebrafish facilities and keep abreast of latest refinements via the British Association of Animal Husbandry, the European Zebrafish Meeting, the Lab Animal Science Association, the NC3Rs, the Institute for Animal Technology and the journal Zebrafish. We receive newsletters and bulletins from these groups. We search the literature for more refined methods. I am a committee member for EUFishBiomed, members of which have recently reviewed use of anaesthetic.

We have meetings every few months with other research groups using fish and the staff that care for the fish and present our research so they can feed back on any best practice they are aware of.

We will keep up to date with changes in the ARRIVE guidelines for the reporting of animal experimentation.

When we find a new method we believe to be best practice, we contact the developer and arrange for training.

13. Targeting brain tumour metabolism to improve treatment outcomes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Intracranial, Brain Tumours, Therapy, Metabolism, Xenograft

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to test the efficacy of new treatment strategies, which have been fully tested in vitro, in animal models of brain tumours. Data generated will provide robust pre-clinical information to inform the development of clinical trials for brain tumour patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brain tumours will kill around 11,000 people every year, many of them under the age of 40, and is the second leading cause of cancer deaths in children and young adults. Current standard of care is only palliative and includes surgery, radiotherapy and chemotherapy; however, these tumours typically recur within a year and are resistant to further treatment. Furthermore, the limitations posed by the blood brain barrier prevents the use of many forms of chemotherapy that have shown success in other cancers. In

addition, the high degree of variability between brain tumours from different patients makes it difficult to identify effective therapies. There is therefore an urgent need to identify new treatments that are more effective than current standard of care, or enhance the standard of care. Treatments targeting tumour metabolism, an alteration shared by virtually all cancers, could provide better outcomes for these patients.

What outputs do you think you will see at the end of this project?

Our work will generate fully characterized mouse brain tumour models using samples from patient tumours. These models can be utilized to test new therapeutic modalities by our group, and nationally and internationally by other brain tumour researchers. We will gain valuable information on the electrical and chemical signals that occur between the tumour and its environment and how these signals change upon therapeutic interventions. The project will also lead to high impact publications and inform the development of new clinical trials for brain tumour patients. We also have the potential to patent some of the therapeutic ideas generated.

Who or what will benefit from these outputs, and how?

Patients with brain tumours will be the primary beneficiaries of this project, as we are specifically testing new treatments on animals with brain tumours. However, we hope that any new treatments we develop will also be of benefit to patients with other types of cancer, particularly since the tumour cells used will have characterized genetic alterations that can occur in other forms of cancer

Moreover, brain tumour scientist around the world will also benefit by having access to mouse models that will be generated

How will you look to maximise the outputs of this work?

We will collaborate with other groups, seeking advice and expertise where necessary. We will also collaborate with other scientists to test new drugs or derivatives of drugs in animals, as well as pharmaceutical companies that have new drugs to test. Our knowledge will routinely be distributed to all research and clinical personnel via monthly research meetings, as well as to other members of our faculty interested in cancer though inter-department talks. We will present our findings at national and international conferences to further disseminate our knowledge across the world. We will generate high impact publications allowing dissemination of our findings to other interested scientists and clinicians who could potentially expand the use of these therapeutics into additional clinical trials.

In addition to disseminating our results to the research and clinical community, we regularly disseminate news of our progress to public and private donors.

Species and numbers of animals expected to be used

- Mice: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

To reliably assess the success of new treatments for brain tumours, we need to have the full complexity of a living, breathing animal. In particular, we need to make sure that any new treatment is safe, that it can get in to the brain, and that it has efficacy on brain tumours. This is easily achievable using mice.

With their relatively short lifespan, we can quickly raise animals to adulthood, and implant a brain tumour to treat. Due to their small stature, adult mice are easy to perform surgical procedures on. We will be using adult mice because our research focus is adults with brain tumours. By using bioluminescent imaging, we can follow the fate of the tumour in terms of its growth and regression and avoid unnecessary prolonged harm to the animals from the tumours becoming too big. Furthermore, scientists have employed mice for brain tumour research for years and so methods used are already very well established.

Typically, what will be done to an animal used in your project?

To test any new treatments, a mouse must first have a tumour implanted. This will normally be carried out by an injection of tumour cells directly in to the brain. Mice will be anaesthetised so that they do not feel any pain or discomfort during surgery. A small incision is performed in the scalp, and a hole is drilled in the skull. A small glass needle is then carefully inserted, and cancer cells are injected directly in to the brain. The skin is then sutured to close the wound, and the mice are taken off anaesthesia and allowed to recover in a warm chamber. When they have woken up and are walking about as normal, they will then be returned to their normal housing. The whole procedure normally takes about 1 hour. The mice will be given pain relief, and both the skull and the skin will heal on their own within 2 weeks, when the stitches can be removed.

After 5-7 days, the mice will be anaesthetised again and imaging will be performed on them. The need for reducing the post-op recovery time to 5 days in some instances will be necessary due to the fact that different tumour cell lines have varying growth rates. Therefore, imaging at this earlier time point will help to avoid the tumours from becoming too large before treatment in initiated. However, any reduction in the 7 day post op recovery period prior to further regulated procedures will only be carried out with the written approval of the NVS and clear justification will be provided for this need. All imaging methods are non-invasive. The mice may receive an injection of a chemical to help us image them. The imaging will typically last 30 minutes, after which the animals will be returned to their normal housing.

Imaging will take place once or twice per week over the entire course of the experiment. The frequency of administration of anaesthetic for imaging is not expected to have a significant impact on the metabolism of the tumour as the duration of anaesthesia is short, lasting no more than a maximum of 30 minutes from induction to full consciousness. In our previous work, administration of repeated anaesthetic had no effect on the treatments tested.

After we have confirmed the presence of a tumour, the mice may be given one of a number of different treatments. The mice may be anaesthetised again and treated using radiation. This is also non- invasive; the animals are shielded to protect their body, leaving only their heads exposed to radiation. This will be done once per week for between 2 and 8 weeks. Animals may also be given an injection of one or two drugs to treat the brain tumours. This will generally not require anaesthesia, and may be given once per day for up to 4 weeks.

We will continue to monitor the animals and image the tumours so that we can see how quickly they are growing. The length of time animals will be kept alive will be dependent on tumour size. Mice receiving no or minimal treatment tend to have large tumours, and they will be humanely killed before they experience major symptoms. Mice that are successfully treated may be kept alive for as long as they remain healthy and the tumour size remains small. However treated animals may also be killed at early time points to follow changes in the tumour composition as a result of the treatments.

Some animals with brain tumours will undergo surgery under terminal anaesthesia to expose the brain. A probe will be inserted in the brain such that it spans both the tumour and surrounding healthy tissue. This will enable us to study changes in electrical and chemical signals between the healthy brain and tumour.

What are the expected impacts and/or adverse effects for the animals during your project?

The injection of cancer cells into the brains of mice is an invasive surgical procedure. However, the animals will be anaesthetised and will not feel any pain or discomfort. To manage the pain caused by the wound that is created, animals will be given pain relief. The pain is not expected to last longer than 24 hours. Animals may experience some weight loss after surgery, but from previous experiments, this is only transient and animals regain the weight within a week. The development of the brain tumour itself will cause some distress but since this is a necessity to test new treatments, mice will be closely monitored to make sure they are not suffering any obvious physical signs of discomfort or symptoms directly related to the tumours e.g. difficulty walking. These may be present for up to 24 hours, but such symptoms will not be allowed to persist beyond this time as animals will be killed.

Animals undergoing surgery to expose the brain and the insertion of probes for brain monitoring will be terminally anaesthetized so will feel no pain or discomfort

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As most of the animals will receive an injection of cancer cells, followed by either imaging, treatment or both, they will all fall in to the "moderate" severity category. We expect most of the animals to experience moderate severity due to the surgical procedures themselves,

as well as due to the presence of tumours. However, we have all of the appropriate refinements in place to make sure any pain or discomfort associated with these procedures is minimised.

The severity of the surgery to expose the brain for electrophysiological monitoring is moderate however it is performed under terminal anaesthesia and animals will feel no pain or discomfort

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst we can test many different treatments in cells grown in the lab using different techniques, we are not yet able to fully replicate the complexity of the human body. New treatments need to be tested on animals to make sure that they are safe, and that they work properly. Only once we have completed these pre-clinical studies can treatments be put forward for testing in humans.

Which non-animal alternatives did you consider for use in this project?

We have used cells grown in the lab to test our new therapies. This includes using normal, healthy human cells to test if a drug is toxic, and using cancer cells to see if a drug stops them from growing or kills them. We have also considered using computers that simulate cells and animals, to test if treatments are likely to work.

Why were they not suitable?

A tumour is not made up exclusively of cancer cells, they comprise many different types of cells, some of which help the tumour grow by providing nutrients, some hiding it from the immune system, and some laying dormant, ready to attack the tumour if activated. In addition, tumours in the brain sit behind a barrier called the blood brain barrier, which filters out lots of chemicals that aren't allowed to pass in to the brain, including many types of chemotherapy. It is these complex relationships that cannot be fully replicated in the lab. We require the complexity of an animal to fully replicate these conditions, so that we can properly test new treatments and prove that they work. In addition, computers are not yet smart enough to be able to simulate every possible reaction to a treatment that a cell or animal could have.

Therefore, these experiments must be done in animals to be able to get a full picture, so that we can safely inform clinical trials in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers estimated here come from a well planned programme of work that aims to test new identified treatment regimes. The project has multiple objectives which we aim to achieve over a 5 year period. On average 150 mice will be used per year. Each experiment will require approximately 20 mice in order to compare new treatments to those already used in the clinic. This is necessary to demonstrate that our treatments are superior than those currently available. Taking this into account, 150 mice per year only equates to 7 experiments, i.e. less than one per month. We believe this number will be sufficient to develop new models of brain tumours and test new treatments as we develop them, with the ultimate aim of progressing these into human clinical trials as soon as possible.

Although we have estimated that we would need a total of 750 mice over the course of this project licence, we have requested an excess for the following reasons:

as a contingency for failure of cell lines to graft. In this case we would need to use alternative patient derived cell lines. Moreover, if we receive more than the expected number of brain tumour cases, we could generate more cell lines for engraftment.

We may need to alter the dose of therapeutic agents and their delivery regimes to achieve maximum efficacy

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, we will test multiple new treatment options simultaneously, so that control groups can be shared between experiments, reducing the total number of mice required. Our experimental design is based on previous work in animals, where we have shown that 6 animals per test group is sufficient to prove that a treatment is effective. We will maximise the amount of data we can acquire fromindividual mice by imaging them routinely using methods specific to each experiment. Moreover, once all relevant therapeutic data has been obtained, further information will be gained from these mice using electrophysiological monitoring under terminal anaesthesia. Whole mouse brains will be collected so that we can have matched tumour and non-tumour sides, allowing us to test the healthy tissue for comparison, without the need for another separate group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, we will collect other tissues such as the liver, spleen, lungs and bone marrow. This will allow us to either pass the tissue on to other groups for analysis in other projects, and to collect immune cells for culture. As we are using common mouse breeds, we will utilise mice that are surplus to requirements where possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will inject cancer cells into the brains of mice to establish a tumour. Unfortunately, there are no naturally occurring brain tumours in mice, so this route of developing brain tumours in mice is absolutely necessary and does give us complete control over tumour establishment. We can use imaging techniques to monitor the growth of tumours to make sure that they don't get too big. This will allow us to stop the experiment before any of the mice get too unwell. Therefore, they should not suffer any unnecessary pain or discomfort during the course of the experiment. Where appropriate, we will anaesthetise the animals so that they are not distressed whilst carrying out certain procedures, and we will also give them pain relief to make sure they are not suffering.

We will strive to only test treatments that have already proved to be safe in animals and have been fully tested in the laboratory setting. For brain monitoring we will perform surgery to expose the brain on mice that have established brain tumours only under terminal anaesthesia. We will then insert probes into the brain to monitor differences in electrical and chemical signals between normal brain and tumour. We will use different types of mice for specific experiments. In cases where we want to test drugs on human tumours, we will use mice that lack key parts of the immune system to do so otherwise these tumours will be rejected.

These mice are perfectly healthy as long as they are kept in sterile environments to minimise the risk of an infection. The latter is provided by properly trained staff at our institution. For experiments with mouse cells, we will use normal mice, which have a fully functional immune system and therefore are unlikely to get any infections. We will test different types of human brain cancer cells to see if out treatments work on different types of brain tumours to reflect the differences in patients tumours. The surgical procedures we are using are well established in the scientific community. They have already been appropriately refined, but we will consult with vets to ensure that we minimise the possible distress caused to all animals. We plan to use female mice only, since they are easier to house together and less likely to fight and harm each other. Although the incidence of brain tumours is slightly higher in men than in women, treatment options do not differ

between males and females so results generated using females can be transferable to males. Our study will focus mainly on adult glioblastoma (GBM) for which there are currently no known causes. In this regard findings in female mice will represent accurate insight for clinical trials. In addition, studies in the lab using GBM tumour cells derived from male and female GBM brain tumour patients have not revealed any differences in our experimental findings.

Why can't you use animals that are less sentient?

We require the full complexity of an adult, living creature to prove that our treatments are safe and effective, so that they can be put forward for clinical testing in humans. This is only achievable with mice or other mammals.

Mice are easy to work with and the procedures we will use are already well established in them so we know that they will work. It would not be possible to use terminally anaesthetised animals in most of our experiments, because we have to allow days or even weeks for tumours to grow, so that we can prove that our treatments work.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For surgical procedures, animals will be given pain relief where appropriate to mitigate any discomfort associated with the procedure. Animals will also be given fluids during long procedures to insure that they do not suffer from dehydration. After procedures involving anaestheisa, the animals will be allowed to recover in a warm chamber until they return to normal activity. After they have completely recovered, then will be returned to their normal housing. Animals will be regularly monitored by staff in the animal unit, as well as the researchers carrying out the experiments, so that they are checked at least once per day. Any animals that appear to be sick or show signs of excessive weight will be specifically check twice per day and killed if deemed necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the guidelines set by our establishment to ensure the experiments are designed and carried out in the most refined way possible. We will also consult technical documentation from the NC3R's website to ensure that we are as up-to-date as possible with regards to new practices and techniques. In particular, we will ensure that our experiments meet the criteria set out in "Responsibility in the use of animals in bioscience research", as well as ensuring that we adhere to the ARRIVE guidelines for reporting animal research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular updates from the staff that run the animal units at our establishment will inform us of advances in the 3Rs. In addition, we will seek out updated information from the NC3Rs organisation to make sure that our experiments are carried out in line with their policies. Any minor changes to the 3Rs will be implemented immediately, assuming that they do

not breach the terms of the project licence. Any significant advances in the 3Rs requiring changes to the project licence will be added as soon as possible. All changes will be discussed with the personal licence holders working under the project licence, and standard operating procedures altered to reflect these changes.

14. Epithelial homeostasis and cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Early Detection, KRAS, Pancreas, Epithelial homeostasis

Animal types	Life stages
Mice	adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Epithelial tissues act as protective barriers to the external environment. Epithelial homeostasis, which describes a balance between growth and death in a tissue, is vital for tissue health. One key aspect of epithelial health and homeostasis is the removal of spontaneously occurring genetically mutated cells from a healthy tissue. Retention of genetically mutated cells in the tissue would lead to a loss of barrier function and would initiate cancer. The main goal of this project is to uncover the molecular mechanisms underlying how healthy tissues eliminate genetically mutant cells and determine how these processes are deregulated during early tumorigenesis. Our current understanding of these processes is poorly described.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Early detection of cancer is key to improving patient survival. Most cancers are easier to treat, and patient prognosis and quality of life improve greatly when cancer is detected earlier. Our research focus is to understand the cellular and molecular biology of early tumorigenesis. A better understanding of the early stages of tumour growth and the timing of when tumours become dangerous, will lead to the development of new and improved early detection tools. It will also directly inform new biomarker discovery, improve our ability to diagnose lethal versus non-lethal lesions, and distinguish cancer diagnosis from non-cancer related pathologies. Early detection of cancer will also directly impact upon drug discovery research by improving patient stratification and recruitment to clinical trials.

What outputs do you think you will see at the end of this project?

This project will generate new information in the biology of epithelial tumorigenesis, particularly on the interplay between genetic predisposition and tissue health. Moreover, we expect to gain insights into epithelial tissue mechanics and health, which will impact upon the field of epithelial morphogenesis.

Novel findings will lead to high impact publications and new grant funding. This project will also generate new experimental models/approaches of sporadic cancers, particularly of cancers of unmet clinical need such as pancreas and lung.

Who or what will benefit from these outputs, and how?

In the short-term, outputs such as new information and experimental models will benefit the cancer research and epithelial cell biology research communities. The clinical benefits of this work are likely to be long term; our principal hope is that by studying the early stages of disease, we may contribute to the identification of new biomarkers and the development of new and improved detection and diagnostic methods, which together will allow us to intervene at early stages of disease and improve prognosis.

Moreover, this work may identify candidate genes and candidate genetic pathways as novel therapeutic targets to treat human cancer in the future.

How will you look to maximise the outputs of this work?

All knowledge generated during this project will be disseminated as peer-reviewed publications and presented at national/international conferences/scientific meetings. Data will be shared via open access journals and repositories. We will continue to actively engage with the general public via events within the University/local communities and via national cancer charities. Progress and successes in key milestones will be released via our establishment’s research pages, newsletters and social media.

Species and numbers of animals expected to be used

- Mice: 8931 mice - we will use adult males and females.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We will use genetically altered mouse models of epithelial cancer and primarily adult life stages (including aged animals; e.g., > 20 weeks old). Mouse models recapitulate human disease accurately at the genetic, tissue and clinical level. Our research goals are to investigate early stages of sporadic cancers in adult tissues, i.e., how cells carrying genetic mutations override normal tissue homeostasis to drive disease. By using genetically altered mouse lines and Cre-lox technology, we will determine genetic predisposition in specific target tissues and unravel whether/how exogenous risk factors such as inflammation cause disease. All mouse lines used in this project will also express a reporter (e.g., fluorescent protein), which will allow us to tag and trace the genetically mutant cells in tissues over time.

Typically, what will be done to an animal used in your project?

Typically, we induce conditional gene expression/deletion in adult mice (e.g., 6–8-week-old) using inducible-Cre recombinases and under the control of a tissue-specific promoter, e.g., tamoxifen induced Pdx-1 CreERT in pancreas tissues. Expression of Cre recombinase also induces expression of a fluorescent protein (e.g., RFP) from the ROSA26 locus. We are interested in sporadic disease; therefore, we typically use one injection of low dose tamoxifen to induce transgene expression. Induced animals are aged to a defined end point (e.g., 7 or 35 days) before being killed by a Schedule I method.

Alternatively, we assign animals to a controlled feeding programme (e.g., high fat diet for 3 months), or induce tissue inflammation (e.g., scheduled intraperitoneal injection of pro-inflammatory agent) before inducing conditional gene expression and ageing animals to a defined experimental time point (e.g., 35 days post induction of Cre).

What are the expected impacts and/or adverse effects for the animals during your project?

We expect that expression of oncogenes such as oncogenic Kras in healthy adult tissues will lead to the development of premalignant lesions that will not have adverse effects on the animal.

Tumorigenesis requires the presence of a second mutation (e.g., loss of tumour suppressor function (p53) or expression of oncogenic c-Myc), or an exogenous risk factor such as chronic inflammation. In these cases, aged animals (e.g., > 100 days post induction of Cre) may experience the adverse effects of malignant tumours such as weight loss, hunching, inappetance, lack of grooming. Additional clinical signs of pancreas tumours may include weight loss from the haunches, abdominal distension, pallor in the extremities (e.g., paling feet). Lung tumours may cause breathing difficulties. Tissue inflammation alone may cause transient minor discomfort. Since we are interested in early tumorigenesis, we will not routinely use tumour burden as an end point and experiments will be stopped before the appearance of clinical signs.

Clinical Signs Health Score sheet for this project is inserted here:

Score Sheet Guidance

A score sheet combines general health indicators with expected adverse effects from your PPL so that Animal Technicians and NACWOs can ensure the highest standards of animal care and welfare, even if they are unfamiliar with this research/strain. It offers clear instructions about the appropriate actions to take at varying stages of sickness/expected adverse effects to safeguard appropriate care.

General health indicators (Wolfensohn and Lloyd)

Parameter	Animal ID	Score	Date/Time	Date/Time
Appearance	Normal	0		
	General lack of grooming	1		
	Staring coat, ocular, nasal discharges	2 each		
	Piloerection, hunched up	4 each		
Weight Loss	Normal	0		
	5% weight loss	1		
	Up to 15% weight loss	2		
	Over 15% weight loss	4		
Natural Behaviour	Normal	0		
	Minor changes e.g. Lack of nest	1		
	Less mobile and alert, isolated	2		
	Vocalisation, self-mutilation, restless or inactive, cold	4 each		
Provoked Behaviour	Normal	0		
	Less active and/or slow movement	1		
	Only moves when directly provoked	4		
	Does not move, even when provoked or displays hyperactivity when provoked	9		

Expected adverse effects for pancreatic cancer or lung cancer models:

Parameter	Animal ID	Score	Date/Time	Date/Time
Appearance	Normal	0		
	General lack of grooming	1		
	Staring coat; ocular, nasal discharges; pallor of eyes, nose, feet; abdominal distension.	2 each		
	Pallor of eyes, nose, ears and feet; Intermittent diarrhoea.	3 each		
	Piloerection, hunched up; complete paling of extremities & animals feel cold; continuous diarrhoea (>72h); abdominal distension affecting breathing or movement	4 each		
Weight Loss	Normal	0		
	5% weight loss	1		
	10% weight loss	2		
	Up to 20% weight loss, particularly at haunches.	4		

	Over 20% weight loss, particularly emaciated at haunches with clear distension of spine/pelvic bones or pelvic bones are readily palpable.	8		
Natural Behaviour	Normal	0		
	Minor changes e.g. Lack of nest, inappetence. Shallow or irregular breathing.	1		
	Less mobile and alert, isolated, reluctance to move; Altered respiration, temporary or intermittent abnormal breathing pattern, Intermittent 'chattering.	2		
	Vocalisation, self-mutilation, restless or inactive, cold; Laboured respiration, prolonged 'chattering'.	4 each		
Provoked Behaviour	Normal	0		
	Less active and/or slow movement	1		
	Only moves when directly provoked	4		
	Does not move, unresponsive, even when provoked or displays hyperactivity when provoked	9		

Parameter	Animal ID	Score	Date/Time	Date/Time
Tumour Phenotypes	Small skin papilloma <0.1 cm.	2		
	Tumour mass <1.5 cm; skin papilloma <0.5 cm	4 each		
	Tumour mass >1.5 cm; ulceration; skin papilloma >0.5 cm.	8 each		
Post-surgical wound; Wound healing	Normal	0		
	Slight redness, clear fluid, scratching/licking	1 each		
	Missing suture/clip, redness, inflammation	2 each		
	Wound shows evidence of herniation/rupture or over 7 days without healing	4		
		Total:		

Score Key

Score	
0	Normal
1-3	Use observation card
4-9	Monitor carefully, seek advice from NACWO
9-12	Pancreatic cancer mice: kill by an appropriate method. Non-pancreatic cancer mice: Observe regularly, NACWO must be involved to discuss whether endpoints have been reached. ***Advice may need to be sought from the NVS regarding ongoing treatment e.g. antibiotics, analgesia, fluid therapy***
13-15	Kill by an appropriate method

Note: The clinical signs outlined in the score sheet will be used to assess the health of experimental animals. However, the judgement and experience of the licensee may necessitate actions at earlier time points, as appropriate. **Clear humane endpoints are detailed in each protocol.**

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect tumour development to have moderate severity. Only animals that carry site-specific Cre recombinases and a combination of conditional alleles will develop tumours.

Expression of oncogenic Kras in healthy adult tissues will not lead to tumour development. Tumorigenesis requires the presence of a second mutation (e.g., loss of

tumour suppressor function such as p53 or expression of oncogenic c-Myc), or an exogenous risk factor such as chronic inflammation. Based on current experimental design, approximately 25% of cohorts may experience a moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse models of cancer are clinically relevant and accurately recapitulate the full spectra of human disease at the genetic, cellular and tissue level. Cancer is multifaceted disease that starts with genetic mutation in cells; however, for tumours to progress to malignancy mutant cells 'hijack' normal biological processes (e.g., immune cell infiltrate, stromal cells, extracellular matrix modification) to support tumour progression. Mouse models accurately model all aspects of tumour complexity that would be technically challenging to achieve using ex vivo or in vitro cell systems alone.

Which non-animal alternatives did you consider for use in this project?

Drosophila melanogaster and ex vivo organoid models may be used as non-animal alternatives for some aspects of this work e.g., a reductive approach to unravel molecular cell biology of a phenomenon at the single cell level. Organoids also allow for high-throughput experimental approaches, e.g., testing efficacy of pharmacological inhibitor or oncolytic virus before administering to animals. However, these systems cannot replace the need for animals in this project.

Why were they not suitable?

Drosophila melanogaster as a model of human cancer is hugely limited as it does not fully recapitulate mammalian/human tissue complexity and physiology. Pertinent to this project is the fact that insect models lack a distinct pancreas and lung tissue, and an adaptive immune system. Ex vivo pancreas and lung organoid models do not robustly recapitulate healthy normal tissue, principally because both pancreas and lung tissues are complex, composed of multiple cell types; are not derived from a distinct stem cell pool; are highly plastic and readily reprogramme following mutational insult and injury. Moreover, we lack capabilities to model all aspects of tissue inflammation or diabetes ex vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

NC3Rs Experimental Design Assistant and Power Calculations. Effect size (m1-m2) and Variance (S.D.) were calculated using current data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All calculations were made using the NC3Rs Experimental Design Assistant and current data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of our phenotypes require transgene heterozygosity; therefore, we will breed heterozygous pairs/trios to increase efficiency. We generally divide target tissues (e.g., pancreas) into multiple fixatives (e.g., OCT versus FFPE) and experimental pipelines in order to maximise the output of each induced animal. In future studies, we plan to use mathematical in silico modelling and collaborative projects to address specific questions, which will reduce the requirement for animals. Where specific signalling pathways are to be interrogated using pharmacological inhibitors, we will use pilot studies to gauge efficacy (e.g., 2-4 animals). We will also make available and share tissue to other projects if appropriate. Wherever possible, we will use imaging techniques (e.g., PET scanning) and/or microsampling of blood to measure longitudinally and maximise experimental outputs on a minimal number of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically altered mouse models and site-specific Cre-lox technology that allows temporal and inducible gene modification in specific epithelial tissues. Mouse strains will also express reporters of Cre that will allow tracing of recombined (i.e., genetically mutant) cells in tissues over time. All genetically altered lines will carry conditional alleles; therefore, only mice that carry site-specific recombinase and the conditional allele will develop tumours. These models are well characterised by our collaborators; experimental time points and timelines of the development of predictable tumour phenotypes is known. We will only use genetically altered animals appropriate to

our objectives (i.e., targeting specific transgenes in a tissue-dependent manner) to ensure that the work carried out is accurate. Our primary research focus is to understand early tumorigenesis; therefore, we will not routinely age tumour-bearing mice or use tumour burden as an end point. Moreover, we routinely model sporadic disease, which requires minimum procedural intervention. In vivo imaging approaches (where appropriate) provide non-invasive methods to monitor tumour progression in the same animal over time.

Controlled feeding regimes will allow us to generate in vivo models of obesity and diabetes without genetic alteration and extensive breeding. Tissue transplantation assays provide approaches where we can uncouple cell intrinsic from cell extrinsic factors in vivo; test putative cancer stem cells and monitor metastasis in short-term assays without the need for primary tumour formation.

Why can't you use animals that are less sentient?

We are primarily interested in Kras-driven epithelial tumours e.g., pancreas and lung. Both pancreatic and lung cancers are adult diseases that have increased risk in ageing populations. Therefore, immature life stages are not appropriate for our research studies. Moreover, developing epithelial tissues are highly plastic, morphogenetic structures that do not recapitulate fully differentiated adult tissues. Moreover, tissue health requires functional tissue dynamics and mechanics, and architecture; all of which cannot be modelled in terminally anaesthetised animals. Less sentient species such as Drosophila melanogaster are good alternatives for some aspects of this work and will be considered where appropriate; however, Drosophila models do not have an adaptive immune system, or distinct pancreas/lung tissues.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements will include frequent monitoring of induced animals, post-operative or anaesthetised animals. Exogenous substances/agents will be administered at the minimum dose, as determined using NC3Rs guidelines for best practice and dosing regimens and following consultation with our collaborators.

All procedures will be carried out by trained and experienced staff with the support of experienced animal facility staff/NACWOs/NVS (e.g., application of anaesthesia, analgesics, surgical techniques). Clear humane end points are detailed for each protocol. Animals will be housed in clean, pathogen free environments to ensure good animal health is maintained and the risk of infection from the environment is minimised.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

This project will be carried out in collaboration with experienced cancer researchers who have excellent track records and are world renowned leaders both in the pancreatic and lung cancer fields, and in the use of genetically altered mouse models of disease.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Engage with NC3Rs representatives on a regular basis via local workshops/meetings, newsletters and social media.

15. Peripheral Nerve Regeneration

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

peripheral nerve injury, stem cells, biomaterials, surgery

Animal types	Life stages
Rats	adult

Retrospective Assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To improve peripheral nerve regeneration following traumatic injury using stem cells and biomaterials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Peripheral nerves carry information from the brain and spinal cord to their target organs. They are essential for movement, sensation and other important functions such as temperature control.

Peripheral nerves are commonly injured following trauma (e.g road traffic accidents, workplace incidents) or following surgical removal of a cancer (e.g. prostate cancer). The

subsequent disability following peripheral nerve injury can be significant and wide ranging effects including (but not limited to) complete loss of a limb's function, sexual dysfunction, inability to control and move facial muscles and pain. Current treatment options are limited and even with optimal access to current treatments, outcomes remain extremely poor.

What outputs do you think you will see at the end of this project?

The primary output of this project is to produce a medical device that (i) replaces the need for a nerve graft (where a healthy nerve is sacrificed in order to reconstruct an injured nerve) and (ii) improves upon outcomes for patients receiving this treatment. Outputs will also include scientific publication of our findings which will inform further research in the field.

Who or what will benefit from these outputs, and how?

Within the short term, researchers looking at further understanding the nature of peripheral nerve injury will be greater informed by the publication of our findings. In the long term, if successful, patients with peripheral nerve injury will benefit from an alternative treatment options to nerve grafting (which otherwise involves sacrificing the function of a working nerve).

How will you look to maximise the outputs of this work?

All work, unsuccessful or successful will be submitted for publication. This will prevent duplication of work by other groups and guide further research direction. Our work is a collaboration between two groups with extensive experience in biomaterials and peripheral nerve, by combining expertise we increase the chance of success.

Species and numbers of animals expected to be used

- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We have chosen to conduct the experiments described on adult rats for the following reasons:

- We have considerable expertise evaluating a similar medical device in rats, and taking this treatment into human trials. This expertise allows us to better plan the experiments required, such that only a minimum number of animals are required.
- The rat sciatic nerve model is similar in size to a human digital nerve and it is therefore pragmatic for suturing biomaterial conduit interventions.
- The rat model of sciatic nerve injury is used by many other researchers internationally and the outcome measures are well documented; therefore by utilising a well established model, it is easier for our research to be appropriately scrutinised and compared to other findings.

- Additionally, there is less need for other groups to duplicate this research, thereby reducing the overall need for further animal research.
- Rats undergo nerve regeneration at a fast rate. Therefore we can assess the outcomes of the experiment in less time, hence minimising animal suffering.
- Immature rats have an even greater capacity for regeneration, such that this may limit the ability to accurately evaluate the benefit of the experimental treatment. In addition, the nerves that we would seek to reconstruct are much smaller and the repair would be less representative of a human repair, nor would the creation of an appropriate sized defect be possible.

Typically, what will be done to an animal used in your project?

Rats will undergo a surgical procedure whereby a nerve to one leg will be cut and then repaired through a variety of methods, including the experimental treatments we are investigating. The majority of rats will then not require a further surgical procedure. They will be monitored closely to support their welfare to the time points already listed. During this time, behavioural studies will also be conducted. For the majority of animals, at set time points, they will be humanely culled and their tissues closely examined to obtain the experimental outcomes. For a subset of rats, they will undergo a further general anaesthetic to allow testing of the nerves function. These rats will be humanely culled prior to recovery from anaesthetic.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are expected to experience mild postoperative pain in the short term and this will be ameliorated with pain-killers. There is likely to be some reduction in function to the limb with the nerve injury. In our experience this does not seem to effect the rats mobility or cause any signs of distress.

In the long-term models (3-6 months), animals could undergo autotomy, where the rat chews the nails of the numb hindpaw. We will mitigate this by housing in groups with a calm environment and the use of strains not thought to exhibit autotomy and, therefore, expect autotomy to be less than 10%.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals are expected to experience moderate severity outcomes due to them all undergoing a surgical procedure resulting in reduction in the function of one limb

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We have created an artificial nerve graft that has been tested successfully in the laboratory but prior to testing in a human would need further evaluation in an animal to ensure safety and effectiveness of its use in a similar environment to those injuries seen in humans. Human injuries tend not to be standardised and it is very difficult to control for a multitude of variables as is possible in an animal model.

Which non-animal alternatives did you consider for use in this project?

We have tested materials in the laboratory cell culture models with nerve cells and stem cells to choose the material most likely to be successful prior to animal trials. Moving forward from here, animal studies are an essential next stage to ensure safety before considering placing these devices in humans.

Why were they not suitable?

Laboratory testing of materials to assess nerve cell and stem cell growth has been considered suitable and carried out, however, this information is not sufficient to move toward human trials. Animal studies would be required prior to human studies to maximise human safety.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Within each experimental group we will use 8 rats. There are 4 experimental groups. Each timepoint will require 32 rats. We estimate utilising at least 8 time points.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Only one material hydrogel is being taken forward via this project as other potential materials were tested using non-animal laboratory techniques thereby reducing the number of animals required. Full review of the published literature has been undertaken to ensure that there is not undue duplication of experimentation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Close monitoring of animal welfare to reduce the risk of loss animal loss.

Any adjustments to materials considered would be tested in the laboratory before testing in animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

From our experience gained over the past years using these animal models, it is apparent that the experimental procedures described in this application do not greatly affect the well being of the animals. The majority of described procedures are carried out whilst the animals are fully anaesthetised. The animals do not appear to have persistent adverse effects from the anaesthesia. From past experience, after the nerve injury, the animals do not show any behavioural signs of pain whether the nerve repair is carried out immediately or with delay. Nerve injury with/without repair can partially affect the gait, but has little effect on the mobility of the animals. The insertion of the nerve conduit at the site of repair does not affect the mobility of the animal, because the biomaterial is soft and flexible, and after harvest histology, showed no signs of adhesion or inflammation in past experiments.

In the long-term models (3-6 months), animals could undergo autotomy. This will be mitigated by using strains of animals that are not expected to show autotomy and using refined animal care strategies.

Why can’t you use animals that are less sentient?

The intervention requires suturing of nerve endings to a device. At a more immature life stage repair is more difficult and less likely to be representative of the repair used in humans. Additionally, at a non- adult stage, the ability to self-regenerate nerve is much greater, and therefore would not accurately evaluate the efficacy of the device being tested. Recovery of function secondary to the intervention is an important experimental outcome therefore utilising only terminally anaesthetised animals would not allow this to be observed.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

All animals will be monitored closely for any signs of pain or distress, especially in the immediate post- operative period. Analgesia will be provided where necessary and consultation with the NVO if there are other concerns.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice guidance published by the National Centre for Replacement, Refinement and Reduction.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The investigators are subscribed to updates from the National Centre for the Replacement, Reduction and Refinement of Animals in Research and will implement any advances in a timely manner.

16. Genetic and physical control of B cell and antibody responses

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

B cell, Antibody response

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main goal of this research is to understand how B lymphocytes, the white blood cells that produce antibodies, detect and respond to infections and vaccines, and why they sometimes fail to protect or even cause an immune disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antibodies are essential to our immunity. They provide long lasting protection from a wide variety of infections and are responsible for the success of most vaccines. Problems in antibody production often cause immune deficiencies. Therefore, there is an ongoing interest to improve antibody production through vaccine design, and thus to combat new and highly dangerous pathogens.

On the other hand, production of antibodies that is too high can cause autoimmunity and allergy, and the cells that produce antibodies also give rise to leukemias and lymphomas.

All of these diseases are on the rise in modern society. Animal models help us to understand the genetic and physical mechanisms that underlie a balanced antibody response and provide insights into human disease.

What outputs do you think you will see at the end of this project?

The primary output of this work will be new information on regulation of antibody responses. We will determine where and for how long vaccine antigens remain in the body and how this impacts on antibody production. We will also identify specific genes acting in antibody production from within B cells. This new information will inform vaccine design and advance our understanding of immune diseases, such as immune deficiencies, autoimmunity and allergy. We will publish our findings in peer- reviewed scientific literature, freely accessible using open access. We will also immediately share preprint articles in publicly available on-line depositories, such as BiorXiv. We will summarise our overall findings for students and trainees in reviews and in viewpoint articles, including articles for the lay public.

Who or what will benefit from these outputs, and how?

Our results will be of immediate interest to a broad range of academics interested in antibody responses, B cell biology, B cell pathology, allergology, and in the role of stromal cells in immunity. The outputs will include both new information as well as new mouse lines generated in this programme. In the longer term, new information gained in our studies will be relevant to clinical researchers and the pharmacological industry designing vaccines, and therapies for patients with antibody deficiencies, autoimmunity, allergy and lymphoma.

How will you look to maximise the outputs of this work?

In addition to publications, we will disseminate raw datasets through publicly accessible databases, including negative findings. Depending on our results, our future plan is to collaborate with clinical researchers to follow up on our findings and study patients with autoimmunity, immune deficiency and severe allergy using established cohorts at our collaborator's sites. We will also pursuit emerging therapeutic options, for example relevant to human allergy, drawing on experience of our current collaborators.

Species and numbers of animals expected to be used

- Mice: 19500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The immune response cannot be fully recapitulated outside of a living animal. Mice are the least sentient animals with an immune system resembling that of humans. There is an enormous amount of tools available to study the mouse immune system, genetic alterations are well developed and a large number of mutant strains are available.

Typically, what will be done to an animal used in your project?

Genetically modified mice will be bred to obtain mutations specifically affecting cells of the immune system. These animals along with wild type controls will undergo manipulation of the immune system, such as bone marrow transplantation, or receive substances modulating immune cells. Typically, the mice will then be immunised with vaccine-like materials to study the antibody response. Some animals will be exposed to allergens to induce allergy.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of our procedures, including breeding, and immune challenge are expected to be of mild phenotype with only a fraction reaching to moderate signs. Immune deficiency due to genetic defects or bone marrow transplantation is typically well tolerated by the animals in specific pathogen free conditions and by supplementation of drinking water with antibiotics. Animals challenged with model vaccines are expected to exhibit only transient discomfort and no lasting harm. Genetic perturbations causing immune disease or lymphoma only manifest in animals aged beyond the duration of our experiments. Exposure to allergens induces asthma-like changes in the respiratory system, which are typically well tolerated.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect that in total, approximately 93% of the animals will experience subthreshold or mild severity. Approximately 7% will reach moderate severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The reason for using animal models for our experiments is that the development of the cells of the immune system and of the immune stroma, and their complex interactions cannot be fully recapitulated outside of the animal. In addition, disease conditions associated with immune system pathology develop as a result of imbalance between factors that are impossible to reconstruct in vitro.

Which non-animal alternatives did you consider for use in this project?

In vitro assays for cell function, immune cell co-culture and organoid experiments.

Why were they not suitable?

While in vitro assays are informative for formation of hypothesis about B cell functions, they do not currently fully capture the complex mechanisms regulating their interactions with antigens and with the immune environment that underlie the immune response. There are currently no in vitro systems that recapitulate the correct architecture and cellular composition of the immune stroma.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals represents the sum of the animals needed for the experiments and the numbers of wild type and genetically modified breeders needed for their generation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experiments use robust statistical determination of the minimal possible numbers of animals to use in the experiments as recommended by the NC3R. We have also implemented cell transfers and modern single-cell analysis techniques that dramatically reduce the number of animals without compromising the quality of the experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are working within institutes where sharing and carefully organised breeding reduces the overall numbers of animals used. Strains not in use will be cryopreserved.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use mouse models of the immune response. Mouse immune system, including the antibody response, has been extensively studied and closely resembles the human immune system. An enormous amount of reagents is available for studying of the mouse immune system, and mouse transgenic and knockout techniques are well established, with mutant strains widely available. This allows us to breed animals in such a way so as to generate mutations only in specific cell types, or inducible pharmacologically. Although this increases the numbers of breeding animals, it limits harmful genetic effects these mutations may have in other cells of the body. In addition, there is extensive previous experience with animal procedures used in this project. This allows us to carry out experiments efficiently and with good knowledge of possible harms.

Why can’t you use animals that are less sentient?

To our knowledge the laboratory mouse is the least sentient species that fulfils the requirements of this research. It has a well developed immune system that resembles that of humans. Lesser sentient animal models do not have similarly developed lymphoid organs and do not produce similarly functioning humoral response or pathology.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

The proposed procedures have already been refined based on current best practices. Any new developments in animal welfare or scientific improvements will be implemented based on recommendations of our veterinary surgeon.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be following current accepted guidelines, the ARRIVE guidelines (Kilkenny et al, 2009) and the PREPARE guidelines (Smith et al, 2017). Our institute also issues a regular newsletter which contains relevant updates and we will implement any advancements published in the scientific literature related to the project.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PI and staff working on the project will attend regular refresher seminars on animal welfare and will undergo competency re-training.

17. Preventing muscle wasting in kidney failure

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Chronic Kidney Disease, Glucocorticoids, Muscle Wasting, 11Beta Hydroxysteroid Dehydrogenase

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify how kidney disease leads to muscle wasting and identify novel treatments to prevent this complication.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Chronic kidney disease (CKD) is characterised by persistent Reduction in kidney function and associated harms to the circulatory, musculoskeletal and immune systems. In the UK, an estimated 6.5 million people live with CKD. Half of these develop muscle wasting and fatigue as a result of their kidney disease. For patients with kidney failure and muscle wasting, the risk of death is 3-fold higher than for patients without muscle wasting. In addition, poor muscle health is linked with increased risk for bone fractures, heart attacks and strokes, admission to hospital and worse quality of life. Therefore, muscle wasting

related to CKD puts a significant burden on individuals, as well as health and social care services. Unfortunately, the causes for muscle wasting in CKD are poorly understood, and there remains a lack of effective medical treatments for managing these patients. This has been recognised in national and international research strategies, where studies designed to understand and prevent muscle wasting in CKD are a priority.

What outputs do you think you will see at the end of this project?

This project will provide new knowledge on the process of muscle wasting in patients with chronic kidney disease. This knowledge will be shared with the wider research community in the form of publications in scientific journals and presentations at conferences. Furthermore, the project will characterise putative therapeutic targets for the prevention and treatment of muscle wasting. These data will inform the development of new drugs and clinical trials with the goal to help patients with CKD and muscle wasting.

Who or what will benefit from these outputs, and how?

In the short-term, the improved understanding of the processes that underpin muscle wasting in kidney disease will benefit many other research groups exploring muscle wasting in human disease. This will include fundamental insights about the origins of muscle disease that are applicable in other conditions (e.g. acidosis or insulin resistance as drivers of muscle wasting are also important factors in diabetes, respiratory failure or critical illness). These findings will be shared with the research community over the next 1-3 years of the project.

In the medium-term, pre-clinical data on 11bHSD1 inhibition as a therapeutic target in muscle wasting and kidney disease will benefit investigators planning clinical trials. It will guide the design of future clinical trials against muscle wasting in kidney disease, in particular whether 11bHSD1 inhibitors hold promise in this condition. Furthermore, 11bHSD1 inhibitors are being explored in a wide range of other

clinical settings, where our data will be valuable to guide general safety and efficacy considerations. These benefits of our research are expected to manifest in 5-8 years.

In the long-term, the development of novel treatment approaches to prevent muscle wasting in patients with chronic kidney disease would mean that patients with this condition are the major future beneficiary of this research. The clinical benefits may be transferrable to other patient groups with muscle loss unrelated to kidney disease, who share common underlying pathophysiology. Reducing muscle loss in people with comorbidity holds the potential to improve general health, wellbeing, reduce care needs and reduce mortality. These benefits may take 8 to 10 years or longer to realise.

How will you look to maximise the outputs of this work?

This research fits within the interest of major research centres of excellence studying musculoskeletal aging. Through our current links and involvement with these centres, we would ensure wider dissemination of findings to research organisations working in this field, as well as interested patient engagement groups. All findings will be routinely

published to inform methodological approaches in appropriate journals and academic conferences regardless of experimental outcome.

Species and numbers of animals expected to be used

- Mice: 1750 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Studying diseases in mouse has contributed to valuable scientific and medical advances for relieving kidney disease and its complications in humans. Mouse bodies share sufficient similarities with human body to permit meaningful scientific study of kidney disease and associated muscle wasting. The requisite scientific methods are well established for mice, meaning that further experiments on animals to develop reliable methods can be kept to a minimum. Exploring novel treatments on animals before humans reduces risks of harm to humans.

The study will use genetically altered animals. Producing and maintaining these animals will employ breeding techniques that involve all stages of the life cycle.

Research on kidney disease and associated muscle wasting requires that animals have completed development and will therefore use adult mice only.

Typically, what will be done to an animal used in your project?

Breeding genetically altered animals involves mating and reproduction of mice by natural means. Small tissue samples may be taken infrequently to track the genetic alterations present in each animal.

Adult mice will receive a modified diet (adenine supplementation) which will lead to slowly progressive Reduction of kidney function over several weeks. During the experiment, mice may undergo blood tests, injections of insulin or glucose, testing of grip strength and short-term single housing for metabolic monitoring. Further samples and data will be collected during non-recovery general anaesthesia or after death.

What are the expected impacts and/or adverse effects for the animals during your project?

Maintaining genetically altered animals does not normally cause significant or lasting discomfort for animals. Animals will be monitored regularly. If an animal is observed to have persistent discomfort beyond mild changes in appearance or behaviour, it will be removed from the experiment at this stage.

Reduced kidney function does not cause pain for animals, but inevitably causes lower food intake and associated weight loss. These effects are expected to become more

pronounced the longer the animal is maintained on the altered diet. The maximum duration for an animal to receive the altered diet is 7 weeks. Body weights of animals on modified diet will be monitored regularly and animals will be observed for altered behaviour. If an animal loses weight rapidly, stops eating or displays persistent abnormal behaviour, it will be removed from the experiment and steps taken to end suffering.

Injections, blood sampling, grip strength measurements and short-term single housing for metabolic monitoring may cause mild discomfort that is short-lasting. In exceptional circumstances when more significant discomfort is observed in an animal with these procedures, it will be removed from the experiment and steps taken to end suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals receiving an altered diet to induce kidney dysfunction are expected to experience a moderate level of weight loss.

The majority of animals undergoing breeding procedures, injections, blood sampling, grip strength testing or short-term single housing may experience short-lasting and mild discomfort.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Muscle wasting in kidney failure is a complex multi-organ disease process. Animal studies are essential to clarify the role of whole body and muscle-specific glucocorticoid metabolism in this condition. Feasibility of cause-effect studies in humans is limited by safety considerations and cost. Whilst cell culture experiments can replicate some kidney failure conditions and provide knowledge on cellular and molecular processes, these types of laboratory studies are inadequate to replicate all the complex interactions that take place in a living organism. Animal studies are needed to confirm the observations from cell culture studies and explore whether new treatments that block glucocorticoid metabolism are effective against muscle wasting in kidney failure. Testing this intervention in animals prior to clinical trials is an ethical obligation and will reduce potential harms for humans.

Which non-animal alternatives did you consider for use in this project?

We have considered analysing existing scientific datasets, conducting studies in humans and using cell culture models of muscle tissue.

Why were they not suitable?

Analysis of existing datasets: We have already analysed existing datasets from observational studies in patients with kidney disease or from clinical trials of 11bHSD1 inhibitors in patients without kidney disease. While the results are generally supportive, these datasets are not sufficiently detailed or applicable to allow a definite answer to our research questions.

Conducting studies in humans: We will perform an observational study in humans with kidney disease looking at clinical signs and muscle tissue biopsies. This will provide valuable information to support and confirm findings from animal research. However, the observational study design will not allow us to prove cause-effect relationships or prove the effectiveness of new treatments. The risks associated with conducting experimental or clinical studies in humans with kidney disease cannot be justified at this stage, without first obtaining further basic scientific knowledge and proof of concept from animal research.

Cell culture models of muscle tissue: We will use cell culture models wherever possible to study cellular and molecular processes and reduce the number of animals required for research. However, tissue culture models cannot adequately replicate the complex interactions between multiple organ systems that occurs in kidney disease in a living organism. Moreover, tissue culture models cannot adequately replicate the specific environment of physical forces that act on muscle during movement. Animal models are therefore needed to replicate human disease faithfully and address our research question with relevance to clinical medicine.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Colony sizes for breeding animals have been determined based on existing breeding protocols for these transgenic mouse models that are ongoing within our Establishment. These are under continual review with expert advice from both the NACWO and NVS to ensure that numbers required for maintenance and breeding new transgenic lines are kept to a minimum. Experimental animal numbers are informed by current related active projects working with 11bHSD1 KO mice and through consultation with collaborators experienced in the adenine diet induced model of chronic kidney disease. The scientific literature has been reviewed to inform how much change in muscle mass is expected to occur in these animals and how many animals will be needed per experimental group to reliably detect this change.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We selected a diet-based model for kidney disease that is more reliable, consistent and has lower mortality compared to alternative surgical models. This reduces variability in experimental outcomes and reduces the number of experimental animals required to obtain meaningful results.

The experiment is devised in a 2x3 factorial design, allowing efficient use of data generated from control groups and thereby minimising the number of animals required.

We have conducted a thorough literature search and consultations with expert collaborators to inform statistical calculations on the lowest required number of animals to detect meaningful scientific results.

The planned pilot study adheres to a design that is embedded in the experimental protocol. This means that data from animals used in the pilot study can contribute to final result analysis, rather than duplicating use of animals.

Care has been taken throughout the experimental design and with selection of outcome measures to reduce unwarranted variability as much as possible. Steps to this effect include randomisation, blinding, or selecting muscle mass as a highly sensitive outcome measure. This will reduce the number of animals required to identify meaningful results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In house resources and expertise will reduce the number of animals needed to deliver this project. C57Bl6 mice with appropriate genetic alterations for this protocol are already available in house, reducing the need to establish new genetic lines or backcrossing animals. Breeding practises will adhere to local standard operating procedures and national NC3Rs guidance to maximise efficiency.

Our research group has previously optimised the data and tissue collection methods required to deliver this project. This avoids need for further optimisation, reduces variability and ensures that high quality data is obtained from every animal. Where operator-dependent measurement variation is possible, we will take precautions to perform measurements according to standard protocols and by the same operator wherever feasible. The use of tissue from each animal will be maximised by sampling all available muscles for subsequent analysis. In addition, primary muscle cell cultures will be derived to further extend material available for molecular analysis.

Finally, we will conduct a pilot study to confirm that our estimates for the minimum required animal number is indeed correct, prior to embarking on the full-scale project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice with genetic alterations in 11bHSD1 will be used. These animals display no apparent abnormalities or signs of harm.

Mice will receive dietary supplementation with adenine to induce gradual persistent Reduction in kidney function and associated changes like muscle wasting. These changes imitate the disease process of chronic kidney disease in humans.

The effects of adenine on the kidney are controlled by the dose and duration of adenine exposure. This allows for fine-tuning the level of kidney impairment to the minimum required for the planned experiments, thereby avoiding undue harm. Furthermore, it means that changes for the animal are mild early on, building only gradually over time. Hence, the animal experiences more significant changes only for a limited duration in the late phase of the experiment. Effects of adenine are very specific on the kidney, as it is concentrated there. Direct harm to other organs such as muscle or liver is avoided.

A diet-based model is technically much simpler and more reliable than alternative surgical models. This pre-empts animal harms and losses related to procedural complications or variation in operators' skill level. Furthermore, it spares animals from distress of anaesthesia and traumatic recovery periods.

To collect scientific data, animals will experience blood sampling, strength testing or a short period of isolation housing. Adverse effects related to these procedures are usually only mild and transient. The procedures will be conducted in the least invasive fashion (e.g. blood micro-sampling) and utilise species-appropriate behaviours (e.g. holding onto a grip bar).

Why can't you use animals that are less sentient?

The research project examines dynamic interactions between organ systems, namely kidney and skeletal muscle, in the setting of persistently reduced kidney function. Lesser developed species (e.g.

invertebrates) or aquatic life forms do not possess kidneys that resemble human kidneys and are therefore not a suitable model. To accurately model the changes in muscle associated with long-term kidney impairment, animals need to be studied over an extended period of time that precludes experiments on immature life stages or animals under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We reviewed the scientific literature extensively for mouse models of kidney disease and developed a collaboration experts in this field. This has allowed us to devise a purpose-specific protocol that allows us to study muscle wasting in kidney disease, while minimising harm to animals. In addition to employing an evidence-based protocol, we will

conduct a pilot study to confirm the validity and tolerance of the adenine-diet protocol prior to proceeding to the full-scale experiment. This will introduce a distinct step at which further Refinement can take place.

Our protocol includes provisions to track changes with kidney function (serum creatinine and urea) and changes in muscle function (grip strength testing) over time. Furthermore, we will test kidney function in a direct and more accurate fashion than blood tests alone (creatinine clearance). This data will help to ensure that the animal model is not progressed beyond the least harmful stage required to address the research question.

Suitable adjustments will be implemented in the care and housing of animals to mitigate adverse effects that may occur. Water and food will be provided in the most attractive and convenient fashion for animals to avoid dehydration or weight loss. Body weight will be monitored regularly and animals will be removed from experiments if they are at risk of severe malnutrition. Animals will be habituated to handling and test procedures to reduce associated distress. We will follow refined handling techniques as recommended by NC3Rs wherever possible (e.g. handling tunnels). If pain is suspected, appropriate analgesia will be provided.

Throughout the experiment, animals will be carefully monitored and welfare will be tracked using a multi-component score sheet. If features of undue adverse effects are observed in an animal, that animal will be removed from the experiment to relieve suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will abide by local best practice procedures for breeding, maintenance and surveillance of animals. National guidance by the Laboratory Animal Science Association, National Centre for the Replacement, Reduction and Refinement of Animal Research, and the Royal Society for the Prevention of Cruelty to Animals was used in the development of this protocol, including:

Avoiding mortality in animal research and testing (https://view.pagetiger.com/RSPCAAvoidingMortalityResearchReport/RSPCA)

Blood sampling techniques, frequencies and volumes (https://nc3rs.org.uk/3rs-resources/blood- sampling, https://www.nc3rs.org.uk/blood-sample-volumes)

Genetically altered mice (https://nc3rs.org.uk/gamice)

Animal handling and husbandry (https://nc3rs.org.uk/3rs-resources)

The PREPARE guidelines (https://norecopa.no/prepare) informed the project planning phase, including engagement of relevant stakeholders and implementation of quality controls. Furthermore, the ARRIVE guidelines have been considered to ensure that results can be communicated with the highest scientific rigour.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will remain in close dialogue with all staff in the care and welfare of animals including the NVS and the NACWOs to extend our knowledge about general and specific welfare issues relating to the experimental animals. We follow published methods to refine animal welfare in the polyarthritis models, attesting our commitment to continuous development of our research methodologies. Furthermore, we are working closely with other national centres for animal models of kidney disease to exchange knowledge advances efficiently. These efforts will ensure that we continuously up to date on the highest welfare standards specifically relating to our animal models and promptly refine procedures wherever possible.

In a dedicated effort to advance on the 3Rs, we will conduct a pilot experiment with 3 experimental and 3 control animals. This will ensure that our protocols reach the desired experimental targets, without leading to undue or unexpected harm to animals. This will include validation and Refinement for the animal welfare monitoring protocol and adjustments to mitigate potential harms or suffering.

Our group is actively engaged in research to replace and reduce animal research projects in the future. We are conducting research to validate and extend the use of muscle cell cultures for the investigation of muscle changes in kidney disease. Furthermore, we are gathering scientific data to prepare a clinical trial on treating muscle wasting in kidney failure. This research is supported by collaborating partners and national experts in the fields of muscle cultures and physiology, steroid hormone metabolism, drug development and chronic kidney disease. Hence, our own efforts and collaborations will inform plans to replace and reduce animal studies at the earliest opportunity.

Finally, we regularly review the relevant literature, attend professional conferences and participate in animal research training opportunities to attain continuous professional development on model-specific advances and animal husbandry in general. Continuous professional development activities also include engagement with resources offered by NC3Rs, such as subscription to the newsletter and attending local 3Rs events.

18. Modulating angiogenesis for health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Angiogenesis, Cancer, Endothelium, Cell Adhesion, Microbiota

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to understand how we can modulate angiogenesis (blood vessel formation) for life-long health and to alter the course of disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Irregular or un-balanced blood vessel formation (angiogenesis) contributes to a decline in health as we age and is a contributing factor in how large number of human diseases develop. The work performed on this project will provide novel insight into how angiogenesis is regulated so that we can help maintain normal angiogenesis as we age. This work will also advance our understanding of angiogenesis so that we can develop new evidence-based interventions to either stimulate angiogenesis in diseases where

there is not enough (e.g. cardiovascular disease) or to inhibit angiogenesis in diseases where there is too much (e.g. cancer).

What outputs do you think you will see at the end of this project?

At the end of this project, we will have:

- A better understanding of how angiogenic pathways integrate to regulate the process. This will include new information on specific molecules known to play a role in angiogenesis, and new information on how host-microbe interactions influence angiogenesis.
- Communicated our findings to scientist (e.g. by publishing our findings in peer-reviewed journals and presenting at scientific conferences) and to the general public (e.g. by engaging with social media platforms and by presenting to "lay" audiences).
- Begun the development of a microbiota based therapy that can be used to modulate angiogenesis.

Who or what will benefit from these outputs, and how?

Because blood vessels are essential to many physiological/healthy and pathological/disease processes, this research will provide insights into fundamental and translational mechanisms that underpin angiogenesis, and will thus benefit a wide range of individuals in both pure and applied contexts.

1. Ultimately, **people** wanting a therapy for maintaining a healthy vascular system throughout life, or patients needing to re-balance blood vessel formation as a disease treatment [>10 years].

2. **Biomedical researchers**. We believe that the mechanisms studied in this work are relevant to many human conditions, including age-related macular degeneration, arthritis, coronary artery disease, stroke and cancer. We expect that an increased understanding of the mechanisms that underlie normal and abnormal angiogenesis will facilitate progress in those areas. Moreover, we will be breeding new genetically modified mouse systems that will be useful to the research communities studying these diseases and we will make them widely available [during the lifetime of the project].

3. **Pharmaceutical companies/clinicians**. Angiogenic modulators have been developed and tested in clinical/pre-clinical settings. Their success, however, has been limited. The reasons for the failures are not fully understood. We anticipate that this project will uncover mechanistic interactions that help explain the, to date, disappointing clinical findings with the existing modulators. The findings from our studies may re-direct the use of current drugs and/or spur the development of new therapies (for example, we are trying to develop microbiota-based therapies geared toward re-balancing disrupted blood vessel formation. We expect the data generated from this study will inform future clinical trials and will impact on the design and implementation of future drugs and treatment regimens [beyond the timeframe of this project, >5 years].

4. **Staff associated with this project**. Training of staff working on this project will increase capacity in the fields of cell adhesion, microbiota, and angiogenesis, helping to create the next generation of scientists studying these processes [within the lifetime of the project].

How will you look to maximise the outputs of this work?

The key outputs of the project will be communicated by:

- Publication in open-access scientific journals. We will seek to upload all material via preprint servers (e.g. bioRxiv; we have done this recently with all manuscripts) so as to provide project findings as quickly as possible to the wider research community. These publications will include both positive and negative findings.

- Meetings with current collaborators to discuss findings and directions. We also anticipate the work will attract new collaborations.

- Engagement with stakeholders (e.g. academics and the general public). This will be through our Institute Press Office, who will manage communication of the project outputs with the media in an appropriate and clear manner.

- Dissemination at national and international conferences.

- Further public engagement. We have extensive experience of engaging with the public about our science, and working in collaboration with our Institute communications team. We will establish project specific webpages on our lab websites, use social media (Facebook and Twitter), make public presentations via talks at science festivals and other outside events (e.g. Pint of Science), press releases, and blogs, throughout the project to communicate our research to the wider public, and also interact with broadcast media (press, radio, tv), via the science media center, and also partake in science programmes as appropriate.

Species and numbers of animals expected to be used

- Mice: 17450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The mouse is an appropriate and extensively validated model for studying angiogenesis, both developmentally and pathologically. It is also a species in which reliable genetic engineering technology, microbiota manipulations, and germ free experiments may be performed. We have also engineered mice which are genetically altered in their ability to express proteins we believe play an essential role in angiogenesis (via tissue-specific inducible deletion); additional models will be generated in this project.

We will use embryos (up to embryonic day 10) to study early brain angiogenesis, as the central nervous system vascularises from embryonic day 7.5 up to birth. For these studies, procedures (e.g. substance administration) are performed on pregnant mothers.

We will use neonates to study postnatal angiogenesis in the brain as this organ continues to vascularise throughout early life.

We will use neonates to study retinal angiogenesis, as the mouse retina vascularises between postnatal days 1 and ~28.

We will use juvenile mice to study mammary gland angiogenesis as the mammary gland develops at the onset of puberty.

We will use adult mice for breeding, and for performing tumour studies.

Typically, what will be done to an animal used in your project?

Most animals used in this project will undergo one (or more) of the following procedures:

- **Tissue sampling** (to perform routine genotyping of progeny); typically **once only shortly after weaning**. This will involve around 80% of animals. Approximately 20% of animals are from wild- type breeding pairs that do not require genotyping.

- Substance administration via **oral gavage** (to induce alterations of the gut microbiota or in gene expression).
  - Neonates, typically 6-18 days, typically every other day. These animals are unlikely to undergo any other procedure.
  - Adults, typically 21-56 days, typically every other day. These animals are likely to also undergo orthotopic surgical implantation of tumour cells.

- Substance administration via **injection** (multiple routes - to induce alterations in gene expression, or to alter tumour progression).
  - Neonates, typically 6-18 days, typically every other day. These animals are unlikely to undergo any other procedure.
  - Adults, typically 21-56 days, typically every other day. These animals are likely to also undergo orthotopic surgical implantation of tumour cells .

- Orthotopic **surgical implantation** of tumour cells; typically once only.
- The remaining animals in this project will be used for **breeding**. Typically these animals are kept alive until they reach the end of their economic breeding life (6 months).

What are the expected impacts and/or adverse effects for the animals during your project?

Potential adverse effects:

- **Pain** associated with tissue sampling (transient; no mitigation required).
- **Pain** associated with substance administration by injection or oral gavage (transient; no mitigation required).
- **Pain** associated with surgery (vasectomy, orthotopic implantation of tumour cells, mammary fat pad clearing and transplantation - several hours; mitigated against by administration of analgesia pre and post surgery).

- Discomfort associated with **tumour** growth (days; mitigated against by Schedule 1 killing at first signs of poor health condition - see Table 1).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild **pain** associated with tissue sampling; 80%.
Mild **pain** associated with substance administration by injection or oral gavage; 80%.
Moderate **pain** associated with surgery; 35%.
Mild to moderate discomfort associated with **tumour** growth; 35%.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals for this project is essential; we need to determine how blood vessels form in whole tissues which contain multiple cell types that must interact with one another and without damaging the tissue in which the vessels are forming. Moreover, the reciprocal interactions occurring between organismal level systems (such as the microbiota and/or the immune system) and the local tissue microenvironment are complex. These interactions cannot currently be readily replicated outside the endogenous physiological environment

Which non-animal alternatives did you consider for use in this project?

- In vitro culture of endothelial cells.
- Ex vivo culture of aortic rings.
- Organs-on-chip models.
- In silico modelling.

Why were they not suitable?

We do use in vitro and ex vivo assays of angiogenesis where possible (see project overview). Moreover, we frequently immortalise endothelial cells (the major cells that make up blood vessels), thereby reducing our need to continually isolate primary cells which have a limited life span in culture. However, these assays, as they stand, cannot adequately model the complete array of cellular and tissue interactions that are important during both normal and abnormal angiogenesis; angiogenesis involves many different

cells types (e.g. pericytes, leukocytes, fibroblasts, etc.) including endothelial cells. In addition, removing cells from their natural environment rapidly induces changes in their functions. Finally, growth factor gradients and tissue oxygenation patterns that depend on blood flow cannot be reliable reproduced in the in vitro or ex vivo systems. Both parameters dramatically influence angiogenesis. Organs-on-a-chip are being developed, but they do not yet reliably model multiple interactions between very complex systems such as the microbiota, the immune system, and local tissue microenvironments. Thus, while we will continue to make the maximum possible use of cells/tissue from animals that do not undergo regulated procedures, it is currently not possible to perform the experiments described in this application without performing procedures on living animals.

Finally we are beginning to form collaborations that will allow us to do some in silico work, but these collaborations are still young, and the methods still in development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Many of the procedures and protocols described in this project have been developed and extensively used during the previous PPL and have produced scientifically robust data that has been published in peer reviewed journals. The total number of animals to be used in this project is therefore primarily based on the use of established protocols. These totals include control groups (e.g. mock or placebo treated) for each experiment which are of the same size containing animals of the same age and sex distribution as the experimental groups, in order to increase confidence in the validity of the data and that any significant findings are attributable to the intervention. The protocols also include replication which is necessary to ensure that the results obtained are reliable and repeatable and not due to operator bias or other extenuating circumstances. Experiments are routinely planned to maximise efficient animal use by, for example, sharing tissues, particularly from non-treated control animals, with other investigators and by sharing data with other investigators to help inform their own studies. We also routinely bank large numbers of tissue samples from all animals for future use in the same or subsequent studies. For those protocols new to this proposal we have consulted with the in-house establishment statistician together with reviewing published studies that use the same or similar protocols to determine the minimum number of animals to obtain scientifically robust findings.

With regards breeding, and whether or not to set up and breed a colony in-house we first evaluate the scientific need and whether the number of animals required and the anticipated timescales justify breeding in-house. We also consider whether the conditions animals have experienced prior to starting the experiment may influence the science and must be standardised. For example, given variabilities in microbiota across different

facilities, and how this can contribute to different experimental outcomes, it is often more scientifically sound to breed in-house than to buy animals (e.g. with wild-type colonies).

Regarding colony maintenance, we perform breeding calculations (frequently in consultation with establishment staff who keep records on colony breeding efficiency) before we plan our experiments and only produce the numbers of animals that we need which is in line with Home Office guidance (Assessment Framework for the Efficient breeding of GA Animals). See below.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals in each protocol has been projected based on the following:

- Previous experience with a specific protocol (we are experienced in the use of all protocols).
- Experimental design planning (and post analyses, see below) in consultation with in-house statisticians, to ensure at the out set of the project that protocols are sufficiently powered.
- Use of the NC3R's Experimental Design Assistant, particularly where novel parameters are being assayed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- **Efficient breeding** of GA lines – GA lines are routinely maintained by keeping ~2-3 breeding pairs per line over the course of the year. This ensures sufficient stock for maintaining the line (we replace pairs when they reach the end of their economic breeding life, typically 6 months) and generally produces enough animals for experimental procedures. Where neonates are required for substance administration to induce changes in gene expression or microbiota composition, dedicated pairs are established solely for this specific purpose and the pairs are culled as soon as experimental needs have been met. Mice under sporadic use are maintained at lower levels and lines are frozen down whenever practicable. We also seek colony management guidance from technical staff within our establishment and from the NC3R's guidance page on breeding and colony management. With these inputs we routinely self-assess the breeding efficiency of our colonies (GA and WT) - this ensures regular review of colony performance so as not to exceed requirements for prioritised experiments. Where possible I maintain collaborations with other on- site licence holders to minimise over-breeding and duplication of experiments.

- Specific mitigations to minimise animal numbers:
    - **Tumour studies** – Tumour lines expressing luciferase or other biomarkers are used wherever possible (in transplantable tumour models) to determine tumour growth and/or metastases longitudinally via in vivo optical imaging. This is a non-invasive technique providing consistent data leading to fewer required animals.
    - **Histological studies** – For qualitative experiments, the amount of material required will be the minimum necessary to provide an adequate description (e.g. of vascular anatomy).Wherever possible, we share tissues with other licence holders to maximise the use of any one animal.

- **Substance administration** – Littermate controls and the use of contra-lateral mammary glands as internal controls provides for accurate assessment of treatment effects. For i.v.,i.p. and subcut. routes of injection, advice from the experienced animal care personnel within our establishment will help maximise consistent substance delivery, minimising the number of animals required.

- Ensuring our data is as robust as possible:
  - **Statistical analyses**. Where are are measuring new/unique parameters, we will employ **pilot studies** using a minimum number of animals, and the smallest amount of suffering, to achieve an experimental objective. These studies will involve two groups only (control and treatment). Effects and standard deviations within groups will then measured and statistical analyses performed, with assistance of in-house statisticians. Power calculations will then enable us to estimate the number of animals required to generate statistically-significant results, and these predictions will guide the decision making process. We also perform meta-analysis on data from pooled experiments to reveal less pronounced effects, thereby reducing overall animal use.
  - **Randomisation**. Wherever possible animals will be completely randomised into experimental groups (e.g. using the =Rand() function in Excel). This will prevent the bias of a covariant on the outcome of the treatment.
  - **Blinding**. Blinding (colour or numerical coding) will occur at multiple stages
    - During treatment. Those administering treatments or surgical interventions will be blinded to the treatments.
    - During result assessment. Those taking longitudinal measurements will be blinded to treatments.
    - During data acquisition and analysis. Those acquiring data or analysing data will know animal groupings, but not treatments.

  - **Methods of analysis**. For data analysis the type of statistical tests to be used depends on the number of variables/groups to be compared, the distribution of the data, and the outcome of consultations with the institute statisticians. We will also employ the expertise of in-house statisticians to perform meta-analysis on data from pooled experiments to reveal less pronounced effects, thereby reducing overall animal use. Conducting and recording of experimental data will follow ARRIVE guidelines.

- **Experimental repeats**. Most experiments will need to be performed on at least three occasions (N=3) to ensure reproducibility.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models of choice:

- The mouse brain, retina, and mammary gland are extremely sensitive vascular systems providing valuable information even in heterozygous animals. In the methods we are employing, their use is largely restricted to animals that have undergone substance administration (to induce changes in gene expression or microbiota composition) via minimally invasive procedures (e.g. oral gavage or injections). Routes of administration, volumes, and frequencies are designed such that they elicit no more than transient discomfort and produce no lasting harm.

- Most of the GA mice used in this project have been generated to produce tissue specific timed gene activation or inactivation in expression of genes we believe to play essential roles in angiogenesis. None are expected to produce harmful phenotypes. These types of models provide the best possible data with greatest detail of mechanistic information, with minimal invasiveness. However, where new models are being created, it is not possible to fully predict the nature or severity of any potential defect. Therefore, for all types of mice there will be careful monitoring for possible adverse effects. Animals exhibiting any unexpected harmful phenotypes will be killed, or in the case of individual animals of particular scientific interest, advice will be sought from the local Home Office Inspector.

Specific methods -

- Surgery: Recovery surgery will be done aseptically according to Home Office guidelines (Minimum Standards for Aseptic Surgery and LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery).

- Analgesia: For pain relief, peri and post operative analgesia will be given and maintained after surgery for as long as is necessary to alleviate pain. Non-stimulus evoked methods (e.g. gait analysis and grimace scales) will be used to quantify “pain-like” behaviour.

- Microorganisms: these will be administered at doses known to induce an appropriate change in microbiota composition. Where the outcome of colonisation is unknown, dosage will be carefully titrated using small-scale trial studies to minimise any adverse unknown effect.

Why can’t you use animals that are less sentient?

Mice are the lowest form of sentient species that can be used for the studies we propose where multiple systems are interacting to regulate angiogenesis within a tissue without disrupting the overall histoarchitecture of the tissue. Because mice and humans are mammals, their mechanisms of angiogenesis, and the systems that come into play, share many similarities. Moreover, because mice are commonly used by other angiogenesis and microbiota researchers, there are many useful materials that have been developed by other scientists that are available for our work.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

We have specifically generated GA mouse strains that affect the endothelial targets we are suggesting as playing essential roles in both normal and abnormal angiogenesis so that we may test our hypothesis.

We use routine and well-tested procedures for studying angiogenesis that provide the most robust data. The procedures we employ have been refined over the years to cause minimal discomfort/adverse effects to the animals. For example:

- We use anaesthetics and analgesics appropriate to each technique.
- We routinely monitor animals for health status, particularly during tumour studies and after surgical manipulation (this includes the use of gait analysis and the mouse grimace scale to assess pain -doi:10.1038/nmeth.1455)
- We try to avoid stress by training animals to cooperate with our procedures.
- The staff in our establishment provide animals with appropriate housing that allows the expression of nesting opportunities.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

As mentioned above, we will subscribe to the NC3Rs e-newsletter and regularly visit the NC3R website so that we may stay abreast of current best practice in the 3Rs. We also actively monitor the published literature in our field(s) for updated/refined techniques being used by other researchers that may be employed by us. Where possible, we will visit other labs to refine our methods. For example, we collaborate with other groups to ensure your own group's skills are kept up to date.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

- We will regularly engage with establishment technicians/staff to review current approaches and discuss whether there are any new 3Rs opportunities.
- We will subscribe to the NC3Rs e-newsletter and regularly visit the NC3R website so that we may stay abreast of current best practice in the 3Rs.
- Will will discuss 3R updates at our regular colony management meetings - this will ensure that updated 3Rs best practice is employed as soon as possible.

19. Nanomedicine platforms for pancreatic cancer therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pancreatic cancer, Drug delivery, Nanomedicine, Theranostic, Nanotechnology

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Pancreatic cancer therapies have not had a major impact on patient outcomes over the past 40 years, nanotechnology is one such platform which has shown great promise in this area. The purpose of this project licence is to evaluate various nanomedicines and nanotechnologies in order to determine whether they are safe to use, better than existing chemotherapy and ultimately whether they should progress to clinical trial.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pancreatic cancer is one of the worst cancers in the western world, currently once diagnosed patients only have a 6% chance of surviving up to 5 years. Pharmaceutical companies are not willing to invest in new technologies for pancreatic cancer therapy without a very solid in vivo case showing that they are more beneficial than whats already

available. This is because pancreatic cancer is so difficult to treat and therefore a lot of new candidates fail in trial. Unfortunately, there is still no adequate non-animal models which can be used to predict in vivo fate and so we must carry out these preliminary trials on mice.

What outputs do you think you will see at the end of this project?

The data acquired from the studies under this project licence, will provide new information as to the feasibility of the novel nanotechnology platforms being used clinically. The data will be collated, analysed and disseminated where possible (unless under intellectual property protection) through academic publication and talks at conference. In addition, dissemination will be used in lay form to engage with clinicians, patients and local support groups to inform them on the progress within the field. Specifically, the outputs will be:

Nanocarriers / drugs / formulations will be tested in order to determine their suitability for clinical use based on a series of testing methods.

It is estimated that 3-5 novel formulations will be tested and reported over the 5-year project licence duration.

Evaluation of pharmacokinetic, pharmacodynamics, safety and efficacy, and anti-cancer activity of the novel formulations identified and reported.

Level of tumour retardation compared with clinically used chemotherapy will be evaluated as the measure of success.

Who or what will benefit from these outputs, and how?

The output of this project will inform as to whether it is worth taking the nanomedicines forward to larger scale or clinical trial. This is a vital piece of information and is required to remove any formulations or iterations of the technology which are not suitable especially due to toxicity problems or adverse events which were not picked up in the in vitro studies.

Long term benefits are the healthcare providers as more effective therapies lead to less cancer recurrence and patient bed-time, so economically these could be favourable. But ultimately all the work in our group focusses on patients as an end point, and we aim to provide better therapies for patients diagnosed with pancreatic cancer.

How will you look to maximise the outputs of this work?

Science is now global with collaborations across continents easier than ever. I work with the best clinicians and researchers within this field to help drive forward the technologies we develop.

Dissemination will happen through the usual route of conference presentations and academic publications, but also in talks with clinicians, patients and support groups. My group have strong links with pancreatic cancer charities, and do a lot of public engagement activities surrounding this, including our recently funded Royal Society of Chemistry outreach grant called Quilting for Cancer, where scientists across the UK

design quilt patterns based on their research which volunteers form into quilts. These are then donated to pancreatic cancer patients who are often cold during their chemotherapy.

Such a project would include the concepts or data collected from the projects within this licence.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We have chosen the species least likely to suffer distress without compromising the likelihood of studies working. We will use special mice with a defective immune system to prevent them having a reaction against the tumour cells. This is the most commonly used species for this type of test.

Typically, what will be done to an animal used in your project?

Animals will have small volumes of cancer cells injected to allow a tumour to grow inside them. This may cause modest discomfort. The size of the tumour will be carefully monitored and animals will be humanely killed before it becomes large enough to cause distress. Drugs may be administered to the animals by injection. The process of administration of the drug is only expected to cause very mild discomfort to the animals. Additionally some animals may be anaesthetised and their tumours irradiated with a laser light, which will help initiate the therapy. The study duration is 4 weeks of treatment, with 4 weeks of monitoring after the treatment has ceased.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects of the nanomedicines themselves depend on the type of formulation we test and which drug they incorporate. Sometimes we are testing drugs that have been used before and we know what adverse effects to expect. However, many of the drugs are new and although they are designed to specifically target the cancer cells, they may have unexpected effects. This makes it hard to know what adverse effects might occur.

To minimise the adverse effects on the animals, we will first test the drug on a small number of animals to identify a dose of drug that has only moderate adverse effects. All further experiments will use lower doses, so we anticipate that the majority of animals will only experience mild severity events in some studies, we may take blood samples (again with a narrow needle) and only small volumes of blood will be collected as infrequently as possible. In some studies imaging of the animals will be carried out, the animals will be injected IP with appropriate dyes, anaesthetised and placed inside an imaging cabinet.

In some studies we will also use laser irradiation to the localised tumour site in order to initiate drug release from formulation. In this instance, the mice may develop scabbing around the area of laser irradiation.

At the end of the experiment, the animals will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate for all studies

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We wish to find new nanomedicine formulations to treat pancreatic cancer. We are testing nanomedicines which specifically target cancer cells incorporating drugs that have been used clinically as well as drugs that are completely new. We need to gather sufficient information to convince the medical and pharmaceutical world whether our formulations are likely to work in patients – it is not reasonable to give a patient who is already quite ill a new drug unless there is a reasonable likelihood that the drug will do more good than harm. To gather this information, we need to test the drugs using a method as close to real patients as possible. Although we can (and will) test the drugs in the laboratory, these types of studies are not sufficiently complex to model what happens in real patients. Animals are not a perfect model, but they are the closest model we have. Using computer simulations can help, but simulations are limited to testing things we already know about. Our formulations are completely new, or they are established drugs being used in a different way, so we don’t know what will happen. We can’t make a computer model of something we don’t know about.

Which non-animal alternatives did you consider for use in this project?

Ex vivo systems such a spheriods or tumour development through microfluidics is reported in the literature.

Why were they not suitable?

The technology is not fully developed for either to give the level of detail which is acquired using the in vivo models. Unfortunately, currently there is no suitable alternative and thus

we must use animals. We do as a group constantly scour the literature for alternatives and when a reliable alternative is available we will use this in place of in vivo trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on usage in previous licence and estimated projects under this 5 year licence

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will design our experiments to minimise the numbers of animals used.

Firstly, all the nanomedicines which are tested in animals will be tested in several different types of experiment in the laboratory to confirm they have the desired anti-cancer activity. We will also try to mimic in the laboratory the conditions in the body. If the drugs do not work in these studies, we will not test them animals. This “triage” process will minimise unnecessary testing.

Secondly, we will conduct studies in the laboratory that form a “bridge” between the laboratory studies and the animal studies. In these we will try to estimate how often the drug needs to be given to the animals. When we move to testing the drug in animals, we will first conduct experiments with a relatively small number of animals to establish the correct dose of drug and the frequency at which is administered.

Both these strategies will minimise the chance of an experiment having to be repeated because it was incorrectly designed. We will also use statistical principles to estimate the minimum numbers of animals we need to use to measure the effect of the drug.

Experimental design will be designed and reviewed in consultation with the named Biostatistician and through Dr Michael Festing’s website www.3Rs-reduction.co.uk . Pilot studies may be performed to assess experimental viability and use will be made of historical and/or published data to appropriately power the study. Prior to each experiment, a literature search will be performed to ensure that the planned work is not duplicating that performed previously by others. The result of the study will be disseminated following the ARRIVE guidelines, to ensure that all outcomes of the work.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We plan to purchase animals on an “as-needs” basis from commercial vendors. Inbred strains will be used to reduce variability. We do not plan to maintain a colony of nude mice because the frequency of experimentation would lead to surplus breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

These studies will be performed with animals of the lowest neurophysiological sensitivity possible. Immunocompromised animals are required, because the animals will usually receive a human xenograft. Nude mice are commercially available and routinely used for these studies, and will be used here. Animals will be maintained in an environment that supports their normal behaviour.

The nanomedicines will be administered by trained personnel through a narrow needle to minimise pain. The animals will also be closely monitored after they have received the formulations and if the adverse effects appear to reach moderate severity, the animals will be humanely killed. In this way, we expect very few animals to experience more than relatively modest adverse effects.

All of our studies have been reviewed to consider how to minimise costs to the animals. Animals will be maintained in an environment that supports their normal behaviour We have considered any likely adverse effects of the procedures we will use, and we will regularly monitor the animals to make sure that the animal are not distressed. We may use optical imaging to help us monitor growth of tumours. Staff will be trained to recognise signs of distress and how to deal with this situation.

Where new nanomedicines are used, the effects of new formulations may not be predictable. Therefore, a low dose, as informed by the in vitro work, will be used and the dose escalated until risk of exceeding moderate severity effects is encountered or when successful outcome is reached.

Why can’t you use animals that are less sentient?

The less sentient option would be to work on zebra fish models. However, these are not yet developed enough to provide use the information we gain from mouse models.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

To minimise suffering, procedures have been designed to evaluate the animals closely during these studies. These include regular monitoring, use of analgesia or other medication as required and euthanasia if necessary. Subsequently, the dose, route or schedule of drug administration may be altered to reduce harmful effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Dr Michael Festing's website www.3Rs-Reduction.co.uk Experimental Design system implemented by NC3Rs

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a group we are constantly assessing the literature for new pancreatic cancer models, discussing with clinicians and collaborators on their effectiveness. Additionally, we stay fully engaged with the work within the NC3Rs research council and output from their work. When a suitable alternative model is available we will switch to using it.

20. Understanding the mechanisms governing ovarian ageing and infertility

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Reproduction, Ovary, Ageing, Infertility

Animal types	Life stages
Mice	adult, embryo, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine the mechanisms governing normal ovarian ageing and how this is dysregulated in disorders resulting in infertility and premature ovarian ageing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ovarian ageing is a naturally occurring process that results in changes in the hormones produced and ultimately in the cessation of ovarian function. As well as causing infertility, ovarian ageing also increases the risk of developing several life-changing diseases, e.g., brittle bone disease, heart disease and impaired cognitive functions. This not only impacts on quality of life, but also results in a significant cost burden to the patient and Health Services. Despite this, our current understanding of how the ovary ages and what

determines the lifespan of the ovary remains limited. Surprisingly, current treatment options for declining in ovarian function are limited, with assisted reproductive technologies including IVF, the preferred treatment option for infertility, which has limited success rate with increasing age. Moreover, hormone Replacement therapy is the only treatment option for delaying of secondary associated health issues, but this can only be taken for a limited time and cannot be taken by all women. This project aims to use mouse models to understand the physiology and molecular mechanisms underpinning normal ovarian ageing and how these are modulated in disorders that result in premature ovarian ageing/infertility. This is essential to highlight novel therapies for preventing/delaying ovarian ageing, to improve quality of life.

What outputs do you think you will see at the end of this project?

On completion of this project, we will have a greater understanding of how changes in the hormones that occur with age impact ovarian function and contribute to ovarian ageing. Expected outputs will include primary research publications, dissemination of research via conference communications and through public engagement and outreach activities including talks with public and schools.

Who or what will benefit from these outputs, and how?

The primary and immediate benefit of this work will be to advance the fundamental scientific knowledge about how the ovary ages in physiological and pathophysiological conditions. We aim to publish our findings in scientific journals, with the study findings likely to be of interest to physiologists, endocrinologists, ageing biologists and cell biologists, with an interest in the mechanics of reproductive physiology.

A medium-long term potential secondary benefit relates to possible clinical application of our findings to infertility and ovarian ageing in humans. Understanding the changes that occur to the ovary as it ages may highlight novel treatment avenues for infertility, and for potential treatment of the secondary health problems associated with menopause.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work, the work will be disseminated via conference presentations and publication of the study findings to the wider scientific community. We have collaborations with researchers from other institutions, both nationally and internationally, in fields outside of ovarian ageing, which will ensure that this work reaches other fields as well as our own. If the findings of this study are of therapeutic potential, collaborations with industry will be sought to explore translational potential.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

Rodents (mice) are the lowest vertebrate group which will allow reliable reproductive physiology studies, in which the reproduction control systems have been well characterised. They are excellent for monitoring ovarian function via oestrous staging and superovulation techniques (hormonal stimulation of the ovaries to produce more than the normal amount of eggs).

Since we are examining the changes in ovarian function across lifespan, neonatal and juvenile, adults and aged animals are required. As the ovarian architecture is completed early in postnatal life, studying of neonatal ovarian composition is required.

Typically, what will be done to an animal used in your project?

Typically, genetically modified animals will be bred, genotyping will be conducted using tissue biopsy collection. Females may be staged for oestrous cycle and mice killed at key time points during their reproductive lifespan, using Schedule 1 methods, or exsanguination with killing confirmed via Schedule 1 methods.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect minimal impact and adverse effects to the animals during the project.

There is a low risk (<1%) of blood clots or leakage of fluid from blood vessels following intravenous injection or perforation of an internal organ following intraperitoneal injection. Any animals displaying signs of adverse effects (as judged from food and water intake, body weight, general and coat appearance, gait or behaviour) will be humanely killed by a Schedule 1 method. Animals will be monitored daily for complications and advice sought from the NACWO/NVS.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severities are mild for all regulated procedures.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This programme of study will use in vitro and ex vivo techniques and animal procedures. The in vitro and ex vivo work will examine biological activity in selected cell lines and tissue to elucidate signal transduction pathways and gene expression using molecular biological techniques. However, animal work is essential to understand as ovarian function is regulated by integrated physiological and endocrine systems, making it impossible to study infertility and ovarian ageing in cultured cells alone.

Which non-animal alternatives did you consider for use in this project?

Non-animals alternatives considered were ovarian cell lines.

Why were they not suitable?

Ovarian cell lines often lack key receptors and the ability to produce hormones that are essential ovarian factors. Ovarian cell lines are currently very limited and do not provide the ability to assess aspects of communication between the germ cells (oocytes) and the surrounding somatic cell tissue. Moreover, assessment of infertility and ageing is difficult in a cell-line based experimental set-up. Thus, the use both primary ovarian tissue and assessment of whole animal physiology is required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have drawn upon our own experience and published studies to ensure we use the minimum number of animals required. We will use statistical power analysis where appropriate before beginning experiments to ensure that we only use the minimum number of animals required to produce valid statistical comparisons between the groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The design of individual experiments will generally involve factorial designs, to maximise the information gathered using the minimum number of animals. Most measures taken will be quantitative, in which case sample sizes will be set using a power analysis, using a significance level of 5% and a power level of 80%. This will generally result in group sizes of ~8 per treatment group. For design of complex experiments, advice of a statistician will be sought.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of factorial designs will maximise the information gathered using the minimum number of animals per experiment. We will also use data generated from in vitro cell lines to inform and reduce the number of animals used in future experiments. We will utilise full post-mortem tissue profiling to maximise the utilisation of tissue, and ensure a small number of animals are made use of as much as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents (including mice) are the lowest vertebrate group which will allow reliable reproductive physiology, in which the reproduction control systems have been well characterised and elucidated. They are excellent for monitoring the ovarian function and fertility. Moreover, mice are most commonly used for genetic manipulation/alteration, making these an ideal model for studying genetic modifications that result in infertility and premature ovarian ageing.

Why can’t you use animals that are less sentient?

Rodents are the lowest vertebrate group which have been highly characterised and extensively used for studying reproductive physiology. This project will heavily utilise 3D ovarian organoid cultures to study aspects of ovarian ageing and infertility. However, assessment of ovarian function, cyclicity and fertility can not be achieved in vitro, nor using less sentient animals.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Animals will be monitored throughout all experiments to minimise pain or discomfort. Any animals deemed to be suffering will be euthanised using a Schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs) guidelines, and ensure we keep up to date on current and new practices in the scientific literature to ensure our experiments are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed on new advances in the 3Rs through the NC3Rs newsletter and through regularly checking the 3Rs website.

21. Models of tissue injury, regenerative repair, and reconstruction in the limb and appendages

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Injury, Wound healing, cell therapy, biomaterials, tissue engineering

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to study how animals that have an enhanced healing ability, respond to injury to their limbs, digits and ears. This will allow us to understand how these tissues regenerate, and where possible capture these mechanisms to use in regenerative biomaterials to repair wounds and create new tissue.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

If we can understand how certain mammals are able to regenerate and heal better, and understand how new tissue is formed, after injuries to their limbs, we can improve on our

interventions such as surgery, and treatments to restore form and function after trauma, disease, or cancer excision. As surgeons, we see these demands on the NHS, and perform repairs and reconstructions on a day to day basis.

Improved healing or engineered tissues that are biocompatible, to replace missing tissues would represents a major shift in surgical care.

What outputs do you think you will see at the end of this project?

The hope of this project is to understand how tissues can be regenerated or replaced to develop new therapies towards the clinic. This may be by development of a new biomaterial therapy or engineered Replacement tissues for patients. We would seek to publish these innovations throughout the course of this project, like we have done in the past. There is much learning to be had from this work and as we have found in the past, when new discoveries are made, we can use the information to modify surgeries, generate high impact publications, use the data to apply for further grant funding, and develop new therapies and patents.

Who or what will benefit from these outputs, and how?

Patients who sustain traumatic injury or organ damage will be the beneficiaries of these outputs in the long term. All parts of the study are designed to have line of sight to patient benefit through our clinical group. This includes rapid translation of the science to change surgical practice (which we have previously demonstrated), but also development of new novel therapies, such as biomaterial and cellular therapies. Our work on engineering blood vessel networks, has the potential to allow for new tissue and possibly Replacement organs to be engineered that would have a significant impact on people’s lives, with conditions or injuries requiring tissue Replacement therapies. We would aim to have successful clinical impact within 10 years.

How will you look to maximise the outputs of this work?

All projects are collaborations between scientists and clinicians, from the biomaterial, cell biology and translational science field. Knowledge will be disseminated through publication and international presentation at both clinical and scientific conferences. Positive results towards clinical benefit will be subject to further grant funding and opportunities to translate wherever possible, this may be in tandem with industry partners.

Species and numbers of animals expected to be used

- Mice: 3500
- Rats: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Mice and rats are being used in the adult stage of their life stage. The justification is based on the fact that these are the lowest sentient mammals, that have anatomical structure and biological processes that are similar to man. Hence the study of injury and repair on these animals provides us with invaluable insight on how they can better heal. Our surgery and anaesthesia can be safely performed on animals of this age and size.

Typically, what will be done to an animal used in your project?

Our study will broadly cover three areas of wound healing interest.

How do animals that regenerate, heal wounds of the digit and ear?

Can we produce regenerative therapies from our understanding of this process?

Can we engineer vascularised tissue/organs that are stable and functional?

We will be breeding animals that have specific genetic changes that will allow us to examine particular areas of wound healing that may allow us to understand how to improve on the healing process. This would require animals that heal better or heal worse, or have genetic characteristics that enable us to understand and visualise the healing process better.

Testing of these animals to have the correct genes will occasionally require us to take a small blood sample from the tail or a small sample from the ear which may cause transient pain.

Some animals will undergo chemotherapy to clear their bone marrow and allow for bone marrow to be transplanted which will allow us label cells in their bone marrow or change the characteristics of their bone marrow cells which may alter how they heal. This would allow us to examine the importance of bone marrow in the healing process. The bone marrow in these animals is always restored to bring the animals back to health.

Within each study, animals will be subject to injuries that are simplified versions of injuries seen in the clinical setting, and then observed for how they heal. This will involve either a cut across a finger or ear where there is no loss of tissue, or excision of tissue across the finger or ear, where there is loss of tissue. Injuries will be studied in animals that can regenerate, and by understanding how they heal better, we will try to harness the biology and apply them to biomaterials as a potential therapy. These injuries are small (several millimetres) and cause minimal pain, distress, and disturbance to the animals. As such these small injuries can be performed on the left and right paws or left and right ears without much disturbance, hence allowing for comparisons of how treatments work without using more animals and without more suffering.

In addition, we will be using our understanding of healing to generate new tissue. This will involve combining surgery, biomaterials, and cell therapies to enhance tissue growth and development into Replacement tissue that may be used to transplant to other animals as a Replacement for damaged tissues.

These experiments will be conducted to observe the full healing process, which is typically 3 months, and the number of procedures will be kept to the minimum required for us to obtain a meaningful understanding of the biology (usually 1 but up to a maximum of 2 per animal). The information collected has to be of sufficient quality so that we can reliably develop therapies for patients

What are the expected impacts and/or adverse effects for the animals during your project?

We aim to use only animals that are healthy in our study but in generating animals used for tracing of particular cells of the bone marrow, this necessitates chemotherapy and bone marrow transplantation. This makes animals susceptible to infection and we try to reduce the chances of this by acidified water, antibiotics and clean caging.

For these studies we will be performing very simple injuries on the digits or ears. These simple injuries can cause pain, bleeding and impact on mobility, but all of this is transient and allow for quick recovery. Having developed these procedures, it is rare to see anything more than transient discomfort in the animals or abnormal behaviour.

In some animals we will be implanting biomaterials that may have a biological effect. They are all tested to be biocompatible and should allow for better healing. However, they may rarely cause tissue reactions that are usually transient. We will provide pain relief to limit the symptoms from this. We also have vascular tissue engineering model that hopes to grow new tissue and organs. Rarely the cells may grow into benign tumours. If this occurs and limits the function of the animals, the experiments will cease.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90% of the mice bred on the licence will be expected to experience sub threshold harms with 10% possibly experiencing mild harms for differences in their genetic make up.

100% of mice undergoing bone marrow transplantation will be expected to experience no more than moderate harms.

100% of mice undergoing surgical procedures which include; 1. injury and repair, or 2. Vascular tissue engineering or 3. Vascular tissue transplantation will be expected to experience no more than moderate harms

100% of rats undergoing surgical procedures which include; 1. injury and repair, or 2. Vascular tissue engineering or 3. Vascular tissue transplantation will be expected to experience no more than moderate harms

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

After tissue injury there are changes in blood flow, inflammation, the formation of blood vessels and tissue remodelling, including interactions between numerous cell and tissue types. No in vitro cell culture can study these interactions in concert.

Which non-animal alternatives did you consider for use in this project?

We have tried to mathematically model these changes to replace the use of experimental animals and are exploring ex vivo models using whole limb perfusion, and organs on a chip technology that will run in parallel to these studies. If specific questions can be answered and validated on these systems the use of animals can be reduced and replaced.

Why were they not suitable?

Mathematical models are not able to model the complex interactions of systemic inflammation in a spatial temporal fashion. The information acquired in vitro and in silico is insufficient to allow progression to trial in human patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any.

These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the numbers of animals used based on our current throughput of animal experiments, what is technically feasible to perform, and the planned scientific questions we are planning to answer over the next 5 years. We have considerable experience in planning the right numbers of animals for the research questions in order to maximise use, and minimise waste. This is also considered in the context of our current group make up and the projects which are funded. The minimal number of animals are used to allow us to answer the posed scientific question.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are constantly evaluating ways to obtain the most information from the smallest number of animals, and this includes using more sensitive methods of quantification, using numerous modalities of analysis on one sample and ensuring the experiments are well-

designed to minimise animal waste. All animal procedures are only conducted once protocols have been discussed with in-house animal facility expertise, including the vet, and signed off. This is supported by pilot experiments to ensure feasibility prior to embarking on bigger studies. We are always looking for other models that can potentially provide us with the same information that does not harm animals including experiments that can gain the data direct from patients. Animal experiments are only considered when the information cannot be obtained from other publications or the clinical setting.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always conduct experiments with the necessary pilot studies so we are in the optimal condition to proceed with larger numbers of animals. We are now also taking more of a systems biology, and non- destructive sample approach to allow us to generate far more information from each animal than previously possible. This is done with comparison to known datasets and in silico models which reduces animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have developed the simplest injury and repair models that create the least disturbance and suffering on the animal which still provides us with useful information to take back into the clinic

Where abnormal behaviour is observed, this usually indicates that the animal is suffering and as such we limit any further involvement of the animals in the experiments. We will monitor for any suffering and where necessary intervene with pain relief, water and food. If this is insufficient, the use of animals in study will end and they will be humanely killed.

We will use models developed in the mouse and rat which are the lowest sentient animals for the purposes of mammalian study. Mice are used for their genetic tractability that allow us to examine the role of inflammation after injury, and rats are used because some regenerative biomaterials cannot be fabricated to a small enough size and resolution to be used in the mouse. The engineering of vascular tissues in the mouse is unique to our group and will be used in our studies to engineer tissue for Replacement tissues and organs.

Why can’t you use animals that are less sentient?

Mice and rats are the least sentient animals that have relevant mammalian biology and also, they have anatomical structures that are similar in composition and configuration to man. As we are interested in how the body heals after injury, it is important that we study how these animals recover as you would expect humans to do the same.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All injury models are developed with clinical scenarios in mind and each surgical procedure has been refined to its simplest form.

All surgeries are designed to be quick, precise, and optimise workflow in theatres. Sterile equipment is used throughout. Complications are carefully monitored for and are fortunately rare. We continue to ensure all procedures lie well within the moderate severity range. The experimental models outlined are well validated, reproducible and consistent injuries, with the minimum amount of pain, suffering, distress and lasting harm. We have many years of experience in refining our techniques and all team members have skill sets attained through extensive training and/or clinical experience. For precision all procedures are performed under high magnification.

In addition to our surgical models, our use of bone marrow transplant models have undergone Refinement by moving away from harsh radiotherapy based bone marrow depletion, to using chemotherapy based depletion which results in far more reliable and less harmful bone marrow depletion. We monitor these animals carefully and provide acidified water, irradiated diet and prophylactic antibiotics to minimise chances of infection.

Suffering is minimised through careful monitoring and by use of analgesia, and good husbandry. We have reduced variability in the surgeries over the years that allows us to obtain meaningful, reproducible results that will continue to be refined. We also ensure careful training of all our staff to be mindful and skilful at surgical procedures and animal care.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We use guidance from PREPARE and ARRIVE to ensure the standards of our animal experimentation and reporting allow for the quality, reproducibility and translatability.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly receive updates from our establishment about new and novel surrogates to animal experimentation. We regularly keep up to date with published activity and calls form the NC3RS and have applied for previous awards. In addition, we actively are trying to develop our own systems that do not use living animals, such as ex vivo perfusion and organs on a chip technology, or perform investigations whenever possible on patients themselves, and perform scientific outcome measures on tissue from patients via our biobank.

22. The development of rodent cancer models and their pre-clinical use as a platform for drug development and drug evaluation.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Anti-tumour

Animal types	Life stages
Mice	adult
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project licence is to identify potential drugs / therapies that reduce, inhibit or prevent the growth of tumours leading to new and improved cancer treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

The benefit of this project will ultimately be the introduction of new and improved

treatments for the management of cancer.

There were 9.6 million deaths from cancer worldwide in 2018. Lung, liver, stomach, and bowel are the most common causes of cancer death worldwide, accounting for more than four in ten of all cancer deaths. Lung, liver, stomach and bowel cancers have been the four most common causes of cancer death since 1975.

Based on our past record we would expect to deliver 10-15 potential new drugs into clinical development during the period of this licence. Whilst not all of these will be successful, as we move to more novel and sophisticated approaches to cancer management, it seems reasonable to predict that approximately 20% of the nominated compounds will reach people living with cancer and provide significant benefit to cancer sufferers. Since most of our approaches here are applicable across a broad range of tumour types it is likely that these could have wide utility. These may not completely cure cancer patients but it is expected that they will enable a significant number to live longer with improved quality of life following the diagnosis of this devastating disease.

What outputs do you think you will see at the end of this project?

The benefit of this project will ultimately be the introduction of new and improved treatments for the management of cancer.

We will share pre-clinical animal data with principal investigators to influence clinical trial designs. Publication of both successful and unsuccessful data in high impact journals, with the aim to publish approximately 15 scientific papers in high impact journals each year.

Who or what will benefit from these outputs, and how?

Since our approaches are applicable across a broad range of tumour types it is hoped that the drugs developed from this project licence will have wide utility across different cancer patient populations. These may not completely cure cancer patients but it expected that they will enable a significant number to live longer with improved quality of life following the diagnosis of this devastating disease.

How will you look to maximise the outputs of this work?

New information will be disseminated at key national and international conferences via poster sessions and seminars. Publication of both successful and unsuccessful data in

relevant journals. We will share pre-clinical animal data with principal investigators to influence clinical trial designs. We work in collaboration with many scientists and groups in which we are able to share data and learning meaning that important data generated from our animal studies can be shared more widely to avoid others repeating work and to help influence other areas of animal use.

We will share good practice with AWERB and also internal in vivo community groups.

Species and numbers of animals expected to be used

- Mice: 100000
- Rats: 10500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

We use animal studies in mice and rats alongside many other experimental approaches and they are crucial in building up a complete picture of cancer biology. Our research using animals has helped drive advances in cancer treatment that are benefiting people with cancer all over the world today.

Our work mainly uses mice (90%), which can grow tumours which mimic those of human cancer patients. Studies of cancer in mice mimic the complex way tumours grow and spread in people with cancer. The majority of our work involves implanting a tumour on the side of the animal. Although this is unlike the patient situation the use of these models over the years has demonstrated utility in selecting viable drug candidates.

Mice can be easily genetically altered to allow us to study the genetic causes of cancer and reproduce tumour types which naturally occur in humans in the correct tissues and body systems.

We also conduct some studies in rats (10%). Some compounds that we need to test may not have sufficient levels in the blood to have an effect on the tumour in the mouse and therefore we need to use the rat as an alternative species. The rat is also usually the species of choice for toxicity studies. These studies would be conducted under a different project licence but it may be necessary to directly compare the dose level of a drug that causes an effect on the tumour to the dose level that produces unwanted side effects. This is to ensure that there is a big enough margin between activity and safety in order to progress to the clinic.

In some instances cancer growth can be influenced by hormones, these are classed as hormone- sensitive tumours. It may be necessary to run some experiments in rats that do not have high levels of circulating hormones and in these instances rats that have not yet become sexually mature will be used. These are classed as juvenile rats.

Earlier Life stages of vertebrates such as zebrafish is an option, and early studies of human xenograft models do show promise of tumour inhibition studies . However the small size and difficulty of collecting meaningful blood samples makes pharmacokinetics essential in our work, currently impossible in that model, meaning that rodent models remain the most effective model at present.

Typically, what will be done to an animal used in your project?

The rats and mice we use are bred at specialised facilities and are then transported to our facility. We primarily use breeding facilities within the UK but on very rare occasions specialised strains may be required to be imported from within the EU or USA. Animals will be transported in safe enclosed boxes that contain bedding, food, water and are maintained throughout the journey within temperature and humidity levels appropriate for the species. Upon arrival to our facility the mice or rats are transferred into clean cages. In our facility these cages are Individually Ventilated (IVC) and each cage has its own clean air, food and water supply. In addition bedding and nesting material and numerous forms of enrichment are included. Enrichment provided such as paper houses, tunnel and chew sticks allow the rats and mice to have improved welfare and demonstrate natural behaviours such as sheltering, nesting, climbing and gnawing. The cages are maintained at the appropriate temperature and humidity for the species. Cages are cleaned at least once a week and water and food is checked daily. Animals are left to get used to their new home surroundings for at least 7 days before any experimental procedures are performed.

Mice and rats are typically housed in small groups as they are social animals. On occasions animals may be singly housed e.g. on occasions male mice naturally fight with each other so may be housed singly for welfare reasons.

In a typical study animals are injected with tumour cells under the skin which grow into tumours. A wide variety of tumour types may be used within this licence. Our work is not focused on one area of cancer but across all cancer types with focus on lung, prostate, breast, ovarian, pancreatic and bladder. The majority of studies use cells that are derived from human tumours. As the human tumour tissue is foreign to the animal, the animals immune system would reject the tumour tissue and therefore we need to grow human tumours in either mice or rats that have an impaired immune system. This allows the tumour tissue to grow and not be rejected.

Tumours are usually injected as cells using a needle, this is done on the lower left or right side of the back (flank) of the animal. In some cases the tumour is not available as cells and therefore a very small piece of tumour tissue needs to be put into this area surgically. The mice or rats would be anaesthetised as this requires a very small cut in the skin so the tumour tissue can be placed under the skin. The cut is then closed using either stitches, special glue or clips. Having tumour cells injected or surgically placedunder the skin allows the grown tumour to be easily monitored and measured and does not affect the animals ability to move around.

All tumour studies will be run in a small number of animals to determine the growth characteristics of the tumour before proceeding into larger studies looking at the effect of potential anti-cancer drugs. In these small pilot studies the animals are closely observed

every day and body weights and condition of the animals are recorded to ensure that the animals are healthy. The tumour is measured at least once a week and the condition of the tumour is observed daily. If the tumour grows in a consistent manner this can then be used in subsequent studies to determine the effect of potential anti-cancer drugs.

In these studies once the tumour has started to grow the animals will start to receive doses of a potential anti-cancer drug. Anti-cancer drugs are usually dosed orally via the mouth and the animal may typically receive up to two doses per day for 28 days. The animals are closely observed every day and body weights and condition of the animals are recorded to ensure that the animals are not unwell. The effect of the potential anti-cancer treatment on the tumour growth is compared to the tumour growth in an animal which does not receive the potential anti-cancer drug. The hypothesis is that the anti-cancer drug will significantly reduce the growth of the tumour.

During the study blood samples may be taken from a vein. The blood sample is analysed to measure the level of the potential anticancer drug in the blood.

At the end of the study the animal is killed and the tumour tissue and other tissues may be taken which can then be used for further investigation.

What are the expected impacts and/or adverse effects for the animals during your project?

The tumour is continually monitored and measured and although the tumour may continue to grow this does not appear to cause the animal any pain or discomfort and they continue to behave normally. The size the tumour can grow is limited by the use of a measurement/condition/size scoring system to ensure that it does not cause any pain or discomfort to the animal.

The dosing procedure for dosing of the anti-cancer drugs does not usually cause any issues but the drug itself may have some side effects. Side effects may include weight loss or abnormal behaviours such as being less active or not socialising or interacting with their cage mates. Strict criteria are put in place to minimise any unwanted side effects to minimise any pain, suffering or distress to the animals. The side effects usually only last for a short period of time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 90% of animals used within the licence will be mice and 10% rats. It is expected that 90% of both the mice and rats will be returned within the moderate category and approximately 10% within the mild category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed in our research to help us understand the mechanisms that underpin cancer, such as the growth and spread of tumours, and to develop new ways of diagnosing, treating and preventing the disease. Cancer is a very complex disease and animal studies are essential to understand these complexities within living organisms. They are also required by regulatory authorities before any trials of new drugs can be tested in humans. Animal studies are only performed after every feasible test has been conducted on cancer cells in the laboratory and where no alternative exists.

Which non-animal alternatives did you consider for use in this project?

Multi-cellular 'organ on a chip' models are available, but as yet have not reached the reliability and integrated multi-system complexity of the rodent model, especially when shaping the treatment of patients in the clinic. There are no immune-competent in vitro models with functionality comparable to the rodent models. Non-animal alternatives are used in the identification and selection of compounds. These generally include measurements of the drug's activity on particular target cells. Activity in particular cell types however cannot predict the activity in humans due to a complexity of issues such as availability of the drug in the body and whether it is able to reach the target cancer cell.

Why were they not suitable?

Available alternatives are not currently as good as the existing rodent models and are not as suitable because they cannot mimic the living organism and the processes that underpin cancer in a living organism.

Reduction

Explain how the numbers of animals for this project were determined.
Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

This licence reflects a well established cancer research program and the numbers of animals used within this project licence are based on the diverse areas of cancer that are being investigated.

We typically run approximately 20 studies per month, each study usually has ~100 animals per study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All studies are designed to ensure that the minimal numbers of animals are used to achieve the question being asked. This is done with help and guidance from a statistician who is a maths expert who uses huge amounts of data to figure out how likely it is that something will happen or not. They ensure that all studies are designed to ensure that we are able to use the minimal numbers of animals to see an effect of a potential anti-cancer drug if there is an effect.

Good experimental design principles such as randomisation are incorporated into all experiments. All study designs are approved by a statistician.

All experiments are performed in accordance with Good Laboratory Standards (GLS). This standard sets the minimum laboratory requirements for all our research and development. This ensures that procedures and results are accurate, reliable, traceable and reproducible and where appropriate, comply with the appropriate regulatory authorities' legislation.

All experiments are performed in accordance with the PREPARE guidelines - Planning Research and Experimental Procedures on Animals: Recommendations for Excellence.

All research that will be published will be published in accordance with the ARRIVE guidelines - Animal Research: Reporting of In Vivo Experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When different project groups want to investigate the effect of their compounds in the same tumour model wherever possible we run these within one study that share the same control group therefore reducing the requirement for multiple control groups if the studies were run independently, leading to an overall Reduction in numbers.

To minimise any side effects associated with treatment of potential drugs, a small pilot study in typically 2- 3 animals is performed to ensure the treatment does not have any unwanted side effects before progressing into larger numbers of animals.

Wherever possible multiple tumour and/or tissue samples will be taken from the same animals and may be frozen down and used in other non-animal experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a wide variety of different tumour models in both mice (90%) and rats (10%). The majority of the tumours are implanted as cells in an area on the animal (the lower left or right side of the back (flank)) which allows the tumour to be easily monitored and measured and does not affect the animals ability to move around. The size the tumour can grow is limited to ensure that they do cause any pain or discomfort to the animal.

In some instances (<10%) it may be required to grow a tumour in the organ where the tumour was originally derived from, for example a breast tumour implanted into the breast tissue. The tumour may be monitored using imaging which can monitor the tumour growth.

The dosing procedure for dosing of the anti-cancer drugs does not usually cause any issues but the drug itself may have some side effects. Side effects may include weight loss or abnormal behaviours such as being less active or not socialising or interacting with their cage mates. The drugs are tested in a very small number of animals initially (typically 2 to 3 per group) and only drugs that do not have unwanted side effects can be used in larger numbers of animals.

It may be necessary to surgically neuter animals to reduce levels of hormones as the growth of some tumour models may be influenced by hormone levels (hormone-sensitive tumours). Any animals that undergo a surgical procedure will be provided with pain medication prior to the surgery (and after surgery where required) and maintained in a warm environment until full recovery to minimise weight loss. Pain medication may be administered after surgery within an edible jelly. The mice and rats will have access to a non-medicated form of the jelly prior to surgery to become accustomed to eating it.

All animals will be housed in specialised cages. These cages are Individually Ventilated Cages (IVC's) which filter the air and fully protects the animals from all micro-organisms. All food, water and bedding is also fully sterilised beforehand. All cages have various forms of enrichment included, for example a cardboard house, sizzle nest, tunnels, chew stick. The temperature and humidity is kept within a specified range that is optimal for the animals.

Why can’t you use animals that are less sentient?

Using less sentient animals for example a non-mammalian species such as the fruit fly, is not possible since they lack a closed circulatory system and so you cannot replicate a number of the complex processes that underpin cancer such as the growth and spread of cancer.

Juvenile life stages of vertebrates such as zebrafish is an option, and early studies of human xenografts into zebrafish models do show promise of tumour inhibition studies (Xaio et al 2020). These models rely on protected life stages of zebrafish, and may need larger numbers, although moving to a vertebrate considered less sentient than a rodent may be a significant Refinement in future (Costa et al., 2020). However the small size and difficulty of collecting meaningful blood samples makes the pharmacokinetics essential in our work, currently impossible in that model, meaning that rodent models remain the most effective model at present. Others have investigated embryo larval life stages of zebrafish that would be unprotected within the EU (since they work before the day 5 threshold of

protection) with some success, but reliable quantification and exposure through internal concentration remains the barrier in this case as well (Hill et al., 2018).

Costa et al 2020 EBioMedicine (The Lancet) https://www.sciencedirect.com/science/article/pii/S2352396419307881 Developments in zebrafish avatars as radiotherapy sensitivity reporters — towards personalized medicine.

Hill et al. 2018 F1000Res https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6234738/

Xaio et al. 2020 Trends in Cancer (Online 17th April) https://www.sciencedirect.com/science/article/abs/pii/S2405803320301217

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be acclimatised for 7 days from arrival before they undergo any experimental procedure.

We closely follow and implement the latest welfare guidelines and therefore handle animals in a way that causes the least amount of harm or stress to them as possible while conducting these experiments.

All surgery is performed in concordance with 2017 LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.

Explore if there are options to apply any palliative treatments to minimise any adverse effects of dosing. Explore use of refined dosing applications in collaboration with the NVS, for example use of pin-port.

We use a new needle for every individual animal injected parenterally. The same applies for when we implant cells.

Use of banked animal tumour and/or normal tissue samples taken from previous studies which can be used in non-animal experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines for the welfare and use of animals in cancer research (Workman, P., Aboagye, E., Balkwill, F. et al. Br J Cancer 102, 1555–1577 (2010))

Animal research: Reporting in vivo experiments: The ARRIVE guidelines. Br J Pharmacol. 2010 Aug; 160(7): 1577–1579.

Percie du Sert N, Hurst V, Ahluwalia A, Alam S, Avey MT, Baker M, et al. (2020) The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research. PLoS Biol 18(7): e3000410. https://doi.org/10.1371/journal.pbio.3000410

PREPARE: guidelines for planning animal research and testing (Adrian J Smith, R Eddie Clutton, Elliot Lilley et al. Laboratory Animals Volume: 52 issue: 2, page(s): 135-141

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I actively participate in the in vivo community, attending and presenting at conferences relevant for oncology preclinical models. I also follow the NC3R's website to keep myself updated on relevant 3R's initiatives (https://www.nc3rs.org.uk/news/using-award-scheme-promote-3rs-innovation). We also actively discuss and implement new 3R's initiatives and run a yearly 3R's competition, sharing information globally across different establishments. We actively set annual Refinement goals, for example alternative mouse handling.

23. Central circuits underlying visceral and somatic sensations

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Somatic pain, Visceral pain, Chronic pain, Neuropathic pain, Spinal cord

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a Retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify distinct nerve cell circuits in the spinal cord that are involved in processing sensory information from the skin, joints, and internal body organs under normal conditions, and to determine how the properties of these circuits change in long-term pain states.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Our bodies have evolved complex circuits of interconnected nerve cells (neurons) to relay information from our skin, muscles, joints, and internal body organs up to the brain for perception of various sensations including touch, temperature, and pain. The information that gives rise to these sensations is relayed to the brain along distinct sense-specific pathways that pass through the spinal cord. In the spinal cord, dedicated collections of neurons form functionally specific circuits that play a crucial role in helping our central

nervous system (CNS) make sense of the barrage of sensory information it receives. For each type of sensation, dedicated neuronal circuits act to prioritise which signals are sent to the brain for perception. These circuits also play important roles in refining the sensory information being processed by our CNS, helping ensure that we mount responses that are contextually relevant. Understanding the cellular make-up of these complex and highly variable neuronal circuits presents a major scientific challenge in our efforts to understand how we respond to our environment under normal conditions. This challenge is compounded when we try to understand how these systems change in diseased conditions that lead to altered sensory perception and chronic pain states.

Chronic pain affects approximately 20% of the global population and is often resistant to any form of treatment. This debilitating condition can lead to patients experiencing heightened levels of pain perception, spontaneous pain, or the perception of pain from stimuli that were previously innocuous (e.g. light touch or brushing of the skin now being perceived as painful). Since changes in the activity of certain nerve cells in the spinal cord is known to play a key role in the development of these chronic pain states, it is vital that we identify precisely which circuits (and which cellular components in particular) change in diseases conditions so we can then develop targeted approaches for the development of more effective pain management strategies. To do this, we must first study how these distinct circuits function under normal conditions and then determine whether (and if so, how) each neuronal component within these circuits change in the various chronic pain states. We have previously identified two distinct sub-populations of dorsal horn neurons and shown that each contribute to different aspects of chronic pain: the loss of normal function of a population of inhibitory interneurons leads to heightened touch-evoked pain, whereas abnormal recruitment of a population of excitatory interneurons leads to increased pain perception. To help develop more effective treatments for a variety of chronic pain states, we now aim to identify other neuronal populations that also contribute to these pathological conditions, determine how/whether their contributions to the circuits they are part of change, and devise ways of restoring their normal function.

In this project, we aim to determine how distinct populations of nerve cells contribute to processing sensory information under normal conditions and establish whether these change in chronic pain states. To achieve this, we will use a series of transgenic mouse lines that allow us to target and manipulate the function of several distinct neuronal populations with precision. Some of these lines will generate mice in which intrinsic fluorescent proteins will be expressed exclusively in our targeted population(s), helping us identify these cells for electrophysiological recording experiments and histological analysis. Other lines will generate animals where specific light- or drug-sensitive channels are expressed selectively in our cells of interest, providing us a means of manipulating the function of these neurons with precision, and in doing so helping us to establish their respective roles in different behaviours. We will then use experimental models of different chronic pain states induced by either surgical procedures or following direct manipulation of our target neuronal populations to determine whether (and if so, how) the functional properties of these cells change. By targeting and manipulating cell populations selectively and with precision, we can determine their respective contributions to both normal and pathological pain processes. It is only possible to conduct these experiments in animal

models, but the findings of these studies will identify novel targets for alleviating chronic pain states in pateints.

What outputs do you think you will see at the end of this project?

Chronic pain is a debilitating condition that is often resistant to treatment. The need to develop more effective treatments to address this unmet clinical problem is evident, but one of the major challenges we face in addressing this problem is our limited understanding of the neuronal processes involved in perceiving pain sensations.

The principal aim of this project is to identify distinct populations of nerve cells in the spinal cord that are involved in how we perceive pain. By identifying these cells, and understanding how they contribute to sensory perception in normal and chronic states, the results of these studies will be important in helping develop new, more specific targets for interventions to alleviate a variety of pain conditions.

The results of these studies will be published in international peer-reviewed journals and presented as talks or conference presentations at academic gatherings and to pharmaceutical companies. Our findings will help other pain researchers and pharmaceutical companies identify novel targets for the development of new pain management therapies and analgesics.

Who or what will benefit from these outputs, and how?

The findings of these studies will be of direct benefit to other scientists working on the somatosensory and visceral systems, as well as those in the pharmaceutical industry, particularly in relation to development of new analgesic drugs.

The ultimate beneficiaries of this collective effort to devise more effective pain management approaches will include human patients and animals suffering from chronic pain, and the clinicians responsible for their treatment. Chronic pain affects approximately 20% of the global population, however, one-in-three patients remain resistant to any form of treatment currently available. The personal impact of chronic pain is widespread and significant: 65% of these patients reporting difficulty in sleeping, 49% develop depression and 16% claim "the pain is so bad that they want to die".

Approximately one-in-five chronic pain patients consider suicide, and between 5 and 14% of these patients attempt to take their own life. The need for more effective pain management therapies is clear, and the work outlined in this project will contribute significantly to addressing this clinical need.

How will you look to maximise the outputs of this work?

The findings of these studies will be published in peer-reviewed journals and presented as talks or conference presentations around the world at academic gatherings and to pharmaceutical companies. The dissemination of this information will allow me to bolster existing international collaborations, as well as help develop new partnerships with both academics and pharmaceutical companies. This information will also be disseminated to the general public through both patient and public involvement and engagement (PPIE)

Events, as well as outreach projects. The development of more effective pain management strategies will have a significant impact on improving the health and well-being of chronic pain patients, and consequently that of their families. Improved treatments for chronic pain will also be of considerable economic benefit to society due to the Reduction in time lost from work.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

The aim of this project is to determine the roles of different nerve cell populations in processing sensory information from the skin, joints or internal organs. Because of the need to match detailed information about both the anatomy and the physiology of targeted neuronal populations with assessment of behavioural responses to manipulation of these same cells, work of this type can only be performed in experimental animals. The mouse is the only species that could be used in this project because of the availability of genetically altered lines in which fluorescent proteins or recombinases are present in specific neuronal populations. These transgenic mice allow us to manipulate the activity discrete components of highly complex sensory pathways using experimental approaches. By manipulating these neuronal targets specifically under experimental conditions, we can determine the role they play in the development of chronic pain states. In some cases, we will administer transgene inducing agents (e.g. tamoxifen) to neonates or pregnant females. This is necessary as it provides the only means of capturing the expression of markers that may only be expressed at early stages of embryonic development. Most experiments will be conducted in juvenile/young adult mice given that the neuronal circuits in the central nervous system are fully established by these stages. This provides us with a means of comparing functionally distinct circuits in naïve and chronic pain states which will help identify how these change in pathological conditions. These changes are likely to underlie the development of the resultant pain states and will provide novel targets for the development of new pain management therapies.

Typically, what will be done to an animal used in your project?

Transgenic mice will be bred under this project for use in studies to further our understanding of how sensory information derived from the skin, joints, and internal organs is perceived under normal and pathological conditions. In this project we will target discrete neuronal populations using molecular-genetic and surgical approaches to establish their role in processing sensory information.

This project employs four protocols that will allow us to address our scientific questions:

Protocol 1; Breeding and Maintenance: This allows us to generate appropriate transgenic mouse lines for use in all subsequent experiments. Animals used in this protocol will typically be young, sexually mature mice less than one year in age.

Protocol 2; Neuronal Tracing: This provides a means of labelling specific neuronal populations using tracer injections (under anaesthesia) or molecular-genetic approaches for use in subsequent anatomical or electrophysiological studies. Animals used in this protocol will typically be young adult mice (of both sexes) and less than four months in age. Animals used under this protocol may be subjected to a maximum of three steps before experiments are ended, or two steps before being transferred to either Protocol 3 or 4.

Protocol 3; Somatic pain models: All animals used under this protocol will undergo recovery surgical procedures under general anaesthetic to either set up models of neuropathic or post-operative pain.

Some animals will undergo implantation of light-emitting diodes that will allow us to control the activity of distinct populations of nerve cells. These animals will then be used in behavioural testing studies (either awake or under terminal anaesthesisa) to establish their responsiveness to various forms of cutaneous stimulation. Animals used under this protocol will typically be young adult mice (of both sexes), and will undergo no more than three of the steps outlined. All experiments will end no later than four weeks after surgery to induce neuropathic or post-operative pain states.

Protocol 4; Visceral pain models: All animals used under this protocol will undergo manipulation of internal body organs to mimic visceral pain states. Some animals will undergo implantation of light- emitting diodes that will be used to control the activity of distinct populations of nerve cells. These animals will then be used in behavioural testing studies (either awake or under terminal anaesthesisa) to establish their responsiveness to various forms of visceral stimulation. Animals used under this protocol will typically be young adult mice (of both sexes), and will undergo no more than three of the steps outlined. All experiments will end within three weeks of surgery to implant light-emitting diodes.

What are the expected impacts and/or adverse effects for the animals during your project?

Given that we are studying the neuronal basis of chronic pain states, it is unavoidable that animals used in this project will experience moderate pain. In many cases, this pain is transient, but may last up to a maximum of 18 weeks. In most cases, experiments will be conducted on animals under general anaesthesia to minimize the impact of these pain states. We are aware of the potential for adverse effects associated with the use of these various models (e.g. weight loss, self-directed tissue damage and locomotor impairment), but incidence of such events will typically be very low (<3%). These experimental approaches are established locally, and research and technical staff are well-versed in spotting these potential problems through a careful post-operative monitoring program.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice used in Protocols 2, 3 and 4 (excluding those on Protocol 1) will experience mild (~30%) to moderate (~70%) levels of pain. Where possible, the pain states in these experimental animals will be managed through the administration of analgesics and close monitoring to minimize undue suffering.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To achieve our scientific aims, we must study functional neuronal circuits in the spinal cord. This is achieved by matching detailed anatomical analyses of neuronal populations, with behavioural readouts of activity within defined neuronal circuits and physiological data generated from tissue preparations derived from transgenic mice. These experimental approaches, which are wholly dependent on being able to target and/or manipulate discrete neuronal populations, are only achievable through the considered use of animal models.

Which non-animal alternatives did you consider for use in this project?

This project assesses the functional impact of distinct neuronal populations on behaviour and must therefore be conducted on live animals. It is not possible to determine the functional significance of neuronal circuits without being able to correlate the anatomical and electrophysiological properties of individual neuronal components with the induction of behavioural responses following targeted manipulation.

Why were they not suitable?

- Not applicable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to target discrete neuronal populations repeatedly and with precision, we will need to breed several distinct transgenic mouse lines for our experiments. These breeding programs will produce animals we can use to visualise and manipulate the activity of distinct circuits specifically. The precision of these approaches ensures our experiments are reproducible, and this leads to a substantial Reduction in the numbers of animals required to generate statistically meaningful datasets than would otherwise be possible.

The intersectional genetic strategies we use to target these neuronal populations require the crossing of several lines, e.g. to generate triple- or quadruple transgenic lines where different recombinases as well as different reporter lines are expressed. Some of the mice we will have to use must be heterozygous, and in complicated crosses, this results in a low yield of viable offspring.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, we have developed breeding strategies that will generate homozygous mice for use in subsequent crossed to produce offspring with the appropriate genotype. It is possible that some offspring of particular genotypes can be re-used in breeding programs to maintain lines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We employ strict quality control measures over all experimental aspects to optimise the number of animals used in these projects, such as genotyping and phenotyping all litters to validate animals designated for continued use. Where possible, tissue is collected at the end of procedures so it can be used in parallel anatomical studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

These studies can only be performed on mice, due to the wide range of genetically modified lines available for this species. Animals that undergo surgical procedures under this protocol will show a moderate level of post-operative discomfort for a short period. This is inevitable, but the molecular-

genetic targeting approach we have adopted ensures we use fewer animals than would otherwise have been necessary if we were to use more traditional approaches. These traditional approaches generally involve very crude manipulation of large groups of neuronal populations and lack precision of selectivity to defined subpopulations in distinct circuits (e.g., systemic administration of drugs to study neuronal circuits in the spinal dorsal horn will also affect circuits in other parts of the central nervous system).

The novel approaches we will use in this project allow us to target and manipulate discrete neuronal populations with greater precision than previously possible. This allows us to influence activity of neurons in defined circuits specifically from which we can determine the functional significance of our targeted population. We can control these populations in awake animals with great precision in a number of ways, with the resultant effects lasting for variable periods: optogenetic approaches using light pulses directed to appropriate body regions changes neuronal activity instantaneously and the resultant effects on behaviour last a matter of seconds; chemo genetic approaches, where administering highly specific designer drugs to activate/inactivate neuronal populations, allows us to influence neuronal activity for periods of up to two hours; genetic silencing approaches allow us to block communication relayed through distinct neuronal populations permanently, without killing the cells; genetic ablation approaches allow us to eliminate distinct neuronal populations selectively. These approaches provide us with the means of dictating the activity of distinct neuronal populations (and consequently the circuits they contribute to). By limiting/controlling the activity of distinct neuronal populations using these approaches, we can establish their functional significance under normal and diseased conditions whilst also minimizing any pain, suffering, distress, or lasting harm to animals under our care. These approaches also provide a consistent means of targeting distinct neuronal populations (and circuits) with great precision, ensuring greater experimental reproducibility and an increased return of data.

Why can’t you use animals that are less sentient?

Given that we intend to study changes to mature spinal circuits under pathological conditions, most of our studies will be in juvenile and young adult mice. It is not possible to carry out these studies in animals that are still developing since compensatory changes at these early stages may mask structural reorganisation seen in the adult nervous system. Nonetheless, we will use animals at embryonic and neonatal stages to label cells early in development but will only look to target and manipulate these cells in mature animals.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

All experimental procedures are reviewed periodically to ensure optimal performance, in consultation with other local groups, NVS and the area Home Office Inspector to ensure best-practice and optimal performance. All of the experimental procedures outlined in this project are established in our group, and are the most refined approaches to address our scientific questions whilst also ensuring minimal pain and discomfort. For example, by defining unique molecular profiles for the neuronal populations of interest, we have developed intersectional genetic strategies to target these cells specifically. Furthermore,

by adopting chemogenetic and optogenetic approaches to manipulate neuronal populations only transiently, our optimised procedures greatly reduce the experimental impact on our animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will perform all studies in line with guidance found on websites managed by NC3Rs and the local institution, as well as in the published literature.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will follow directives from our area Home Office Inspector, local NVS, and updates from NC3Rs directly (www.nc3rs.org.uk/the-3rs), as well as keeping up-to-date with best practices as described in the scientific literature.

24. Immune protection to influenza virus

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

influenza virus, lung, vaccine, T cell, immune memory

Animal types	Life stages
Mice	adult, pregnant, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Following an influenza virus infection, your body builds up specific defences to protect you from future infections. We aim to understand how different cells in the lung, including immune and structural cells, communicate to provide this protection to multiple different viral strains following an influenza virus infection or vaccination.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Influenza virus is a prominent human pathogen. It has caused multiple world-wide outbreaks over the past several 100 years and is an annual seasonal disease. Influenza infects the airways and lungs. In certain individuals, the infection causes severe pneumonia, which can lead to death. Annually, there are around 4 million severe cases and approximately 400,000 deaths from influenza virus. In the UK, 1000-3000 people are admitted to intensive care units annually and around 5% of these individuals die as a consequence of the infection. It is estimated that in high income countries, seasonal

influenza infection cost €56.7 million per million people. The cost of a global pandemic that could, like COVID19, paralyse countries, would be considerably more.

Influenza virus infection educates the body's immune system leading to the formation of immunological memory. This means that the immune cells that respond to influenza virus can respond more quickly and more effectively to a second infection with the same virus. This immunological memory is the basis for the success of vaccines that also educate immune cells that protect the body from infection.

Current influenza virus vaccines are much less effective at generating long term immune protection compared to an actual infection with the virus. We think that this is because the vaccines are less efficient than the virus at educating a particular type of immune cell called T cells. T cells that are educated to respond to influenza virus are important as they can protect against lots of different types of influenza virus. This contrasts with current vaccine derived immune protection that leads to the generation of antibodies that, because of mutation of the viral surface proteins, are only able to protect against that season's influenza virus variant. T cells can provide broader protection to many different strains as they recognise parts of the virus that are conserved across many different strains.

We have only a limited understanding of the cells and molecules that are required to direct the development of long lived educated T cells following influenza virus infection. We also have an incomplete understanding of how the educated T cells protect against subsequent infections, and what other cells in the lung work

What’s the aim of this project?

Following an influenza virus infection, your body builds up specific defences to protect you from future infections. We aim to understand how different cells in the lung, including immune and structural cells, communicate to provide this protection to multiple different viral strains following an influenza virus infection or vaccination.

Why is it important to undertake this work?

Our work will address which cell types in the lung are involved in generating longterm protective immunity following influenza virus infection. This is important as it could highlight which cells vaccines need to act on to ensure longterm protection to different influenza virus strains. We will also examine whether newly identified parts of influenza virus that are highly conserved across most influenza virus strains, stimulate an immune response and can provide immune protection. These studies may help identify novel parts of influenza virus that can be used in a 'universal' influenza virus vaccine.

What outputs do you think you will see at the end of this project?

Our studies will generate new information related to the immune response to influenza virus infection. This information will be shared with the scientific community through oral and poster presentations at national and international meetings and through publications that will be free for all to view (open- access).

Who or what will benefit from these outputs, and how?

In the short-term, the main beneficiaries of our work will be other scientists as our data adds to a body of knowledge about the immune response to influenza virus. We will communicate our new knowledge by presentations at scientific meetings and via publications in scientific journals. These data will help to move the field forward and generate new hypotheses relevant to how our bodies fight infections.

In the longer term, this collective body of work will help scientists to design novel vaccines that can generate local immunity within the respiratory tract and lung to many different strains of influenza virus. Improved vaccines for influenza virus would reduce the number of serious diseases and deaths caused by this virus. The research may also be more widely applicable to other respiratory viruses, for example, respiratory syncytial virus and SARS-CoV-2.

These longer term impacts of our research have social and economical benefits too. Vaccines are one of the most cost-effective forms of health care. New, more effective vaccines will reduce the number of people who become ill following infection, reducing the number of people who take time off work and/or require hospital treatment, or who die as a consequence of the infection.

How will you look to maximise the outputs of this work?

We will maximise the outputs of our research by ensuring that as much of our data as possible is published, either in primary scientific articles or via publications that are methods focussed. We will also share our data at national and international scientific conferences through oral and poster presentations. We will also share our methods and data in discussions with former and current colleagues, collaborators, and will provide detailed step-step methods to any researchers who request this.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

We use mice for our experiments for a number of reasons:

They are phylogenetically the least complex mammal with similar immune system to humans. This means that we can extrapolate our data to understand what might happen in human disease.

They have been used in many similar studies to ours. This means that we can make sense of data in the context of the wider field and accelerate our understanding of disease.

There are many genetically modified mice available. This means that we can ask very precise questions that enable us to understand which cells and molecules are involved in the disease process.

In our studies we use adult mice to examine how a mature immune system responds to viral infection.

Typically, what will be done to an animal used in your project?

Typically, mice in our studies will be infected with influenza virus. We will then examine the immune response in the lungs and in immune organs in the subsequent days to weeks. In some studies, we will give the mice a vaccine and examine whether they are protected from a subsequent infection with influenza virus. In other experiments, we will manipulate cells and molecules in the lung either before or after influenza virus infection to determine what role these cells and molecules play in protection the host.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice infected with influenza virus are likely to lose weight; rarely they will show other clinical features (hunched, reluctance to move, isolation and failure to groom). Typically weight loss begins 6-7 days following infection and mice have regained their starting weight by day 12-14 after infection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Subthreshold: 10%
- Mild: 20%
- Moderate: 70%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although studies using cells grown in the lab can recapitulate some aspects of the interactions between the different cells we study, they cannot adequately model the complete and complex array of immune responses involved in the generation of protective memory response against a pathogen. The many interactions between the cells of the

immune system, lung structural cells and with the infectious agents cannot be fully modelled by cells grown in the lab. Therefore, further animal studies are required.

Mice are used in this project as they represent the least complex vertebrate group where the influenza virus infection model has been developed. Moreover, the transgenic and knockout models, which will allow us to understand how the cells we study work, are only available in mice.

Which non-animal alternatives did you consider for use in this project?

For immunological studies, the only non-animal alternatives open to us are using cell lines that have already been established, using human cells, or using data have already been generated in mathematical based models.

Why were they not suitable?

The aim of our studies is to examine how cells within the lung change following influenza virus infection in the short (days) to the longer term (months). Some of the cells we examine can move into and from the lung over this time course and therefore our studies require an intact circulation system. Our studies examine the long term effects of communication between different cells in the lung. This includes immune cells, such as T cells, and structural cells, including epithelial cells and fibroblasts. The communication of these populations is dependent on their precise location within an intact, living organ over the days, weeks and months following infection.

For these reasons, current in vitro techniques using isolated cell types or artificial organs grown in vitro are not able to replicate the complex dynamic relationships of the different cell populations that we study in the intact animal.

Current cell lines do not accurately represent the immune and structural cells that we examine. In the main this is because the cells we study are heterogenous populations while cell lines are, by nature, non-heterogenous, and because cell lines have been treated so that they can survive in culture. This artificial cell life-time means these cells do not act in the same way as cells from an animal. Human cells are not an option for us as we examine lung cells at defined times after influenza virus infection. Finally, there is not currently enough information about the consequences of longterm communication between immune and structural cells for us to construct accurate mathematical models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practicesthat are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Within an experimental system we need enough animals to be certain that any changes we observe between an experimental group and a control group reflect real differences. If we want to examine whether a particular cell type has changed following influenza virus infection and whether these changes help protect the animal following a subsequent infection, we will need to set up two different types of experiment.

To address the first question, we will need to examine the cell type of interest in animals that have and have not been infected. Here we need around 4-5 mice in the two groups to give us confidence in any difference that we observe. This number is based on the level of variance that we see in uninfected and infected animals in previous similar types of experiments over the last 19 years and similar to numbers used by other researchers who use influenza virus infection in mice. We also do these experiments at least one more time to make sure our results are consistent and reliable. This is standard practice and we would not be able to publish our results in scientific journals without doing this.

Experiments to test whether any changes to a particular cell are involved in protecting the animal from a subsequent infection are more complex. Here we typically need around 10-12 animals per group as we see more variation in these studies. We also need more groups to ensure that our experiment has worked as we expected. For example, we need to treat a group of animals in a way that we know will protect them from infection, and/or to have a group in which the cell type or interest is present and one in which the cell type is removed. These groups are required to give us confidence in our data.

The number of mice needed are also based on the different time points we will examine following influenza virus infection. We are interested in how immune and structural cells change in the lung change following influenza virus infection and for how long these changes persist.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When planning experiments, we take into account guidance from NC3Rs through the experimental design assistant. For experiments that involve new reagents or new analysis, we seek guidance from colleagues with experience in these areas.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For some experiments, we will perform pilot experiments. This includes when we are using new chemicals or have a new way to analyse our data. These pilot experiments will contain fewer mice and fewer groups as their aim is to test the chemical or the experimental read out rather than address a scientific question. This will ensure that when we perform the full experiment, we are confident that our reagents or experimental read outs will provide us with reliable data.

In some cases, when the conditions and timing of the pilot experiment are exactly the same as the full experiment, we will be able to include the data from the pilot experiment in

the full experiment. This will enable us to reduce the number of animals used in some of the control groups in the main experiment.

As many of our objectives require tissue from mice at different time points following influenza virus infection, the researchers will be able to share tissues to address their own specific questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In many of our experiments, we will infect mice with influenza virus. This is essential for our project which is aimed at understanding how cells in the lung change following an infection and how these changes lead to protection from a subsequent infection. The infection will lead to weight loss lasting from about day 6 to day 10 following the infection. Additionally, weight loss is a readout of immune protection in our infection challenge studies.

We ensure that the dose of virus that we use for these studies is sufficient to drive a consistent immune response but is low enough so that it does not cause more suffering or distress than is necessary. If we used a lower dose of virus, we would risk some animals clearing the virus without the induction a strong and persistent immune response - i.e. in these animals no adaptive immune response against the virus would be generated and we would not be able to use these animals in our studies. This would mean more mice would need to be infected to ensure we had sufficient animals who did have a strong and persistent immune response to use in our studies.

Why can’t you use animals that are less sentient?

The major aim of our project is to understand how different cells in the lung communicate with each other during and following an infection. We need, therefore, to examine the lung immune and structural cells at different times following infection. We use adult mice, as younger mice do not have fully developed lungs. Mice are most appropriate animal to use for our studies as their immune systems are similar to humans and we have a great deal of knowledge about immune responses in mice, helping us to put our data in the context of a wider field and accelerate new understanding.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Mice on our procedures are monitored when we expect them to show signs of ill health. This occurs following infection with influenza virus and we monitor them by weighing and by observing their behaviour and appearance. Typically, we carry out this monitoring between days 4 and 12 following infection. This is based on our extensive use of the influenza virus infection model. Should we find that infected mice begin to lose weight before day 6, we will begin monitoring then from day 2 rather than day 4 of infection. Mice that fail to regain their starting weight will be weighed until they do, usually by day 20 post-infection.

We euthanise mice if they lose 20% of their starting weight or show unexpected clinical signs, including reduced movement. Animals that fail to regain their starting weight 40 days following infection are also euthanised as a failure to re-gain weight would suggest ongoing clinical disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow guidance from 3R and the ARRIVE guidelines and any additional local guidelines within our establishment.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Up to date guidance will be monitored via the NC3Rs website (http://www.nc3rs.org.uk/) and through communications from our animal facility.

We keep up to date on relevant scientific literature using the influenza virus infection model in mice. Should there be relevant and feasible modifications to the current methods that would enable us to reduce the numbers of animals we use, we would first test whether these altered our main read outs of disease and immune response, and if our main findings could be replicated, adapt these modifications.

25. Neuronal Control of Sleep

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Sleep, Energy metabolism, Potassium channel, Oxidative stress

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Sleep is one of the great biological mysteries. Each night we disconnect ourselves from the world for seven or eight hours—a state that leaves us vulnerable and unproductive. But despite these risks and costs, we still don't know what sleep is good for. Whatever sleep's purpose is, however, is clearly essential: chronic sleep loss shortens life.

Studies in fruit flies have revealed that the need to sleep is tied to the efficiency with which brain cells (and perhaps other parts of the body) burn the food we eat. The proposed project will test whether the same sleep-regulatory mechanism also operates in mice. The work is expected to advance our understanding of the regulation and function of sleep and identify new strategies for the treatment of sleep disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sleep disturbances are among the most common medical problems. A large majority (75%) of adults in Western societies report at least intermittent sleep disruptions; up to a quarter suffer from persistent daytime sleepiness; 10% experience chronic insomnia.

Sleep disturbances contribute to a number of medical, psychiatric, and neurological conditions and are a leading cause of traffic accidents. Diseases associated with impaired sleep include diabetes and obesity, mood disorders, and many neurodegenerative diseases, including Alzheimer's and Parkinson's.

Although sleep medications are among the most commonly prescribed drugs, the value of the prescription drug market for sleep indications has declined sharply in recent years as patents have expired. This decline is a vivid testament to the failure of the pharmaceutical industry to materialise innovation, despite significant risks and adverse effects of existing drug treatments.

The importance of the proposed project is two-fold: the work will aim to define a novel mechanism connecting energy metabolism and sleep, and it will seek to harness this insight to devise rational new strategies for therapeutic intervention.

What outputs do you think you will see at the end of this project?

New information. The proposed work will investigate the role of potassium channel β-subunits—and, in particular, their oxidoreductase activity—in the regulation of mammalian sleep. It will determine the identity and sleep-relevant sites of action of potassium channel β-subunits in the brain and determine whether the administration of β-subunit substrates induces sleep in mammals. Together, these studies promise to lay the foundation for a rational new approach to the treatment of sleep disorders, with potentially significant health and economic benefits.

Scientific publications and public engagement. We will disseminate our findings to biomedical researchers, health professionals, and the general public.

Training of graduates and postgraduates. Its hypothesis-driven agenda, rigorous mechanistic outlook, wide methodological range, and considerable application potential make the proposed programme an excellent training opportunity for junior colleagues.

Who or what will benefit from these outputs, and how?

Researchers in many different disciplines will benefit from the results of the proposed project.

Neuroscientists, biochemists, and cell biologists, because our work connects different aspects of their fields and in a surprising, seamless fashion: the regulation and function of sleep, mitochondrial electron transport, lipid and redox metabolism, the biophysics of action potential generation, and the regulation of enzymatic catalysis and ionic conductivity.

On channel biophysicists, because the identity of the endogenous molecules that serve as substrates for potassium channel β-subunits and couple a cell's excitability to its metabolism remains an important open question.

Biomedical researchers, because energy expenditure ('rate of living'), oxidative stress, and sleep have been implicated repeatedly and independently in ageing, lifespan, and degenerative disease. Our work aims to generalize and solidify an underlying mechanistic connection suggested by studies in fruit flies.

Pharmaceutical researchers and clinicians, because our work formulates and tests a new concept for the management of sleep disorders.

In the long run, if this concept for the management of sleep disorders is validated and introduced into clinical practice, there may also be medical and economic benefits.

How will you look to maximise the outputs of this work?

In addition to sharing our findings through standard academic channels (preprint servers, peer- reviewed publications, conferences, and seminars) and social media, we will ensure that significant discoveries are accompanied by press releases and short video clips intended for non-specialist audiences.

We will also rely on media contacts to communicate the health implications of our research and any attendant lifestyle advice (provided, of course, that the advice is based on solid scientific evidence and there are no conflicting intellectual property considerations).

Species and numbers of animals expected to be used

- Mice: 19500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Previous research in the fruit fly has shown that energy metabolism, oxidative stress, and sleep—three processes implicated independently in lifespan, ageing, and degenerative disease—are mechanistically connected. The crucial link consists of redox-sensitive potassium channel β-subunits that regulate the electrical activity of sleep-promoting neurons. Given the great fundamental and clinical importance of sleep, and the potential of KVβ substrates to define novel prototypes of sleep-regulatory drugs, it is important to test whether the same sleep-control mechanism also operates in mammals.

Because the use of mammals is integral to the question at hand, we will use mice, the phylogenetically lowest, commonly used mammalian laboratory species with a brain sufficiently large to accommodate the recording devices required by this project. Techniques for chronic neuronal recordings, the analysis of sleep stages, and viral and germline genetic modification are well established in this species.

Typically, what will be done to an animal used in your project?

Typical procedures involve injection of viral vectors into specific regions of the brain, implantation of recording devices, and long-term recording of brain activity for days to weeks. A minority of mice will enter longevity analyses.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected adverse effects include the consequences of genetic modifications (sleep impairment, increased probability of seizures, and reduced lifespan), stress from single housing, side effects of pharmacological interventions (weight loss), and rare complications from surgery. The adverse consequences of genetic modifications are likely to last from early adulthood to death unless successfully counteracted by compounds discovered during this project. Stress due to single housing and other protocol-related effects (e.g., weight loss) will last for the duration of the experimental intervention.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity = 9000 Moderate severity = 10500

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sleep is a behavioural state that can only be defined and investigated in intact animals. While invertebrates, especially the fruit fly Drosophila, are a powerful model for fundamental research, the explicit aim of the present project is to probe the extent of functional conservation of sleep- regulatory mechanisms between insects and mammals. The use of a mammalian species is therefore a sine qua non.

Which non-animal alternatives did you consider for use in this project? Computer models, cell cultures, and phylogenetically lower model organisms.

Why were they not suitable?
Sleep cannot yet be modelled in computers or cell cultures; testing the hypothesis in phylogenetically lower model organisms than the fly, such as the nematode, would defeat the very purpose of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimate is based on a Mendelian ratio of inheritance for the generation of homozygous mutant mice that includes a 10% contingency. Because a minimum of 6 mutant lines must be tested, breeding and maintenance accounts for the majority (13,000) of the total estimated number of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental designs take advantage of randomization, allocation concealment, automated data analysis, and blinding to prevent subjective bias, and of within-animal designs to minimize the total number of animals to be used. Only genetically modified lines showing relevant abnormalities (e.g., sleep impairments and/or sleep- related symptoms) will be continuously maintained, while those with non-relevant abnormalities will be discontinued as soon as possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Complex surgeries that require precise targeting will be first extensively practiced on cadavers to reduce both variability and the total number of animals used. Breeding will be done in an efficient manner and closely monitored so as to prevent overproduction. Genetically modified mouse lines that do not, upon rigorous testing, show robust sleep phenotypes will be cryopreserved and discontinued. Where applicable, within-subject experimental designs will be employed so the animals can act as their own controls.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used for this project. This model is the most appropriate to address the Objectives of this project.

Various state-of-the-art methods, such as stereotaxic cranial surgery and electroencephalography will be used to target specific regions of the brain and record brain activity as an animal sleeps. Given that no alternative, more refined methods exist to address the Objectives of this project, the methods selected will cause the least pain, suffering, distress, or lasting harm to the animals during the course of this research.

Why can’t you use animals that are less sentient?

Animals at a more immature life stage cannot be employed because only adults can wear the recording implants required for this research. All background research for this project derives from work in "less sentient" species, but the purpose now is to test the generality of what was found in the fruit fly in mammals. The mouse model is the least sentient animal that can be used to address the Objectives of this project.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Animals will be monitored daily and intensively following any advanced procedures, and extensive post-operative care such as pain management will be rigorously applied to minimize welfare costs. The earliest humane endpoints consistent with the scientific goals will be applied.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3R's guidance to best practice will be followed to ensure the experiments are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular attendance of meetings that address needs and updates of advances in the 3Rs; subscription to newsletters and bulletins; discussions with colleagues and staff.

26. Investigating Sex-Based Differences in Immunity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Sex Chromosomes, Sex Hormones, Autoimmunity, Inflammation, Immunology

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how sex hormones and sex chromosomes affect immune system function during health and inflammatory disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite the appreciation that immune responses differ in males and females, using sex as a biological variable in experimental studies does not routinely take place. In addition, not all published animal studies report the sex of the animal used during in vivo experiments and experiments with isolated cells rarely report the sex of the donor. This means that in many situations it is not known whether the reported effect is applicable to both male and female immune systems. Greater understanding of the mechanisms by which the immune

response varies between males and females may allow the development of better targetted therapeutics, especially in disease where there is a noticeable sex-bias such as lupus and arthritis.

What outputs do you think you will see at the end of this project?

The outputs for this project will include greater insight into the how the immune system differs in males and females, leading to publications and in the future better ways to treat male and female patients more targetted manner.

Who or what will benefit from these outputs, and how?

The short-term benefits of this project (within the next five years) will include greater insight into the how the immune system differs in males and females. This information, which we intend to publish in peer- reviewed journals and report at conferences, will inform the work of researchers who work on related projects where there is also a sex bias in disease onset/outcomes (such as Lupus, COVID-19, certain cancers and sepsis). With the emergence of the concept of personalised medicine, it is both important and timely to consider the mechanism underlying the differences in observed pathophysiology of disease between males and females.

In the long-term (>10 years), our research has the potential to benefit the management of disease in patients with lupus and rheumatoid arthritis by obtaining a greater understanding of the cause of these complex diseases and providing new therapeutic strategies. Rheumatoid arthritis is a highly debilitating disease that affects 0.8% of the UK population and results in a reduced life expectancy. In 2010 it was calculated that rheumatoid arthritis alone cost the NHS £560 million/year. The cost to the wider economy of rheumatoid arthritis was calculated at £1.8 billion in terms of sick leave and work-related disability. Lupus has a lower prevalence in the UK population than arthritis, affecting around 28 in every 100,000 people in the UK, however it is also a potentially fatal disease; of the 396 patients we have followed over the past 25 years, 14% have died, with an average age of 57 years. While the economic burden of lupus to the economy as a whole has yet to be assessed, in 2000 it was estimated that direct treatment costs/patient/year to the NHS were £7913, equivalent to around £140 million for the UK population every year (this is likely to be significantly higher now). To date, there is little data concerning the mechanisms which underlie the sex-differences observed in patients with autoimmune disease.

In terms of animal benefit, by considering sex as an important biological variable we hope to increase long-term reproducibility of data by increasing the reporting of the sex used in animal experiments. This will lead to a long-term reduction in the number of animals used for experiment medicine. It may also lead to refined procedures where male and female mice are treated differently during experiments, as they are likely to benefit from different humane end-points depending on sex.

How will you look to maximise the outputs of this work?

We will maximise the outputs from this work by communicating the research locally in departmental meetings and to the wider scientific community at national and international meetings. Once completed, this work will be published, open access, in journals with the highest possible impact. We will also publish negative findings in open content journals such as the Public Library Of Science (PLOS). At the Centre for Adolescent Rheumatology, there is also a thriving patient participation, involvement and engagement (PPIE) community, which will be used to disseminate and discuss ongoing findings with patients and their carers, to make sure that the animal research undertaken is relevant to patients.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We will use mice in our experiments as these animals have well characterized immune systems that share many similarities to humans. Research with mice has been fundamental to the development of many drugs that are used to treat immune system related diseases. We are using adult and juvenile mice to allow us to compare how the immune system changes over age in both males and females.

Typically, what will be done to an animal used in your project?

An animal used in this project license will typically be given an inflammatory stimulus by injection to induce the development of a rheumatological disease such as arthritis or lupus. The experiments will last approximately 2-3 weeks. However, some models require us to keep the animals alive for longer (max 6 months).

What are the expected impacts and/or adverse effects for the animals during your project?

As we are inducing inflammation and the development of autoimmune disease, we expect mice to experience some pain and swelling at the affected site. Depending on the model induced, we expect the pain to last between 1-3 weeks. In some mice, pain will be limited as we will be testing experimental substances that may suppress disease development.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold - 15% of the animals on this project license.

Mild: - 50% of the animals on this project license.

Moderate: - 35% of the animals on this project license.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Autoimmune diseases develop as a result of a the complex interaction between multiple organ systems and multiple immune system cell types. Thus, unfortunately, at present, we are unable to model autoimmune disease using isolated cells from humans or healthy animals, or cell-lines in a test tube.

The data and results obtained from experiments where we look at the kidneys, liver, spleen, blood, lymph nodes and joints of animals with disease are more representative of human disease. Kidneys will be taken from mice with lupus; joints will be taken from arthritic mice; liver, spleen, blood and lymph nodes will be taken from every mouse to analyse the immune response. Where possible we use cell lines or samples taken from humans instead.

Which non-animal alternatives did you consider for use in this project?

We considered using human samples and cell lines.

Why were they not suitable?

Where possible we will use human samples. However, they are not suitable for the majority of this work as we can only access peripheral blood samples from human patients due to ethical limitations.

Autoimmune diseases are multi-organ diseases that affect many different sites and to understand why there are differences in susceptibility between men and women, we need to analyse the tissues that the disease affects such as kidney's and joints. It is also important to understand how diseased tissues 'talk' to healthy tissues and whether cells move between sites. This is also true of cell-lines which do not recapitulate the microenvironment of complex tissue anatomy. In addition, many cell lines do not state the sex of animal/human they are derived from which means they are not suitable for our study.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the numbers of animals we will use based on previous experiments and pilot data. The differences between the sexes were subtle and therefore a larger amount of mice are needed to obtain statistically significant results. However, as we are comparing sexes within every experiment, we have the ability to use experimental designs that reduce the amount of animal needed to get statistically significant results. As well as input from in-house statisticians, the NC3Rs experimental design tool will also be used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Careful consideration is given to calculate the minimum number of mice needed to give statistically significant results. The size of experimental groups has been decided after consultation with the statistician at our institute and we will continue to consult with statisticians for optimization of the experiments throughout the life of the licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will take many steps to reduce the number of animals used. This includes purchasing wild-type animals from reputable commercial sources (reducing the numbers of mice needed to maintain a colony). We will also share tissues with other researchers in the department where possible. In addition, where we have new programme of work (e.g. cross hormone treatment in mice), we will start by carrying out pilot experiments to refine our protocols. We will then carry out power calculations prior to embarking on the full programme of work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Experimental procedures carried out on our mice can be broadly divided into two categories: inducible- models of autoimmune disease and spontaneous models of autoimmune disease. Mice used under these protocols will experience a moderate level of severity at most, and many steps are in place to prevent prolonged suffering or the development of a high level of severity. As the models we are using reflect human autoimmune diseases the adverse effects will include some inflammation, some weight loss, and well as some pain at inflamed sites.

Why can't you use animals that are less sentient?

Many autoimmune mouse models are only inducible in adult animals and take some days/weeks to develop. Unfortunately, this precludes the use of immature life stage animals and animals that have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We use mice in our experiments as these animals have well characterized immune systems that share many similarities to humans. Research with mice has been fundamental to the development of many drugs that are used to treat immune system related diseases. In our research we will start by using inducible models of disease that result in short-term, highly reproducible disease with almost >95% incidence. The reproducibility and reliability of the mice getting disease will allow us to use fewer mice. Following identification of biological processes that may be involved in disease development, we will look at these pathways in spontaneous mouse models of autoimmunity that are more translationally relevant to human autoimmune disease, which is also spontaneous. In general, to minimise welfare harm, we inspect the mice daily and administer pain relief where possible. We will also use the most refined inoculation route and as much as possible use agents that illicit and immune response that are less inflammatory. We will also where possible use fewer toxic compounds to achieve the same goal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use animal welfare scoring sheets, which were designed using advice from the following website:

https://www.humane-endpoints.info/en/score-sheets

We have also designed maximum sampling sheets for all researchers working on the PPL, using advice from the following website:

https://nc3rs.org.uk/blood-sampling-mouse

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult our NC3R regional programme specialist and check the NC3Rs website regularly. We will also attend courses through the university that update us on these regulations. Updates will be disseminated round the team working on the project license and in the case of big advances/changes to 3Rs recommendation we will have a lab meeting or short seminar to discuss in more detail.

27. Tumours - Therapy, Diagnosis and Models

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, therapy, drug delivery, Nanomedicine, targeting

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to allow evaluation of promising diagnostic and therapeutic approaches to cancer such as anti-cancer drugs or nanomedicinesand to identify relevant animal models or suitable in vitro replacements that provide predictive data for the clinical translation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Scientific and technological advances mean promising compounds and drug delivery technologies are being developed in the laboratory but to accelerate the transition of these into the clinic it is important to select only the most promising candidates for further clinical development.

The new molecules and delivery systems or nanomedicines are typically first tested and developed in cell-based assays. However, cancer cells growing in isolation in the

laboratory only replicated limited aspects of how drugs/delivery sytems are going to behave in actual tumours or inside the body. It therefore becomes necessary to test the most promising candidate systems in animals to ensure that they are efficacious and safe before they undergo further clinical development. Where we develop novel in vitro replacement models they will require validation in animals models to understand whether they are likely to be predictive of the clinical performance of such therapies. This will accelerate and simplify pre-clinical development and is well aligned with the objectives of the 3Rs.

What outputs do you think you will see at the end of this project?

The outputs from the project will include specific information about the effiacy and safety of novel therapies and diagnostics against a range of cancers; furthermore, they will bring improved mechanistic understanding of the underlying causes for this performance, and should allow identification of such factors which could be testable in vitro models and then allow pre-clinical in vivo validation of such models.

Examples would include our work on cancer gene therapy, anti-cancer peptide pill, improved therapy of Glioblastoma Multiforme (GBM) (as we have published over the last period) or ongoing work which includes improved therapy of child hood leukaemia, replacement of intravenous paclitaxel with oral/tablet formulations, targeting of breast cancers.

This information will further translate into outputs for dissemination (e.g. publications) and candidate interventions for clinical evaluation.

Who or what will benefit from these outputs, and how?

The immediate benefit will be to inform the scientific work of our group and our collaborators. In the near term (2-5 years) this will also inform the work of others working in this area in terms of knowledge and hypotheses for further development, but also improved or simplified models that may allow more rapid in vitro evaluation and reduction of downstream in vivo testing requirements.

In the longer term (5 - 15 years), our work will potentially create economic benefit linked to the development of novel interventions and ultimately to potential patient benefit with improved and safer cancer therapies and diagnostics if these clinical programs prove successful.

How will you look to maximise the outputs of this work?

We will work with other scientists and engineers to make sure that we fully understand what these tiny particles are capable of as medicines. We will collaborate with scientist from other disciplines and consult with clinical colleagues regularly to focus the research on the most pressing clinical needs.

Where candidate interventions have been identified we will also consult other stakeholders e.g. patient groups.

We continue to facilitate translation of our efforts by identifying and supporting efforts to support clinical development via a commercial or non-commercial routes, as appropriate.

We will publish and disseminate all of our work regardless of whether it was successful or not in order to inform other scientists, in order to avoid duplication of in vivo work and to facilitate the development of appropriate replacements to in vivo models.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The mouse is the lowest mammal to support the study of solid tumours in an organism. Cell culture experiments currently to not replicate the complexity of tumour development and the challenges of delivering therapeutics or diagnostics to tumours.

Typically, what will be done to an animal used in your project?

Tumour cells will be injected into the flank of animals so that they develop a small tumour under their skin over the next couple of weeks. Novel treatments previously tested on cells will then be given to the animals to evaluate whether they are likely to offer benefits in terms of future cancer therapy.

What are the expected impacts and/or adverse effects for the animals during your project?

The growth of the tumour does not lead to apparent suffering. Similarly, the novel therapies and diagnostic interventions are not expected to be harmful. The procedures these animals will undergo are similar to those a human cancer patient would experience. This could therefore include adverse effects such as temporary unwellness or weight loss; animals having to undergo procedures will potentially cause temporary stress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around 90% of animals will fall into the moderate severity category. Other animals are expected to experience mild harms only.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer cells grown in isolation are a very limited model for tumours which develop (and need to be treated) in an animal or human.

Which non-animal alternatives did you consider for use in this project?

Cancer cells grown in vitro are used routinely before more promising approaches are evaluated in animals.

Why were they not suitable?

It is currently not possible to fully replicate the complex interactions of different cell types and tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For many of the experiments we have decades of experience in terms of typical animal numbers required. Where this is not known, pilot experiments allow us to carry out power calculations to estimate the minimal required animal numbers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are developing novel ways to allow multiple read-outs to be obtained from one experiment. Where desired effect sizes are known power calculation tools will be used (e.g. InVivoStat).

Tumorigenicity studies will be fully documented to gain profiles of the tumours to reduce repeats of pilot growth studies. Use literature and seek other establishments that have data on tumour models to know how best to grow tumours. Look at needle size: cell size to ensure the most appropriate needle is being used and doesn’t hinder the growth prospects of tumours.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where there are significant unknowns in terms of experimental design or effects of novel interventions, we routinely use pilot experiments before planning pivotal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Novel interventions will be first evaluated in normal mice without tumours to minimise suffering. Where tumours are essential for the evaluation, we typically work small tumours. Where interventions are likely to cause pain and suffering monitoring and analgesic interventions will further reduce suffering.

Why can’t you use animals that are less sentient?

The mouse is the lowest mammal to allow replication of the most relevant elements of the tumour/body interactions. Aspects such as mammalian circulatory system, cells with macrophage activity (reticuloendothelial system), blood protein components, tumour stroma among other aspects are known to modulate nanoparticle biodistribution and would not allow meaningful results to be produced in lower species such as amphibians or nematodes.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

The animals will be closely monitored after any intervention and where surgical procedures are required, they routinely will have the necessary post-operative care and pain management. Humane endpoints have been defined to prevent unnecessary suffering and where animals do show clinical signs these are recorded and suffering and distress assessed in a cumulative fashion using the Distress Score Sheet.

Monitoring will be adaptive, i.e. the frequency of monitoring will be adapted based on the nature of the procedure and the risk for suffering associated with it in the specific context of each experiment; for example, when animals are inoculated with tumour cells during the tumour development initial frequency for slow growing tumour models or tumour models in the perivascular phase will be lower than for more rapid growing tumours or tumours for which we have less experience with. This could mean animals will for example be clinically inspected daily in those situations.

Similarly, when animals are dosed with novel compounds e.g. in dose finding pilot experiments initially continuous and then more frequent monitoring may be required while for routine dosing with known drugs less regular monitoring may be sufficient.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work will follow the guidelines published by Workman et al (2010, Br J Cancer, 102, 155).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Subscription to NC3R newsletter and alerts as well as CRACK-IT website; in addition to this academic journals that cover novel methods such as organ-on-a-chip etc.

28. The role of glia in nerve regeneration and cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, nerves, regeneration, glia, microenvironment

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, aged
Rats	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The work in this proposal addresses how glial cells become cancer cells. The glial cells are found in the nervous system and are key ifor maintaining and repairing nerve cells. The development of tumours (tumourigenesis) appears to mimic the process that takes place in glial cells and the associated inflammatory and regenerative response following an injury to the nerve.. We therefore want to understand the nerve regeneration process to help us to understand tumour development and other diseases of nervous tissue. Moreover, these regenerative processes appear to mimic the growth of nerves into growing tumours, which appear to be important for both tumour growth and tumour spread. We aim to understand these processes using mouse models of tumour development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We study the mammalian peripheral nervous system to understand the establishment of a stable tissue, how a tissue can regenerate in the adult following an injury and how these processes may affect tumourigenesis. There is increasing evidence that the supply of nerves (innervation) is an important aspect of all solid tumour formation and is a

mechanism by which many tumours spread- a process known as perineural invasion (PNI). It is important to undertake this work to understand these processes, so we can improve nerve regeneration following injury and stop aberrant regeneration that can result in pain. Moreover, we would hope our findings will lead to new approaches for cancer preventention and treatment.

What outputs do you think you will see at the end of this project?

The primary potential benefit relates to new knowledge about the mechanisms underlying regeneration of the peripheral nervous system, the development of tumours in this tissue and the unappreciated importance of innervation and PNI in the initiation and spread of many tumour types. Additional benefits will include increased understanding of the blood nerve barrier in health and disease. This understanding could lead to new approaches for the treatments of diseases such as neuropathies, cancer, diabetis and neurptoxicity. The findings will be published in academic journals and are likely to be of great interest to pre-clinical and clinical scientists with interests in nerve injury, neuropathies and cancer. The second potential benefit relates to the possibility of the identification of new molecular targets and/ or devices, which may be of benefit for the treatment of these diseases. Evidence for this approach is the interest of clinicians and interactions with therapeutic companies based on our previous findings.

Who or what will benefit from these outputs, and how?

In the short term, the scientific field will benefit from an increased knowledge of nerve function, how nerves can be damaged and regenerate, the role of nerves in cancer and the blood nerve barrier. In the longer term, we would expect benefits to human disease. These include the development of new devices and protocols to improve nerve repair and to inhibit aberrant nerve regeneration. It may also

lead to new strategies to deliver drugs to the nervous system. In this regard, we are already in a collaboration with a pharmaceutical company in an attempt to increase the delivery of therapeutics into peripheral nerves. Other longer term benefits may include new approaches to prevent and treat cancer and to develop new approaches to protect patients from drugs that damage nerves as a side-effect, such as chemotherapy, which is a major limiting factor for chemotherapeutics.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work through specific strategies.

To disseminate our research and discuss the results (including unsuccessful approaches) with scientists who are world-renowned experts in the relevant fields (These include experts in neuroscience, cancer and tissue regeneration), we will present our research findings in national and international conferences on an annual basis.

The results of our research will be published in high-profile scientific journals that normally reach the wider scientific community. Publications will be open access.

The techniques developed in our laboratories will be highlighted and shared with our collaborators and with other researchers during discussions in informal meetings and in the course of national and international conferences and publications. Advanced skills workshop run locally and we will are part of these communities aimed at sharing expertise in our Institute.

Species and numbers of animals expected to be used

- Mice: maximum of 4900 per year
- Rats: maximum of 1000 per year

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

While we have made great attempts to develop in vitro (not in live animals) culture models, it is clear that it is currently impossible to fully model the behaviour of nerves or glial cells in vitro. This is particularly the case for studying the role of homeostasis (maintenance), regeneration and tumor formation of the complex peripheral nervous systm. We will therefore perform many of our studies using mouse models and in some cases cells derived from rats , although we will use the in vitro models when appropriate.

Typically, what will be done to an animal used in your project?

Many mice and rats will be sacrificed to provide tissue to produce cells or samples.

Some mice and rats will undergo peripheral nerve injury and will be injected with substances to analyse the process or treat the process. These mice may be kept for several months.

Some mice and rats will be injected with substances to analyse tumour formation or prevent tumour formation. These mice may be kept for several months.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the experiments described in this application require the use of genetically-modified mice that express forms of genes that are mostly indistinguishable from any other mouse. . For a majority of the experiments, the animals will be bred to produce cells or tissue for in vitro experiments.

Some of the experiments will involve manipulation of genes in vivo (in living animals) that will result in tumour formation or nerve damage . Other experiments involve injections of tumour cells to assess tumorigenic development and spread. These animals will be monitored regularly and any animals showing signs of distress will be humanely culled. Based on previous work, the likelihood of distress in the animals is considered low and the

severity level is judged as moderate. Animals will not be allowed to develop tumours greater than 1500mm3 and the tumour mass will not exceed 10% of bodyweight.

Some experiments require the damage of a nerve in mice/rats. These experiments will be carried out under general anaesthesia. The recovering animal will be medicated for pain and closely monitored. Based on previous work the suffering is minimal as the animals are able to move around and feed normally. In the unlikely circumstance that any animals show signs of infection or discomfort, they will be humanely culled.

Some experiments involve in vivo imaging of cell migration. These animals will be anaesthetised and will be culled at the end of the imaging experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild

- 47% of all mice will be in the mild category
- 33% of all rats will be in the mild category

Moderate

- 53% of all mice will be in the moderate category
- 67% of all rats will be in the moderate category

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Complex processes such as nerve regeneration and tumorigenesis and tumor innervation cannot be satisfactory modelled in vitro. The role of the microenvironment in these processes is crucial and still widely unexplored, thus impossible to reproduce in in vitro conditions. Therefore it is necessary to use animal models.

Which non-animal alternatives did you consider for use in this project?

We work in vitro with primary Schwann cells and can recapitulate some of the processes by which Schwann cells interact with other cell types. Moreover, we have in vitro assays for tumourigenesis. We have used both model systems to identify important signalling molecules involved in these processes and will continue to do so.

Why were they not suitable?

Many effects that we, and others, can observe and measure in vivo are not reproduced in vitrot. In particular, the role of the immune system and how cells behave in complex tissue environments cannot be reproduced in vitro. Therefore, it is always critical to test our models in animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The proposed experimental designs and methods of analysis have been discussed with our experts in statistics to maximise the information obtained from the minimum resource. Randomisation and blinding methods will be used when appropriate.

Our extensive use of in-vitro methods limits the number of animals required for the in-vivo stage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The proposed experimental designs and methods of analysis have been discussed with our experts in statistics. Where relevant, factorial experimental designs will be used to maximise the information obtained from the minimum resource. For most of the quantitative experiments, sample sizes may be set using power analysis, generally using a significance level of 5%, a power of 80%, and a least practicable difference between groups of 25%. The number of mice per treatment group will be calculated to provide statistical significance.

Our extensive use of in-vitro methods limits the number of animals required for the in-vivo stage. To minimise animal usage, prevent the unnecessary production of animals showing adverse effect and to ensure that animal breeding is inextricably linked to research requirement, the project licence holder will:

Ensure high standards of animal care, welfare and utilise the most appropriate breeding methods.

Ensure that colony sizes are monitored and adjusted within a formal forecasting system to meet the requirements of the research programme(s). Transgenic mouse lines that are not expected to be used in the next 6 months will be suppressed and embryos will be cryopreserved for future use

Ensure that breeding colonies are always kept to their minimum size so as not to over produce.

Ensure that Personal Licensees working on this project are appropriately trained and suitably competent to enable a high success rate to be achieved and thus minimise the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Additionally, to what is explained above, we will use the least number of animals to provide an adequate description, generally on the basis of previous experience (ours, or from the literature). In terms of the numbers of animals required, we expect that 6-8 animals per treatment group should be sufficient to obtain the required results. For the tumorigenesis studies more mice per treatment group may be required, if tumour initiation does not occur in all animals of one treatment group.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse and rats for our studies. Generally, the anatomy, physiology and genetics of the mouse and rat are similar to humans, and thus they represent a powerful system to model human biology and disease. Rats and mice are the animals in which nerve structure and regeneration have been most studied and mice are the in vivo model of choice for tumorigenesis studies. The mouse is the only mammalian species for which transgenic techniques are widely available and is therefore the model of choice for genetic studies. It is widely accepted that mice NF1 tumour models are a good model for the human disease. Moreover, the nerve regeneration process is similar in rodents and humans.

For our nerve injury studies, only one nerve is injured and the animals are able to move freely with such damage. For our tumorigenesis studies, the animals are sacrificed prior to the animals suffering any measurable distress.

Why can’t you use animals that are less sentient?

We are studying processes that need to occur in a living, adult animal often taking place over days- months, therefore terminal anaesthetised animals are not suitable. Less sentient animals do not show similar behaviour or there are not suitable genetically modified animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Each protocol used is carefully designed to ensure physiological significance and to minimise suffering and where appropriate we are developing relevant in vitro models.

The mice and rats are kept in purpose-built accommodation. The animals are mostly kept together for companionship and are given materials to encourage their natural behaviour. The animals are bred and cared for by a dedicated team of highly-skilled technicians. Animals are closely monitored for signs of ill-health or distress. The technicians have the expert assistance of two "named persons", the named Person Responsible for Animal Care and Welfare and the Named Veterinary Surgeon.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Some experiments require the damage of a nerve in mice/rats or injection of cells of substances into nerves, neck, mammary fat pad or the pancreas. These experiments will be carried out under general anaesthesia. The recovering animal will be medicated for pain and closely monitored. Based on previous work the suffering is minimal as the animals are able to move around and feed normally. Any animals showing signs of infection or distress will be humanely culled.

Some experiments require testing for the ability to form tumours in vivo. Animals will not be allowed to develop tumours greater than 1500mm3 and the tumour mass will not exceed 10% of bodyweight. Any animals showing signs of infection or discomfort will be humanely culled.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are in close contact with the animal housing staff and exchange news and advances in the field of animal welfare. The website of the National Centre for the replacement refinement & reduction of Animals in Research (nc3rs.org.uk) is a great additional resource to check for advances and updates on this topic.

29. Development of non-invasive imaging markers for understanding cancer biology and detection of treatment response

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

cancer, imaging, therapy, biomarkers, microenvironment

Animal types	Life stages
Mice	juvenile, adult
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop in vivo imaging markers of tumour metabolism, hypoxia, blood flow and structure which can then be used to evaluate treatment response.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite the use of aggressive combinations of surgery, radiation therapy and chemotherapy, cancer remains incurable in most cases. This is due to a lack of effective treatments as well as an absence of sensitive non-invasive imaging methods that can accurately detect early treatment response so that alternative treatment can be performed before it is too late. While newer drugs and treatment modalities are entering clinical trials, treatment efficacy is generally evaluated in the clinic using a decrease in tumour volume. Unfortunately, a change in tumour volume occurs relatively late after starting therapy and thus, may not be able to detect early resistance to therapy that would warrant a change in treatment. It is therefore, important to develop accurate and sensitive imaging methods that can detect and assess early response to therapy. Using multi-modal imaging technologies, we aim to develop imaging markers that would not only be complementary to each other, but provide sensitive and specific markers for the underlying biology of the tumour. Such markers would be more efficacious than simple changes in tumour volume. In addition, as many of the proposed imaging technologies such as MRI and PET are routinely used in the clinic, these markers could potentially be readily translated to the clinic to aid in cancer diagnosis and monitoring of treatment response.

What outputs do you think you will see at the end of this project?

Unlike traditional methods of evaluating treatment response in cancer such as biomarker assays from blood samples that lack spatial information or post-mortem pathology analyses, in vivo imaging methods provide non-invasive assessment of the tumour in three dimensions, providing a comprehensive picture of tumour heterogeneity. As such imaging can be performed non-invasively under anaesthesia, the same animal can be imaged repeatedly, substantially reducing the number of animals required. Similarly, the same animal can be used as its own control reducing the biological variability, which further reduces the number of animals needed in order to achieve statistical significance.

The proposed programme of work will exploit the complementarity of imaging modalities in probing the basic mechanisms of cancer growth and metastasis. Further refinement of existing methods as well as development of newer quantitative imaging biomarkers will be used as surrogates of early treatment response for a range of therapeutic interventions including conventional chemotherapies, targeted drugs, radiation therapy, and kinase inhibitors as well as cell therapies. The data are typically comprised of images or spectra from which quantitative parameters of tumour perfusion, hypoxia, metabolism and heterogeneity can be derived.

Research outputs will include:

1: The research will provide insight on the ability of preclinical imaging to detect and characterise tumours, and to detect their early response to chemo- or radiotherapies. Drug and contrast agent toxicity and efficacy will also be assessed. Novel imaging methodology will be assessed and optimized for in vivo tumour assessment.

2: Preclinical in vivo imaging will allow reduction in the number of animals by reducing the reliance on post-mortem biomarker assays and cohort studies. Imaging methods are also minimally invasive reducing the burden of suffering on the animal refinement. Therefore,

developing these methods creates an avenue into cancer research with a substantially reduced burden placed on the animals.

3: Most of the imaging methods proposed are functionally equivalent to human clinical practice. The outcomes of the research therefore have a direct and obvious route to clinical translation and potential to influence the standard of clinical care.

4: The results will be published in peer reviewed journals to disseminate the findings of this work so that the research community can use and build upon the scientific findings. We will also share the potential benefits of preclinical in vivo imaging with the research community at large. Any novel methods developed can then be implemented at other sites improving best practice.

Who or what will benefit from these outputs, and how?

Short term:

This project aims to develop a series of imaging markers for treatment response of tumours and to determine whether they can detect treatment response earlier than traditional measures of tumour volume change. This work will directly benefit basic researchers working on cancer biology and treatment, especially regarding treatment response, the mechanisms of response and timescale over which that response occurs.

We also aim to develop novel/improved in vivo imaging methodologies. This work benefits preclinical imaging research as it demonstrates new techniques and ways to interrogate in vivo biological systems, metabolism, and microstructure. This research has general application well beyond cancer as in vivo imaging can be applied to image any tissue (e.g. liver, brain).

The project will also provide insight into tumour response to drug or radiotherapy. It should reveal the timescales of the treatment response in a variety of tumour models providing a solid starting point for further imaging biomarker research and validation.

Medium term:

Clinical research into imaging biomarkers of tumour response to treatment will benefit from the output of this project. As the imaging methods proposed in this project are largely based on technologies routinely used in the clinic, this project will provide a starting point for investigating the potential for a clinical imaging biomarker of early treatment response. The project should also provide a detailed investigation of the biochemical, genetic, and structural changes underlying observed imaging responses aiding in their clinical interpretation.

This project will provide tools to investigate the response of preclinical cancer models to potential new clinical treatments, particularly with regards to blood supply/neovascularisation, hypoxia and drug response. This will benefit preclinical cancer research.

There is the potential to investigate whether such observations as are made in preclinical tumour models can be replicated in a human clinical context. The fact that preclinical and

clinical in vivo imaging is largely based on similar fundamental technology enables relatively straightforward clinical translation of methods. This will benefit researchers working on understanding human tumour biology.

Longer term:

In the much longer term, this project aims to lay the groundwork for potential validation of clinical imaging biomarkers for treatment response in cancer. Without the understanding of the fundamental biology underlying imaging markers of cancer, it is difficult to interpret imaging biomarker results. Such biomarkers would enable clinicians to change treatment regime early in the treatment time course when that treatment proves ineffective/inadequate. Such biomarkers would benefit both clinicians by providing new tools for treatment/diagnosis/stratification of patients and also patients who would receive a more personalized healthcare better adapted to their unique pathologies.

How will you look to maximise the outputs of this work?

Our work is highly collaborative in nature and our ongoing collaborations have resulted in multiple where we have primarily assessed changes in spectroscopic markers of treatment response. Our ongoing collaborations focus on development of a novel MRI marker to measure tissue conductivity as a contrast mechanism to understand the tumour microenvironment. The results of the imaging experiments, including negative experiments, will be published in peer reviewed journals that will aid other researchers.

Our proposed work on PDX models will aid in maintaining the clinical relevance of our work and in driving clinical translation of imaging studies. We have strong collaborations with treating oncologists and with oncology surgeons that helps us focusing the direction of our research such that it remains clinically relevant. This aids in maximising the translational potential of our work and its relevance on clinically relevant aspects of tumour biology.

Species and numbers of animals expected to be used

- Mice: 1050
- Rats: 1050

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Rodents are the most commonly used model animals in cancer research because of the marked similarity of their genome to the human genome, relative ease in the development of tumours, cost and reproducibility. A substantial body of published work exists on which further work can be based, along with available and characterized rodent tumour cell lines. We have chosen to use either juvenile or adult animals as the tumour take rate is much

higher in these age groups and because most tumours in humans occur during these stages of life.

Typically, what will be done to an animal used in your project?

Most animals will typically undergo either injections of tumour cells or surgical procedures for implantation of tumour cells under anaesthesia. Depending on the tumour type (growth pattern), it may take anywhere between a few days to several weeks (8-10, in rare occasions) for the tumours to grow. Longitudinal imaging studies (under anaesthesia) will be performed to evaluate tumour growth, physiology, metabolism or response to treatment with therapeutic drugs. Imaging studies may involve injection of contrast agents and therapeutic studies may involve administration of drugs. Animals may undergo multiple imaging studies to evaluate changes in tumour metabolism or organ function in order to develop novel imaging methods as markers of assessing treatment response, particularly early treatment response.

What are the expected impacts and/or adverse effects for the animals during your project?

Surgical procedures are likely to cause pain. However, these procedures are performed under anaesthesia and the animals recover normally in most cases. Development of tumours may cause discomfort, pain, or other clinical signs and some drugs may induce toxicity. Most of these effects are transient in nature and will be closely monitored. If clinical signs of suffering are present, the animal will be either treated with analgesia or euthanized as necessary using the scoring sheets (Tables 1-5) .

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In naive animals, we expect the severity to be from mild (most) to moderate (about 5 - 10%). In tumour bearing animals, we expect the severity to be mild in subcutaneously injected tumours. In a limited number of cases (5-10%) invasion of subcutaneous tumours into underlying tissue may occur. We expect the severity to be moderate in most orthotopic and metastatic cancer models.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the tumour/host interaction is critical for the support and survival of the tumour, recapitulating the clinical case requires the study of an orthotopic tumour. This system cannot be recapitulated using a different model system. As such, a proper understanding of tumour growth and response assessment can only be performed on live animals. In addition, potential toxicity of the therapeutic agents to normal organs cannot be assessed in cell-based systems.

Which non-animal alternatives did you consider for use in this project?

In vitro studies on cells and organoids can provide some information on the growth pattern or how effective is a novel drug in killing tumour cells. Similarly, use of the chick embryo CAM model has some potential to allow initial testing of novel drugs targeting, for example, angiogenesis. Unfortunately, due to the small size of the tumours grown in the CAM model, and the lack of interaction with host tissue and immune system, its application beyond these initial stages is limited.

Why were they not suitable?

In vitro cell studies or on organoids will not be able to tell us the effects of the tumour host environment (location, blood flow) and its interaction with immune cells of the body (T-cells, macrophages). Similarly, due to an absence of host vasculature these alternatives are unable to determine the role of blood flow in tumour hypoxia and in the delivery, and hence efficacy, of therapeutic drugs in the treatment of cancer. In addition, these alternatives do not mimic the clinical scenario and hence the imaging methods (on cells) would not be translatable to the clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals was estimated that would be sufficient to distinguish tumour from normal healthy tissue when evaluating the relative effects/abilities of different imaging contrast agents and imaging methods. In addition, as we will evaluate several therapeutic drugs, both as monotherapy and combination therapy, we estimated the minimum number of animals needed to detect statistically significant differences between treatment and control animals. This is based on several published studies including studies using the novel choline kinase inhibitor JAS239 that we have previously used in work conducted under our existing Project Licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs EDA tool for experimental design as well as consultation with the statistician, to determine the minimum number of animals needed to test each hypothesis under different experimental conditions. By using longitudinal studies, each animal can serve as its own control further reducing the number of animals required and avoiding the need for larger cohort studies. Similarly, the experiments are designed to provide multiple pieces of data from each cohort of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies in a small cohort of animals to determine contrast agent biodistribution, optimisation of image contrast and sensitivity, or for evaluating drug toxicity while using therapeutic agents. This allows method development/optimization before implanting tumours in larger numbers of animals. This reduces the risk that technical optimisations may compromise the entire experimental cohort. The developed imaging contrast agents as well as imaging protocols will not only be useful for reducing the number of animals needed for drug studies in this project, but this information will be shared with other cancer researchers so that they do not need to repeat these studies. Since we are primarily interested in assessing cancerous tissue, we will share any other tissues/organs with other researchers at the end of our experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals.
Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodent cancer models as they are well established and extensively used in preclinical research settings. The models have been chosen due to their suitability for the imaging technologies to be tested in the project and for being relevant to the human clinical conditions. The subcutaneous tumour models will cause the least suffering to the animals and will be used where possible. Where subcutaneous tumours provide an adequate scientific analogue of the orthotopic tumour, initial studies will be conducted in subcutaneous tumours where the suffering imposed upon the animals is minimized. Orthotopic models are needed to recapitulate the clinical human tumours and may cause some suffering to the animals; these protocols have been designed to minimize this suffering as much as possible.

Use of in vivo preclinical imaging to assess tumour physiology inflicts a minimum of suffering on the animals as the procedures are non-invasive and performed while the animal is under general anaesthesia. As alternative methods to assess tumour biology are invasive and destructive, preclinical imaging is a considerably better option in terms of

animal welfare. Where possible, animal handling and physiological maintenance while undergoing imaging is under continual development and improvement.

Why can't you use animals that are less sentient?

Less sentient models, including development of cancer models in the chicken embryo are currently being evaluated for some studies. Whilst these models are useful for some aspects of the research, such as comparing tumour growth pattern differences between different cancer cell lines, they do not fully recapitulate the human clinical condition. As the tumours are typically grown in the CAM membrane of the chicken egg, it is not possible to evaluate the host-tissue interaction and its impact on tumour survival or upon therapeutic delivery of drugs.

Since we are developing imaging methods to assess longitudinal changes in the tumour microenvironment and to assess treatment response in the same animal, it is not possible to test these methods in terminally anesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The NVS will be consulted and any recommendations for alleviating pain or improving pain management (e.g. analgesics) will be provided to the animals. Monitoring of vital signs during surgical procedures and during imaging is standard practice in our laboratory. In addition, we closely and frequently monitor animals in the post-surgical phase and after the tumours become visible on in vivo imaging. Where a procedure that is less invasive or incurs a lower burden of suffering on the animals (e.g. subcutaneous tumour model) proves to be adequate to answer a scientific question, it will be used in place of more invasive procedures. Optimization of imaging methods as part of this project also allows methods that are demonstrated to be unnecessary, or ineffective, to be omitted from further studies and for total imaging times to be reduced.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the NC3R guidelines for imaging methods and tumour models to perform the studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Non-invasive imaging has been recognised as a key tool in 3Rs, especially for reducing the number of animals required for research. Since the same animal can be imaged several times thereby reducing the need to cull the animals at each time point, conventional cohort-based methods of assessing drug distribution or for assessing treatment response are not required.

In addition, we work with NVS and BSU and actively engage with NC3R to keep ourselves abreast of the advances in 3Rs and have implemented some of the refinement methods already in our existing project. We will continue to work with relevant authorities and will

effectively implement any advances in the 3Rs in relation to our imaging work and tumour models.

30. Individual health and population processes in wild ruminants.

Project duration

5 years 0 months

Project purpose

- Basic research
- Protection of the natural environment in the interests of the health or welfare of man or animals
- Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

Population, Ecology, Genetics, Immunology, Microbiome

Animal types	Life stages
Sheep	neonate, juvenile, adult, aged, pregnant
Red deer	neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the causes and consequences of variation in the gut ecosystem; to determine the sources, mechanisms and impacts of maternal effects in the wild and to determine the mechanisms by which populations are changing under environmental change.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Understanding how free-living populations work is critical to informing the management of over- abundant species and the conservation of endangered species. As our planet warms

and humans modify or destroy natural habitats, the pressures on wild animal populations are changing and intensifying. Our individual-based studies provide detailed insights into how animal populations respond to natural environmental conditions, allowing us to predict how they will respond to new environmental pressures and whether they can persist in the face of rapid environmental change.

What outputs do you think you will see at the end of this project?

Conservation of Soay sheep:

Data and tools to inform and improve deer management: Our research on red deer will benefit landowners and managers of deer populations across the UK. Our study population is the only closely monitored deer population in the region, and by improving our understanding of how and why deer numbers fluctuate naturally in response to environmental variation, we can help inform deer management strategies. For example, outcomes of our research would inform and allow managers to vary their culling strategies depending on annual climate conditions or local habitat conditions to provide a more refined and adaptive deer management. As calving date advances, we can also advise on the determination of open and close season dates.

Discoveries of fundamental scientific importance: Our work will shed important new light on how gut ecosystems, maternal effects and climate change shape the dynamics of unmanaged animal populations. Our findings will offer new understanding and shape thinking across a broad range of related scientific disciplines, including ecology, evolutionary biology, behaviour, space use, demography, microbiology, parasitology, immunology, and epidemiology. There are few, if any, other long-term field studies of vertebrates that have the requisite baseline data and sampling capacity to tackle these questions with the power and completeness offered by the sheep and red deer systems we work with. As well as providing new discoveries relating to our overall aim and individual objectives, we will use our discoveries to make computer models which will offer insights and opportunities for further study and investigation far beyond these two study systems.

Who or what will benefit from these outputs, and how?

The scientific research community (including animal behaviour, ecology, evolutionary biology, demography, microbiology, parasitology, immunology, epidemiology): The new discoveries provided by our research and from the new technologies and computer models we develop using our data and findings. Our findings will help provide important answers to open questions about the role of gut ecosystems, maternal effects, animal behaviour and climate change in driving variation in life histories and population dynamics in naturally regulated systems and provide new tools to more accurately predict the consequences of environmental change or disease outbreaks for wildlife and livestock.

Veterinarians and farmers (Soay sheep research): In the UK, gut worm infections cost the livestock farming industry an estimated £80 million annually, whilst gut protozoan infections result in an estimated 6-9% gross margin reduction. Resistance to available worming drugs is emerging rapidly and is a major current concern for the industry and

policy makers. The non-invasive monitoring methods we will develop to monitor gut parasite communities in Soay sheep can be applied in agriculture to monitor changes after drug treatment to better understand the consequences for different worm and protozoan species and improve targeting of treatment. Furthermore, the epidemiological models we will develop can help identify optimal strategies to reduce worming treatment and will offer a platform for the development of evolutionary models of worm drug resistance to help limit its spread.

Wildlife managers (red deer research): Our research on red deer will benefit landowner and managers of deer and other wildlife populations. Our study population is the only closely monitored deer population in the region, and by improving our understanding of how and why deer numbers fluctuate naturally in response to environmental variation, we can help inform deer management strategies.

Outcomes from our research will allow managers to vary their culling strategies depending on annual climate conditions or local habitat conditions to provide a more refined and adaptive programme of deer management. As calving date advances, we can also advise on the determination of open and close season dates.

Conservation: The conservation of the unique lineage of Soay sheep has intrinsic value to many members of the public, as well as conservationists, historians and farmers. Our research will enable us to monitor threats to the Soay sheep population's viability, for instance from climate change or novel infections, and work with the archipelago's owners to develop and implement mitigating actions. For example, our continuous screening of the bacterial, protozoan and worm diversity in the Soay sheep should identify any novel infectious or pathological agents that might accidentally be. More generally, we anticipate our work on gut ecosystems will have significant impacts for in- and ex-situ conservation management. We will be developing methods to monitor diet and gut community structure from faecal samples, and new techniques to analyse the data produced. Wildlife and conservation managers often need to know how gut health and community structure differs between wild and captive individuals (e.g. for reintroduction programs), and the nature and degree of parasite transmission to threatened wildlife species (e.g. from livestock). Our project can provide readily useable and transferable protocols, tutorials and support in all these areas, offering more affordable and flexible methods and allowing conservation organisations to reduce reliance on commercial kits or services. Not only will this save them money, but crucially it will increase capacity to perform monitoring in developing countries, where sample transfer is difficult for legislative or political reasons.

How will you look to maximise the outputs of this work?

Scientific community: Through publication of our work in respected peer-reviewed journals in appropriate disciplines, and presentations of our work at meetings and conferences. Additionally, our work is publicised via our project websites and associated Twitter accounts.

Veterinarians and farmers (Soay sheep research): Our collaborators at other research institutes and universities have close contact with the veterinary and agricultural communities and we will work with them to communicate relevant findings via displays at

agricultural shows, presentations at meetings and conferences, and educational webpages, videos and animations.

Wildlife managers (red deer research): Our research can help management of red deer in the study area specifically, through communication with the area's owner, and nationally through communication with deer management organisations. We will also use our close contacts within the deer management community across the UK to disseminate findings and support their use in deer management practices and plans.

Conservation: We will continue to work closely with the owner and manager of the area and communicate any findings relevant to the conservation of Soay sheep to them and help develop and implement efforts to mitigate any threats we identify. We have also established links with conservation biologists and will work with them to communicate the methods we develop and discoveries we make about the gut ecosystems of Soay sheep and red deer to the conservation community.

Species and numbers of animals expected to be used

- Sheep: 1800
- Red deer: 650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

If we wish to understand the factors governing variation between individuals in natural populations and how they build up to population level processes like population dynamics and evolutionary change, then we have to study animals in the wild. Abundant diurnal mammals make excellent subjects for this work because they can be easily observed and they cannot disperse by flying or swimming - so it is possible to get very high quality information on breeding success and survival. In each study area we try to catch and mark all individuals as soon as possible after birth in order to be able to follow individual life histories from the start and for the rest of their lives.

Typically, what will be done to an animal used in your project?

Soay sheep:

Typically (for ~90% of sheep born in the study area), a sheep is caught as a neonate in the first few days of life and a blood sample, ear punch and morphometrics are obtained and identification tags applied and then it is released back to its mother. Each August around 50% of the animals resident in the study area are then caught in corral traps and blood samples and morphometrics are obtained. If an animals has not been caught before, ear punches are taken and identification tags applied. All animals are then released to the wild. A sheep that lives for several years may be caught every summer or not at all if it lives on the edge of the study area.

A small number (~35 per year) of untagged sheep, nearly all males that enter the study area to rut, are caught by darting and anaesthesia. A blood sample, ear punch and morphometrics are obtained and identification tags applied before reversal and release to wild. Unless such sheep become resident in the study area, these individuals are rarely caught again in their lives.

Red deer

Typically (for ~90% of deer born in the study area), a deer is caught as a neonate in the first few days of life during the lying out phase and a blood sample, ear punch and morphometrics are obtained and identification tags (and if female, expanding collar) applied and then it is settled back in the place where the mother is expecting it. Once caught, individuals are only very rarely caught again in their lives.

A small number of adults (up to ~20 per year) are caught by darting and anesthesia to allow sampling and marking of animals that have not been caught during early life or to allow for reapplication of lost identification marks before reversal and release to wild. We do not dart animals a second time.

Apart from these events all animals are monitored remotely throughout their lives until lost to death or follow up.

What are the expected impacts and/or adverse effects for the animals during your project?

To minimise adverse effects during capture of young, the handling of neonates is kept to within 10 minutes and animals are observed closely after release to ensure they are successfully reunited with their mother.

To minimise adverse effects during anaesthesia, we avoid anesthetising animals that appear in poor body condition and we watch animals until they appear to be fully alert and mobile. We do not anaesthetise any individual repeatedly.

In the sheep, when we capture animals in corral traps, we monitor individuals closely while they are in the traps, prioritise the processing and release of any animals that appear in poor condition and observe animals closely post release

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All severities are expected to be mild.

What will happen to animals at the end of this project?

- Set free
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In situ ecological, evolutionary and conservation studies such as ours cannot be replaced by studies of cells in Petri dishes or computer simulations, because we need to observe individuals over lifetimes as they face the variation thrown at them by the (unpredictable) natural environment.

Which non-animal alternatives did you consider for use in this project?

We have considered using in silico models of individuals and communities based on existing empirical data collected from free-living animal populations, and we have considered undertaking a purely observational study which did not require sampling or capture of any sort from our deer and sheep populations.

Why were they not suitable?

There is only limited empirical data available from natural populations capable of informing in silico models of the ecological and evolutionary dynamics of such systems. This is particularly notable in regard to the questions of how gut communities influence the dynamics of host populations in the wild, where few if any suitable longitudinal studies exist currently. Without studies such as those we are proposing here, we cannot build well-informed in silico models that would allow us to understand and predict such dynamics. Purely observational studies, without capture and sampling of individuals, would also not provide the necessary information to address our scientific questions as they would not allow us to monitor individuals longitudinally through time or to obtain samples required to link genotype, physiology, gut ecosystems and fitness.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on the number of unmarked individuals we have caught per year over the last five years of study as neonates or older individuals in each study system.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Note that these are not experimental studies in the sense of manipulations with treatments and controls, they are observational studies.

We study all the individuals living in specific study areas, because we wish to understand how events at the level of individuals build into the higher properties of the populations (e.g. population dynamics). The size of these study areas is set so as to be practically manageable for field data collection and to provide sufficient sample sizes for statistical analysis. Although it does not result in any reduction per se, we are extremely keen on sharing our data with other researchers for analyses of new questions, to maximise the use of the data collected across research questions and scientific disciplines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We catch and process as many individuals living in our study areas as possible.

In the case of the sheep born in the study area, ideally this is once at birth and once each August thereafter. For rams born out with the study area which immigrate for the mating season, we aim for only one capture.

In the case of deer we capture once at birth or once as an adult by darting. Occasionally, we dart deer that have lost all their marks to replace the marks.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals.

Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We do not use animal models in the parlance of mouse research. We use wild sheep and deer. Our research relies on observation of what happens to individuals due to natural processes. It would be counter to our objectives to cause such suffering that the lives of animals were affected by capture.

Therefore, our protocols are designed to cause minimal suffering before the animal is released back into the wild. For example, we aim to capture, process and release a lamb or calf within 10 minutes.

Why can’t you use animals that are less sentient?

We require to follow entire life histories so immature life stages or terminally anaesthetised animals would be inappropriate.

Species that are less sentient: There are a small number of long term, individual based studies around the world like ours and they are mostly on vertebrates (mostly birds and mammals). This is a reflection of the fact that it is impossible to collect such detailed information on, for example, individual insects in the wild.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are always looking for ways that might improve our capture and processing for the animals. Whenever more refined approaches become available during the course of this study either through personal communication, publications or veterinary advice, we will investigate their use.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

With our kinds of projects, the appropriate activity here is to analyse the data by the most powerful and appropriate statistical methods possible and to publish our code and data alongside our papers so the community can replicate our analyses. This is now widely encouraged by journals in our research area.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will monitor all opportunities for talks and meetings on the subject and attend where I can and implement advances if they are appropriate.

31. Understanding the Factors that Regulate Wound Healing

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Wound Healing, Diabetes, Ageing, Skin, Senescence

Animal types	Life stages
Mice	adult, aged, neonate, juvenile, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project licence is to provide new insight into the processes that regulate normal wound repair and to specifically identify factors that lead to poor healing in aged and diabetic mice.

This will support development of future targeted therapies to promote healing in aged and diabetic patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Chronic, non-healing wounds (which include diabetic foot ulcers, venous ulcers and pressure sores) are a major problem in the elderly and diabetic. Poor wound healing causes extensive psychological and physical suffering to patients, often leading to severe amputations and loss of life. The number of people affected by chronic wounds is

increasing due to the ever expanding elderly and diabetic populations. It is predicted that by 2025 there will be 5.4 million people in the UK with diabetes, while one in five people living in the UK will be over the age of 65. It is therefore not surprising that non- healing wounds are also a huge financial burden, currently costing the NHS a staggering £5 billion each year to treat.

Unfortunately, many non-healing wounds persist for months to years, preventing patients from living normal lives. Yet poor healing remains an entirely underappreciated area. Current treatments are wholly inadequate due to incomplete understanding of the factors that cause delayed healing in the elderly and diabetic. The work outlined in this application is specifically designed to address this gap in knowledge and support the development of more effective treatments to promote the healing of human chronic wounds.

What outputs do you think you will see at the end of this project?

This work is expected to provide new insight into the factors regulating normal healing and will identify new therapeutic targets for delayed healing in ageing and diabetes. This is important as non-healing wounds cause substantial physical, social, and psychological effects to patients and are a huge economic burden to the NHS. However, there are currently no universally effective treatments for non- healing wounds, with many patients facing life-changing amputations or loss of life entirely.

Academic Benefits

The work outlined in this project licence will uncover new factors that are associated with normal healing and are altered in poor healing (aged and diabetic) wounds. A focus of the project will be understanding how ageing at the cell level contributes to the way that skin heals. Wound healing is a major research field with over 10,000 research articles published each year. Our research will be of interest to a wide range of scientists in fields spanning biomedical sciences, basic biology and chemistry. Publication of this work will additionally allow researchers in other biomedical fields to explore whether our newly identified targets also contribute to other diseases (e.g. cancers). We will publish big data sets (e.g. genetic data containing over 40,000 genes) that can be used by other researchers as a resource to identify targets for their own research purposes. This will reduce the need for others to repeat this work, allow other researchers to use less animals in their own research, and it will increase the likelihood of others obtaining useful and valid results.

We will combine our animal research data with our findings in human models, which will result in a number of high impact publications in field-relevant journals and dissemination at international conferences. This approach will maximise the likelihood that the outputs from this licence will lead to follow on funding and first-in-man clinical studies. In addition, we will have the opportunity to patent our work, both in identifying new targets and re-purposing drugs for wound healing.

Patient Benefits

We will identify new factors that contribute to poor healing and use drugs to target these factors to see if they improve wound repair. We will first validate their effects in our human cell and skin models in the laboratory, before confirming their efficacy in our aged and diabetic mouse models. If these drugs prove effective in promoting wound healing in aged and diabetic mice, this will provide the proof we require to move these drugs into clinical studies for patient benefit within 3-5 years. Overall, this work could result in new, effective and safer treatments for non-healing wounds in humans.

Finally, if we identify a range of targets (biomarkers) that are linked to poor wound healing, then these can be used by clinicians to predict whether patients will heal their wounds or not. This would improve patient care by allowing patients, with wounds predicted not to heal, to receive tailored early treatments before it is too late.

Who or what will benefit from these outputs, and how?

In the short-term (1-3 years) researchers linked to this project (and others in the field) will benefit through disseminating work at conferences, publishing scientific articles, patenting novel targets and re- purposed drugs, and receiving grant funding from pilot studies.

In the mid-term (3-5 years) identification and validation of therapeutic targets for poor healing will lead to setting up clinical trials that will begin to directly benefit patients. At this stage trials can also be set up to determine whether identified targets (biomarkers) can be used to predict whether patient wounds will heal.

In the long-term (5-10 years) we would expect to see wider patient benefit if clinical trials prove effective. This will include:

The clinical implementation of a new and effective therapy for the treatment of non-healing wounds.

The ability to classify patients based on biomarker identification, which will ensure patients receive the care and treatment required to improve healing outcome.

How will you look to maximise the outputs of this work?

Outputs of this project will be maximised as follows:

We will meet often to discuss findings within our group, at seminars and with collaborators, including our clinical partners to determine how the research can be used for patient benefit.

Research findings and publications will be disseminated to the general public through outreach events, patient support groups and via our communications team.

We will aim to publish our findings, even if they do not show a positive effect, to prevent others from repeating the work unnecessarily.

We will publish our big data sets to provide a substantial resource (40,000 genes plus) for the research community to use in their work. This will significantly enhance the field by

allowing other researchers to identify whether their targets of interest are linked to poor healing.

Species and numbers of animals expected to be used

- Mice: 2080

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Wound healing is a complex process that involves multiple cell types that behave in different ways throughout the course of repair. The wound healing process has evolved over millions of years to allow us to heal injuries quickly and efficiently. Lower organisms (e.g. flies and frogs) lack some of this complexity and have very different skin structures to humans. The most widely used models for human wound healing are mice, rats and pigs. These animals go through the same wound healing stages as humans and have very similar skin structure and function. For our work to translate to the clinic to benefit patients, we need to use models that better mimic the human wound healing response.

We use mice because they are the least sentient of the appropriate models and can be easily genetically altered to explore the influence of certain genes to wound repair. There are also widely published and validated mouse models of ageing and diabetes. As our major aim is to understand the factors that drive poor healing in the elderly and diabetic, these models will give us important information about ageing and diabetes that can be used to improve poor healing in humans. We also require adult mice because the immune system and skin of young mice is not yet fully developed.

Wound healing in underdeveloped skin is completely different to what we see in adults and will therefore not give us useful information that can be translated to the clinic.

Typically, what will be done to an animal used in your project?

An animal will either be bought in from a registered supplier or bred in-house for use in experiments. When the mouse reaches adulthood, it will be given general anaesthesia to fall asleep. The mouse will be placed on a heated pad to keep it warm, and the back of the mouse will then be shaved with clippers and cleaned. Two small skin cuts will be made on the back of the mouse while it is asleep, and pain relief will be given via an injection to prevent any short-term pain when the mouse wakes up. While the mouse is still anaesthetised, we may also add treatments to the wounds. The mouse will then be moved to a fresh cage with fresh bedding, food and water and will be placed in a heated, ventilated cabinet to recover. The mouse would only be under general anaesthetic for a few minutes and would wake up within one or two minutes of the procedure. The mouse would then typically be put under brief general anaesthetic every few days to allow us to take digital images of the wounds as they heal. The mouse would not undergo any other procedures.

Imaging would only take a minute and the mouse would only be asleep long enough to take a photograph of the wounds. At the end of the experiment, the mouse will be culled painlessly, and the wounds will be collected for laboratory analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no expected adverse effects from the procedures performed other than potential mild and transient pain. All animals are expected to make a rapid recovery from the anaesthetic and should only experience transient pain from their small skin wounds. They will be given pain relief at the time of surgery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Genetically altered mice bred under the breeding protocol are not expected to experience any harmful phenotype (100%). The wounding procedure itself is not expected to cause more than mild and transient pain (90% of animals). However, the diabetic mice we will use will gain weight and develop diabetes, which in itself increases the severity of their experience to moderate. Up to 20% of the mice we will use in wounding procedures will be diabetic. As diabetes is a progressive disease, we will also only use diabetic mice up until a certain age, to limit the severity of their experience.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The wound healing process has evolved over millions of years to rapidly repair damage to injured tissues. It is an immensely complex process involving interaction between circulating immune cells, local tissue cells, signalling molecules and the tissue matrix that surrounds cells. Skin is also a highly complex tissue which includes blood vessels, nerves, hair follicles, sweat glands and sebaceous glands. There are no current in vitro (cell) or ex vivo (whole tissue) models that come close to fully replicating the complexity of the wound healing process.

A number of animal models are available that heal wounds in a broadly similar manner to humans. The main models used are pigs and rodents, but in this study we will use the least sentient, informative model (mice). There is extensive published literature demonstrating that:

Mouse skin structure broadly resembles human skin structure.

The main processes that are involved in tissue repair (inflammation, proliferation and matrix remodelling) are all found in mouse wound healing.

In addition, this project will explore the causes of delayed healing in the elderly and diabetic. There are well validated diabetic mouse models that faithfully mimic human diabetic delayed wound healing. By contrast, there are no suitable in vitro or ex vivo models of diabetes (which is a whole-body disease). The ultimate goal of our research is to move our findings forward into clinical studies, testing newly identified pathways and drug targets for poor healing wounds. In vivo safety and efficacy data is currently a pre-requisite for obtaining ethical approval for first-in-man clinical studies.

Which non-animal alternatives did you consider for use in this project?

Our group routinely use a range of in vitro and ex vivo models alongside in vivo studies to comprehensively evaluate the wound healing process. This is also essential to maximise the likelihood that effects shown in mice will also translate to the clinic. The assays that are available complement, but cannot currently fully replace, in vivo studies. They can however reduce the number of animals needed.

In Vitro Assays

We routinely use a wide range of in vitro wound healing assays when possible. These include scratch migration assays with different types of human skin cells, assays using human immune cells (e.g. to measure their ability to kill bacteria), assays to measure blood vessel formation, and assays that measure the growth of cells and their ability to make collagen and other skin proteins.

Co-Culture

To better model the complexity of actual wounds, it is possible to grow different cell types together. These models include growing two different cell types in close proximity so they can share secreted factors and communicate with each other (co-culture).

Skin Equivalents

Building upon the concept of co-culture, it is possible to grow very simple skin-like structures in the laboratory that contain some of the cell types found in skin. These are known as skin equivalents. Theycan be wounded and will undergo some of the processes observed during in vivo wound healing but they still lack many important components of actual skin and the wound healing response.

Ex Vivo Wounding

A relatively new model for skin and wound studies involves culturing actual human skin in the laboratory for up to seven days. This skin can be obtained from surplus material following surgical procedures. Ex vivo skin can be wounded and will heal to a certain extent outside the body. But again, it lacks several of the key processes involved in wound healing (such as a circulating immune cell response).

Pathological Wound Healing

Each of the above models can be modified to mimic poor healing, for example by using cells and tissues from aged and diabetic individuals, or by culturing cells in high glucose to mimic the diabetic environment. However, progress in this area is extremely limited and no models fully replicate ageing and diabetic wound healing.

Why were they not suitable?

We do use almost all the above non-animal models where we can. For example, we pre-screen drug compounds using in vitro and ex vivo models before moving to in vivo studies. However, it is widely acknowledged that none of the available models are currently able to fully replace in vivo studies.

There are broad limitations that apply to all the non-animal models. These include:

The inability to evaluate whole body effects on wound healing. Most models use individual cell types in isolation rather than evaluating how they interact together in whole tissue.

The inability to give drugs that affect the whole body (e.g. oral tablets).

The short nature of non-animal models. Human wound healing can take up to two years, while these models generally only last up to seven days.

These models also have limitations when considering ageing and diabetes. Ageing and diabetes change cells throughout the entire body. They also alter the way that cells interact with each other, and they change the environment that cells inhabit in ways that are too complex to mimic in currently available non-animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate to use 1000 mice in our breeding protocol over the course of the five-year licence. This equates to a continual maintenance of four breeding pairs which will collectively produce 200 mice per year.

We estimate to use 1080 mice in our wounding protocol over the course of the five-year licence. An average wounding experiment will use 36 mice with 6 mice per group (range from 24-48 mice per experiment) and we envisage conducting one wounding experiment on average every two months. This equates to 216 mice per year.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Literature searches will be performed to determine the safety of proposed drug treatments for use in animal experiments, and their safe dosages. Safe drug treatments will first be screened (within a range defined from the literature) using our in vitro human wound assays and our established ex vivo human skin wounding model. This will allow us to screen a range of drugs at different concentrations and using different dosing strategies to find the most effective treatments and optimal dosing regimens for use during in vivo experiments. Using this pre-screening technique in non-animal models will significantly reduce the number of mice required for in vivo wounding experiments. The advantages of this approach are two-fold. Firstly, it demonstrates proof of effectiveness prior to undertaking in vivo studies, and secondly, it increases the likelihood that observed in vivo effects will translate into human clinical studies.

We have consulted the NC3R's Experimental Design Assistant in planning our studies, along with the PREPARE guidelines. In all experiments, standard protocols will be used. These include all relevant control groups, treatment randomisation with each mouse being an experimental unit, time-matching of control and experimental groups, and matching for gender, age and weight. We will not use sham surgery controls. Data from pilot studies will be included as experimental data where possible to reduce the number of mice used in subsequent studies. For example, if a pilot study using 3 mice per group showed that 8 mice per group were required to gain significant findings, the follow-on study would only use 5 mice per group and would be combined with the pilot study to give 8 mice per group.

All analysis will be carried out blinded so that researchers do not know what groups each sample was placed in. Interventions and outcome measures will be optimised to validate the study hypothesis with the minimum number of animals. We will photograph wounds throughout the experiment to assess healing over time and we will only collect the mice at specific time points post-injury. By photographing wounds and only collecting mice at one or two healing time-points, we will significantly reduce the number of mice that we will use (as we will not need to collect animals each day/every few days). We will collect mice at time-points post-injury that will be the most informative based on our extensive experience of the mouse wound healing response. We will also maximise the amount of tissue we collect from each animal, collecting samples for cell isolation and using two wounds per animal, with each wound collected and evaluated for multiple outcome measures. We follow a standard protocol for tissue collection and use established laboratory procedures.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Extensive literature searches have been carried out to avoid the unnecessary repetition of experiments. The work of others in the field will be constantly reviewed by the research team and disseminated to every member of the group. We will reduce experimental variation significantly by extensive training of investigators, the use of optimised techniques and by reducing factors such as age, genetic background and hair cycle stage.

We will use extensive in vitro and ex vivo pilot studies to optimise experimental treatment conditions prior to undertaking in vivo work. Where possible we will maximise the use of tissue obtained from experimental animals, sharing with other groups as appropriate. We

will continuously monitor breeding pairs and litters to ensure we do not overbreed mice. Mouse littermates that are not genetically altered will be used as experiment controls. Additionally, our institution routinely sends out a tissue sharing list to allow other researchers to make use of any surplus animal tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice exclusively as they are the least sentient species that are appropriate to address the aim of this project. We will use highly validated and optimised dorsal incisional and excisional acute wounds (small injuries to the skin on the back). We have chosen these wounding methods as they cause minimal discomfort compared to other models (e.g. burns, infection and pressure ulcers) but still allow us to address the aim of this work. There is an upper limit to the size of the wounds we will use to minimise the amount of inflammation and pain to the animal. In addition, mice will be put to sleep briefly for the procedure and will be given pain relief to reduce any post-surgery pain. From experience, pain experienced will be short-lived and mild and mice will make a rapid and full recovery, returning to normal behaviours within minutes (e.g. grooming and eating).

Mice will be singly housed after the procedure but only for the minimal time needed to ensure early wound healing is not affected by mouse interaction (maximum two weeks). Treatments will always be administered by the least invasive appropriate method, often topically applied to the wound.

Why can’t you use animals that are less sentient?

We will use mice exclusively as these are the least sentient species that are appropriate to address the aim of this project. Other models are available ranging from embryos and developmental models (flies and frogs) through to large animals (pigs). A main focus of this project is understanding the factors that drive poor healing in ageing and diabetes. As such, embryonic and developmental models, while less sentient than mice, are not appropriate as they cannot model human ageing and diabetes. A potential less sentient model to use would be zebrafish. While zebrafish can be a useful model for laboratory research, there are a number of reasons why they are not a good model for human healing. Zebrafish skin structure is significantly different to human skin. The epidermis of the zebrafish is also covered with scales and lacks the hair follicles and glands present in the skin of mammals. In addition, wound healing stages in zebrafish occur in isolation, and do not overlap like in mice and humans. Another difference is that zebrafish heal with little scarring, while in humans, this only occurs under very specific circumstances (e.g. in the

mouth and during fetal development). As a result, the mouse has been selected as the least sentient species available to adequately assess aged and diabetic mammalian healing, but also has the advantage of being able to be easily genetically altered. Terminal anaesthesia is inappropriate for this study as we will be assessing wound healing over a time frame of days and weeks and cannot keep the animals under general anaesthetic for this amount of time as it is harmful and not practical.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

After all procedures, animals will be monitored at least daily for signs of distress. Following surgery, animals will be placed in a clean cage inside a warm, ventilated cabinet and monitored until they recover. Analgesia will be administered as required to alleviate short-term discomfort to the animals. Extensive training will be provided to researchers undertaking experiments to ensure standardisation of the wounding technique and to ensure awareness of animal welfare and humane endpoints. Any treatments will be administered using the least invasive method to reduce harm to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the PREPARE guidelines to design and implement experiments in the most refined way. There is no official best practice guidance for wound studies per se, but there are a number of recently published methodological reviews (e.g. Rhea and Dunnwald, 2020, J Vis Exp) that we will use to establish standard operating procedures and ensure best practice. We will continuously review our protocols and procedures in line with updates to the PREPARE guidelines and published literature.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly attend international conferences and are part of a large network of in vivo researchers. Specifically, we have carried out extensive literature searches to ensure this project avoids the unnecessary repetition of experiments and we will keep up-to-date with the scientific literature.

We will always adhere to the ARRIVE Guidelines 2.0 (du Sert et al., 2020, Plos Biology) when publishing and the PREPARE guidelines when designing and implementing experiments (Smith et al., 2017, Lab Animal). We subscribe to the NC3R's, FRAME and Animal Free Research UK newsletters and keep abreast of topical advances in 3Rs research and policy. To ensure that the research team are kept up-to-date with the latest developments in the 3Rs, we will hold regular group meetings, attend institutional seminars and review pertinent case studies.

32. Imaging of Cell Therapy In Tumour Models

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Cancer, Therapy, Imaging, Stem cells, Immune cells

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to evaluate cell therapies for the treatment of cancer and compare them to other available cancer therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer affects 1 in 3 people worldwide, with incidence rates projected to rise by 2% in the UK between 2014 and 2035. Cell therapies such as chimeric antigen receptor (CAR) T cell therapies have shown remarkable results in patients with blood borne cancers but have shown highly variable results in patients with solid tumours. This program of work will develop imaging biomarkers to assess cell uptake and infiltration in correlation with tumour therapeutic readouts to aid the development of cell therapies for the clinic and compare their treatment out comes with those of available drug treatments (clinical gold standard) for known cancer types.

What outputs do you think you will see at the end of this project?

This project aims to develop new cell labelling imaging approaches to determine the effectiveness of cell therapies to cancer. We aim to produce cell labelling products capable of monitoring therapeutic cells throughout the body that can be translated to clinical practice. These, cell labelling products will provided new information on the fate of cells after injection which will benefit scientists and clinicians working on the development of cell therapies. We have already produced one cell labelling product that has been approved for a first-in-man study where it will be used to image a cancer cell therapy in humans with lung cancer. Due to the increase in the development of cell therapies for cancer I therefore expect the demand for these cell labelling imaging strategies to continue to grow over the next 5 years of this PPL in accordance with clinical need.

Expected outputs derived from this PPL:

Products:

New cell labelling imaging agents. New information:

Although cell therapies have been applied to hundreds of clinical trials very little is actually understood about where the cells go and how long they live for within the body. We aim to answer these important questions.

Publications and public engagement:

The data obtained from this work will be communicated by publications to scientists and by public science engagement events.

Clinical Translation:

The best cell labelling imaging products will be translated to the clinic for imaging cell therapy in human cancer patients.

Who or what will benefit from these outputs, and how?

The overall aim is to develop and test the safety of cell therapies in a range of tumour models to enable their clinical translation.

Who will benefit:

Basic science - The novel cell labelling products developed in this proposal will have a direct benefit for academic research scientists (both nationally and internationally) that are working on cellular therapies, medical imaging or the underlying scientific disciplines used to make the cell labelling products (e.g. chemistry, genetics).

Clinical translation – The ability to accurately track cells to their target site and monitor cell integrity over time provides crucial information on how effective the cell therapy will be and how long the cell therapy will last, which aids clinicians plan effective patient treatment plans.

Patient benefits: CAR-T cell and stem cell therapies are aimed at cancer patients with advanced cancer where all other therapies have failed. CAR-T cell therapy has already shown benefits in patients with blood cancers but we aim to apply this therapy to all cancer types. Whereas stem cell therapies have been shown to be effective in lung cancer which is one of the most lethal cancers in the world today.

Clinical investment: The global commercial cell therapy industry was estimated to have an annual turnover of £8.7 bn ($11.2 bn) in 2017 and is estimated to grow to £26.6 bn ($34,4 bn) by 2025. The UK regenerative medicine platform is also investing £45M over 8 years and is working in conjunction with the Technology Strategy Board's Catapult which represents £1bn of private and public sector investment across seven centres of which cell therapies is one. The charitable investment in regenerative medicine was approximately 20% of public funding between 2005 and 2009, and it is anticipated that charitable funding will also increase significantly.

Expected short and long term benefits.

Short term: To design and test new cell labelling products sensitive enough to be able to image cells throughout the whole-body and use them to assess the distribution of cells after transplantation and optimise their uptake in target organs by changing the injection route. We will identify the effectiveness of cell therapies in a range of tumour models and compare these outcomes to standard drug therapies such as chemotherapy. We will also identify potential safety considerations that could lead to long term health concerns.

Long term: To provide knowledge and clinical cell imaging products to aid the translation of cell therapies to clinic practice for the treatment of cancer patients.

How will you look to maximise the outputs of this work?

This project is a continuation of a previous 5 year project which has been highly successful in the production of cell labelling products and publications. The work has facilitated numerous new collaborations with experts within the cell therapy and imaging communities as well as clinical translation. This project proposal will maintain these collaborations to ensure continuity between the old project and the new. New collaborations will be including the use of computational modelling, where data sets derived from our cell imaging can be used to train the computer simulation to predict cell behaviour thereby reducing the use of animals in our future research.

We will distribute our data through the most appropriate channels, such as by presentations at national and international meetings, publications and public engagement events.

Species and numbers of animals expected to be used

- Mice: 7000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

The mouse is the most appropriate model species for this investigation as they are the lowest animals in the evolutionary tree in which suitable models of cancer can be carried out. The project also requires the use of genetically modified mice strains where the mice have a compromised immune system to prevent the rejection of human cell lines. It is important to test our cell labelling products in human cells so that they are safe for use in clinical practice.

The rat will also be used in the case of protocols 1 and 3. These maybe wild type or athymic nude rats. Rats have previously been used as the main species of choice for brain metastases as their brain is bigger than the mouse with better image resolution. They also have a bigger blood pool which allows for serial blood sampling for quantification of tracer pharmacokinetics which is essential for translation into the clinic. This quantification in rats is more accurate mice. As protocol 1 covers the development of tracers in control animals including pharmacokinetics, and 3 covers the brain metastases model, rats will only be used in these two protocols.

Typically, what will be done to an animal used in your project?

In general animals will receive an injection of tumour cells to induce tumour formation, which may be via a surgical procedure. All surgical procedures are short procedures (up to 20 minutes) and are used by trained experts. The use of surgical procedures has also been refined by the use of ultrasound guided techniques where possible to aid animal recovery.

Animals are scanned using non-invasive imaging (1 to 2 times weekly up to 1 hour) to monitor tumour development. Once tumours have reached treatment size (typically within 2- 3 weeks) the animals will be randomised into groups for treatment.

Tumour bearing animals will be given either single or multiple doses of therapy (cell or drug) dependent on the route of injection e.g. intravenous may be given multiple times (dependent on the dosing table) whereas injections via a surgical route will be given only once.

Animals will be continued to be monitored non-invasively via imaging (see above) to follow treatment outcomes such as changes in tumour size and tumour cell death. The typical duration of experiments will be 1 to 2 months depending on the growth rate of the tumour.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will experience tumour development and tumour treatment and may experience weight loss. Animals will be monitored 2 to 3 times a week and any animals experiencing 10% weight loss will be weighed daily. As tumour growth can also affect animals weight, they will also be assessed by their body condition and behaviour.

Surgical procedures and cell injections can cause internal bleeding or vascular occlusion. Animals are assessed rigorously during procedures and directly after upon recovery, any animal showing evidence of bleeding or vascular occlusion will be humanely culled immediately.

If any animal reaches 15% weight loss with at least one other clinical sign, body condition score <2/5 or exhibits any evidence of with 24 hours: neurological changes such as seizure/fitting, respiratory distress, marked piloerection with hunched posture, reduced mobility, pallor, persistent ocular/nasal discharge, or diarrhoea, the animal will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Non-invasive imaging will be used to monitor tumour development and tumour response we have therefore refined our expected impacts/adverse effects as much as possible as we are able to identify small morphological changes in vivo prior to the onset of clinical signs, thereby using much milder disease.

All tumour models and injection routes are routinely used within the group and undergo constant refinement to keep the severity level and potential adverse effects as low as possible. The severity is maintained as moderate due to the need for tumour modelling, surgical implantation and non-invasive imaging.

Expected mortality: In previous experiments we observed a low (0-5%) mortality as a result of these experimental procedures (NB. mortality is mainly from cell injections rather than the experiments as a whole).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to investigate the potential of different cell therapies to target and kill cancer throughout the body. Cell therapy is dependent on cell delivery and cell infiltration into tumour tissue which is highly affected by the solid tumour environment and which organ the tumour is situated in within the body. Cell assays cannot replicate all of the complexities of the solid tumour environment within a host making cell therapy unpredictable. This proposal aims to address this by applying imaging to monitor cell therapy in mouse models of solid tumours.

Which non-animal alternatives did you consider for use in this project?

We use in vitro assays to enable us to identify the therapeutic potential of all cell therapies prior to moving into a mouse tumour model system. We also aim to use our imaging data to train computer generated model systems that can be used to predict cell therapy outcomes.

Why were they not suitable?

Although in vitro assays can replicate some of the events present in cancer they do not replicate the biological, chemical and mechanical properties of the body, organ or solid tumour tissue. To optimise cell delivery and infiltration to solid tumours their behaviour needs to be monitored within a host with underlying disease. For this reason, there is no in vitro alternative to animals that we can consider.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate the numbers of animals we will use from data obtained from previous experiments or from the literature. However, when working with novel tracers, tumour cell lines and cell therapies, means and standard deviations will be taken from preliminary pilot studies consisting of 3 to 5 animals. The experimental design of these preliminary pilot studies will include appropriate controls to allow the detection of the effect of change of individual variables. Appropriate statistical analysis methods are then applied to the data obtained to obtain our estimates.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All in vivo studies are designed with assistance from the NC3Rs Experimental Design Assistant.

Monitoring animals by in vivo imaging makes a major contribution to the reduction in animal numbers as each animal can be scanned over multiple time points following disease progression and therapy. This allows us to use fewer animals to achieve the same statistical power as conventional designs in which cohorts of animals are required for each time point. Therefore, a classic experiment where 5 animals are humanely killed at 3 time points for histological analysis would result in 15 animals per group. Whereas, with imaging this can be reduced to 5 animals per group as each animal is scanned to obtain the results at the 3 time points.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In establishing a new cell labelling product, tumour model or assessing a new cell therapy a small number of mice (3-5) will be used as a pilot study where the mice will be assessed and adjustments made to make sure that models are robust with minimum severity before being applied to a full experimental cohort. This will reduce the total animal number and constantly refines our protocols.

We aim to use the imaging data derived from this project for computer modelling where our 3 dimensional data of cell distribution will be used to train the computer simulations which will be used to model and predict cell behaviour.

Tissue will be taken for histology, immunohistochemistry and ex vivo validation to ensure our therapeutic cells are within the tumour tissue and to confirm the therapeutic effect shown by imaging. We ensure that any tissues generated from experiments are archived and stored appropriately therefore ensuring that unnecessary repetition of experiments is not necessary.

As part of good laboratory practice, all experimental designs including data analysis will be approved by the PPL holder before the experiment can start, and a protocol record for each experimental animal has to be kept by the PIL holder which will include the description of the experimental steps, treatments, and animal monitoring.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most appropriate model species for this investigation as they are the lowest animals in the evolutionary tree in which suitable models of human cancer can be carried out, no use of species phylogenetically closer to humans is proposed.

The tumour models we have chosen are well documented and well validated to produce reliable results within a moderate severity band. The tumour inductions are short procedures, and therefore the animal recovery is rapid and no adverse effects are expected. Visible tumours will be measured by callipers.

Whereas internal tumours will be monitored and sized by rapid MRI, CT, BLI or ultrasound scans to generate growth curves. Due to this, tumour growth in all settings, will be closely monitored and will not be allowed to reach a point where it may cause any discomfort to the animal.

The rat will also be used in the case of developing of cell tracking techniques within the brain. These maybe wild type or athymic nude rats. Rats have previously been used as the main species of choice for brain metastases as their brain is bigger than the mouse with better image resolution. They also have a bigger blood pool which allows for serial blood sampling for quantification of tracer pharmacokinetics which is essential for translation into the clinic.

Why can't you use animals that are less sentient?

As stated above the mouse is the most appropriate model species for this investigation as they are the lowest animals in the evolutionary tree in which suitable models of human cancer can be carried out.

Host microenvironmental changes during animal development will influence tumour growth and cell behaviour which will continuously alter until adult hood adding unknown variables to the data and may result in irreproducibile data being generated. Adult animals have reached full organ development and therefore removes this variable, also due to size of the animal proposed adult animals are necessary for the procedures required for tumour implantation, cell injection and imaging to be conducted using refined and practised methods.

Tumour models will be generated in adult mice at ages 6 to 8 weeks to ensure tumour reproducibility and cell therapy as our data has indicated that increased age effects tumour implantation, animal recovery and immune status in some animal strains.

The aim of this project is to assess cell therapy in tumour models which are conducted over a period of weeks not hours we are unable to use terminally anaesthetised animals to conduct all aspects of these experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals undergoing surgical procedures will receive peri-operative analgesia. Animals will be monitored intensely after surgical procedures and after cell implantation to check for clinical signs. Directly after the procedure the animals will be constantly monitored until they have completely recovered from the anaesthesia. Animals will then be monitored every 20 minutes for the first hour, then every 1-2 hours within working hours and first thing the next morning. If no clinical signs are shown and the wound shows no infection or bleeding then the animals will be monitored 2 to 3 times a week.

The procedures within this project are run routinely and, in our experience, animals recover rapidly after surgery and very rarely require further post-operative analgesia after 24 hours except in the case of suture failure where the wound has needed to be re-sutured (within first 24 hours).

When assessing animals after surgery and tumour implantation the assessment of pain will be assessed using the "grimace scale" and will form part of an animals clinical signs assessment. A post-surgical/cell implantation monitoring sheet will be completed each time the animal is checked over the first 24 hours using the animal's unique identifier code.

The monitoring sheets are specific to each of the protocols and cover the expected clinical signs for that protocol.

Animals will be weighed 2 to 3 times a week. Any animal that reaches 10% weight loss will be weighed daily to make sure that it does not exceed the 15% weight loss.

Animals will also receive ultrasound guided injections where possible rather than surgical routes. This reduces any risk to infection and vastly increases animal recovery and limits pain.

To maintain that animals are not fasted for longer than designated time frame and if food cannot be removed at the desire time, we will make sure that a measured number of pellets will be left in the hopper.

Lastly, we will constantly refine our protocols during the 5 year duration being guided by our imaging developments and the support of the NACWO and NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All in vivo studies are designed with assistance from the NC3Rs Experimental Design Assistant and will abide by the ARRIVE guidelines. Myself and my group regularly consult the NC3Rs resources available in conjunction with our establishments guidance, training and meetings.

However, as mentioned previously imaging measurements can often be used to refine protocol with milder disease than with other assessments by providing earlier humane endpoints and rigorous inclusion/exclusion criteria. By working closely with the NACWO and NVS we aim to incorporate imaging mediated refinement where possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All PPL holders must attend yearly 3Rs meetings. We are committed to the principles of the 3Rs and will continue to seek the support of local NC3Rs representatives.

With the support of our Named Animal Care and Welfare Officers (NACWOs) and Named Veterinary Surgeons (NVSs) I strived to use our imaging methods to refine our tumour models and surgical protocols i.e., develop ultrasound guided injections rather than surgical implantation.

When using imaging measurements of small morphological changes in animals, it is often possible to use milder disease than with other assessments. Non-invasive imaging of animal disease models can therefore provide earlier humane endpoints and rigorous inclusion/exclusion criteria.

33. Investigating how genomic imprinting influences brain and behaviour

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Behaviour, Brain, Imprinted genes, Pregnancy, Neurodevelopment disorders

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how genes subject to genomic imprinting influence brain and behaviour, and how expression of these genes may in turn be influenced by the maternal environment before and just after birth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In animals, genes that are subject to genomic imprinting (referred to as 'imprinted genes') are unique to mammals. Although they represent a small proportion of the genome - ~200

genes of a total ~22,000 - correct activity, or expression, of imprinted genes is absolutely critical for normal development to proceed. Unsurprisingly, mutations that affect imprinted gene expression in humans have been linked to several genetic disorders, including many neurodevelopmental disorders such as Prader-Willi and Angelman syndromes.

We want to understand how imprinted genes influence brain and behaviour. Many imprinted genes are expressed in the brains of mammals, and can influence behaviour directly. However, our previous work has shown that imprinted genes expressed in other tissues, such as the placenta, can also influence behaviour via indirect mechanisms. This project will investigate both the direct and indirect action of imprinted genes on brain and behaviour. In addition, we will also examine how the pre- and post-natal maternal environment may alter the expression of imprinted genes, which in turn has knock-on effects on brain and behaviour.

What outputs do you think you will see at the end of this project?

The main outputs will be extensive datasets, many of which will be included in scientific research publications.

Who or what will benefit from these outputs, and how?

The main beneficiaries of this work will be the research community, particularly those involved in understanding imprinted genes. Additionally, as much of the work outlined here has a direct link to neurodevelopmental disorders (e.g. Prader-Willi syndrome) it is hoped that this research will have translatable benefits (such as the guidance of best practice and/or development of therapeutics); this will be helped by our relationship with the patient charity, the Foundation for Prader-Willi Research (US).

How will you look to maximise the outputs of this work?

We will strive to make all our data freely available via the use of project planning and data repositories such as the open science framework (osf.io). Preregistering projects will allow scrutiny of methodology and statistical methods before the experiments have begun, thus further refining any experiments involving animals. Similarly, where possible we will make use of registered reports, which will lead to further refinement of methodology before the experiments start, and will also mean that any data generated, whether positive or negative, will be published. All data generated from these projects will be made freely and openly available.

We will also adopt open publishing practices where possible. In addition to using preprint servers such as bioRxiv, we will, funds permitting, publish our work as Gold open access articles.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

It is necessary to perform whole animal studies to achieve the experimental aims, since in all instances integrated physiological systems are affected. Behaviour is an emergent property of brain function, involving co-ordinated activity both within and external to the CNS. It is also not possible to model pregnancy using cell lines or any other in vitro system. Pregnancy and placental development are features of mammals generally not observed in other vertebrates. Consequently, it is not feasible to use a non-mammalian model.

Mice are the best experimental model for this project since their physiology is well studied, they are genetically modifiable and they are the lowest vertebrate group appropriate for studying fetal growth and pregnancy.

Typically, what will be done to an animal used in your project?

The aim of this project is to understand the brain and behavioural role of a unique group of mammalian genes called the imprinted genes. Typically, we will modify the expression of one or more of these imprinted genes and look at the consequences of this manipulation on brain development and function. To do this we subject an animal to a number of tests that examine basic behaviours such as activity levels or anxiety. An animal may then also be tested on a more complex test of cognition, examining memory, attention or impulse control. In total, all these experiments may last 6-8months. Another particular focus of this project is parenting behaviour. Here we would monitor parenting behaviour remotely via video cameras in the mouse's home cage or examine parenting behaviour of males and females using a series of tests that measure the time taken to perform basic parenting behaviours such as nest building or gathering the pups into the nest. These experiments last 3-4 weeks in total. There are possible links these groups of tests. For instance, a pup exposed to poor parenting behaviour may then be tested on aspects of cognition when adult.

In addition to genetic alteration, we know that the expression of imprinted genes is also affected by the environment in early life. As part of this project, we will also examine the effects of certain adverse environments on imprinted gene expression and subsequent behaviour. This could be an altered maternal diet during pregnancy (duration of 18.5 days), or being exposed to poor parenting behaviour whilst a new born.

We will also explore the possible links between the genetic alterations and early life environment. For instance, a pup exposed to poor parenting behaviour may then be tested on aspects of cognition when adult.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of impact seen in the animals used on this project will be behavioural in nature, and many may not display any abnormal behaviour until probed to do so; i.e. normal functioning within the homecage will be unaffected, and behavioural abnormalities will only emerge upon specific testing.

These abnormal behaviours are likely to be present throughout the lifespan of the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (~90%) of the genetically altered mouse lines we will use are classified as “mild”, with a minority classified as “moderate” due to the survivability issues. In addition, we aim to examine the consequences of altering the maternal environment, in particular maternal diet, on gene expression in the offspring brain. We have refined this protocol to minimise harms to the pups when born, but generally this is classed as moderate.

Most of our behavioural testing is either unregulated or classed as mild (~50%). However, to motivate animals to learn and perform some of test of cognition we will be restricting their normal access to food or water. This has no long lasting effects, and indeed we have shown it can prolong the lifespan and health of the animal, but nevertheless it is as moderate (~50%).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is necessary to perform whole animal studies to achieve the experimental aims, since in all instances integrated physiological systems are affected. Behaviour is an emergent property of brain function, involving co-ordinated activity both within and external to the central nervous system. Consequently, changes in gene expression processes may affect brain functioning, and hence behaviour, at multiple levels. In particular, we are investigating parental behaviour, and the link between gene expression and maternal diet on changes in offspring behaviour. It is not possible to model pregnancy using cell lines or any other in vitro system. Finally, genomic imprinting is a uniquely mammalian phenomena in animals, therefore it is not possible to use other model species.

Which non-animal alternatives did you consider for use in this project?

We considered using in vitro, or cell culture models. Where possible, we will use these cell culture to directly examine the effect of manipulating a gene on neuron physiology.

Why were they not suitable?

Much of this project is focused on the physiological interactions between mothers, placentae and foetuses; and then, following birth, the relationship between mum and/or dad, and the newborn offspring. Currently, this aspect of behaviour, which involves complex co-ordinated interaction both within, and external (i.e. from the newborn pup) to the central nervous system, cannot be modelled in a cell culture system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we estimate will be used in the course of this project is based on our experience and knowledge of breeding the necessary GA lines, and the numbers of animals required for a given experiment.

This number deviates from the simple sum of the animals used in each protocol (2000+200+1000+2000) because some animals will be used in more than one protocol. For instance, some animals initially bred under Protocol 1 will then have their parenting behaviour tested under the aegis of Protocol 3. Similarly, animals that were exposed to abnormal maternal diet in utero in Protocol 3, may then go on to be tested for behavioural abnormalities as adults under the aegis of Protocol 4.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As a routine measure, we carry out power calculations based on previous experimental data, generated by ourselves and others, in order to optimise the size of the experiment. To aid this, and our experimental design generally, we use the Experimental Design Assistant provided by the NC3Rs.

We also have the benefit of experience in making initial estimates of the numbers needed in a behavioural study to obtain statistically significant differences. We examine the reliability of our conclusions using a range of statistical tests, suitable for both parametric and non-parametrically distributed data. We make routine use of multifactorial methods (e.g. ANOVA, ANCOVA) that combine the power to detect significant differences with the minimum number of subjects. We have substantial experience in the use of statistics and we take advice from, and interact closely with, University statisticians, as well as making use of external sources of guidance (e.g. NC3R's Experimental Design Assistant).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have a number of close collaborators. Because our research addresses similar questions, but looking at different biological processes, where possible we reduce our numbers by combining studies.

Example A: Breeding and maintenance of GA lines used by both our group and collaborators (e.g. Cdkn1c, Syn-cre), is carried out only by one group.

We cryopreserve lines when not in use.

We maintain all our breeding lines in a single facility so that lines are not duplicated

Where appropriate, we use animals that are not GA but have been born as part of the process of generating GA animals that are not needed, as controls. These animals may be used in new mattings (Protocol 1) reducing the requirement for wild type animals from wild type mattings.

Where appropriate, we will use non-invasive techniques to examine brain function (eg MRI scanning). MRI also allows longitudinal studies using the same animals, thus reducing numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are chosen as an experimental model since their physiology is well studied, they are genetically modifiable, and they are the lowest vertebrate group appropriate for studying fatal growth and pregnancy.

Many of the behavioural methods used in this project are measures of spontaneous natural behaviours in response to a stimulus. Of those where training and learning is required, we only use appetitively reward tasks.

Why can’t you use animals that are less sentient?

Genomic imprinting is a uniquely mammalian phenomena in animals, therefore it is not possible to use other model species such as fruit fly or fish.

In addition, a large part of this project is focused on the physiological interactions between mothers, placentae and foetuses; and then, following birth, the relationship between mum

and/or dad, and the newborn offspring. Currently, this aspect of behaviour, which involves complex co-ordinated interaction both within, and external (i.e. from the newborn pup) to the central nervous system, cannot be modelled in a cell culture system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely genotype animals from hair samples. Where possible, we will avoid ear snips for genotyping and use hair sampling. For example, experimental cohorts (behavioural and neural studies) are genotyped from hair samples. Whilst genotyping from hair is appropriate for experimental cohorts that will be re-genotyped at the end of testing, a robustly reliable genotyping method is required for animals used for breeding. Consequently, these animals will continue to be genotyped from ear-snip samples.

Together with collaborators we have refined the manipulation of maternal diet whilst pregnant by returning them to a normal basal diet at E18.5 (just prior to birth). For the low protein diet in particular, this modification of the procedure reduces the risk of cannibalism of the pups by the mother shortly after birth but still produces the changes in offspring brain gene expression and behaviour we aim to study.

Environmental enrichment is provided for all animals, which can include cardboard houses or cardboard tubes, chew sticks and the avoidance of singly housed animals where possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs publications and blogpost; best practice guidance from AWERB and NACWOs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

In addition to local advice from the AWERB and NACWOs, we will also regularly engage with NC3Rs via the Regional Programme Managers.

34. Neuronal communication in fish

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

zebrafish, vision, neuron, synapse, olfaction

Animal types	Life stages
Zebra fish	embryo, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to understand how neural circuits in the retina and other brain centres process sensory information.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is expected to improve our understanding of nervous system function in three main areas. First, the basic processes by which neurons communicate at the synapse. Second, the way these processes transfer visual information in the nervous system. Third, the manner in which visual, olfactory and mechanical stimuli interact in the brain ("sensory integration"). We also expect that the methods we develop will be applicable to other areas of the brain, for instance allowing us to investigate the processing of olfactory signals, or motor signals in the cerebellum. Previously, it was only possible to monitor the activity of a few synapses at any one time, but we have made a major advance by monitoring the activity of hundreds of different synapses and neurons simultaneously. This will allow us to investigate how a large number of synapses cooperate to carry out an information-processing task. This work is immensely worthwhile because it directly addresses a key

function of the nervous system: the transformation of signals as they are transmitted between neurons.

What outputs do you think you will see at the end of this project?

This work is expected to improve our understanding of nervous system function in three main areas. First, the basic processes by which neurons communicate at the synapse. Second, the way these processes transfer visual information in the retina. Third, the manner in which visual, olfactory and mechanical stimuli interact in the brain ("sensory integration"). We also expect that the methods we develop will be applicable to other areas of the brain, for instance allowing us to investigate the processing of olfactory signals, or motor signals in the cerebellum. Previously, it was only possible to monitor the activity of a few synapses at any one time, but we have made a major advance by monitoring the activity of hundreds of different synapses and neurons simultaneously. This will allow us to investigate how a large number of synapses cooperate to carry out an information-processing task.

This work is immensely worthwhile because it directly addresses a key function of the nervous system: the transformation of signals as they are transmitted between neurons.

Who or what will benefit from these outputs, and how?

These outputs will benefit many people by adding to our understanding of sensory processing in the brain. This knowledge may be useful in understanding causes of blindness and other diseases of the nervous system as wall as providing examples for bio-inspired robotics.

How will you look to maximise the outputs of this work?

We will maximize the outputs by collaborating directly with several other laboratories in Europe and the US; by communicating our work through seminars and meetings; by publishing papers in scientific journals and through various websites, including our own.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): A maximum of 42000 over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of life stages.

Larval zebrafish are an excellent animal for studying the senses of vision and smell, for two major reasons. First, we can manipulate genes in this animal in a relatively straightforward way. Second, the larva is relatively transparent so that we can use specialized microscopes to observe the activity of neurons and synapses as the animal responds to stimuli. Zebrafish are an excellent model system for vision in humans because there is a great deal of similarity in the two visual systems at the anatomical, molecular

and physiological levels. Fish are therefore also a model system that is relevant to understanding medical conditions that interfere with vision in humans.

Typically, what will be done to an animal used in your project?

Zebrafish will be bred and we will collect the fertilized eggs, into which we will inject DNA to make a transgenic animal. This DNA normally causes the offspring to express a fluorescent protein which is harmless to the animal but which generates optical signals when neurons and their synaptic connections are activated. When these genetically modified animals them selves breed, we use their larvae 6-9 days after fertilization. The larvae are anaesthetized and then placed in a specilaized microscope that allows us to observe changes in the fluorescences of proteins in neurons. This experiment will typically last 1-2 hours, at the end of which the larval zebrafish is killed humanely.

What are the expected impacts and/or adverse effects for the animals during your project?

- No common adverse effects are anticipated.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All procedures have been categorized as "mild" for all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no substitute for the retina or brain to understand how the retina or brain works in processing visual information. The fish visual system represents an excellent alternative to mammals for the study of many aspects of nervous system function that are conserved among vertebrates.

Which non-animal alternatives did you consider for use in this project?

It might be possible to study small parts of the general question (such as the basic mechanisms by which synapses work) using neurons in culture. But this is not the major question that this project sets out to answer of the project.

Why were they not suitable?

Cultures of neurons cannot see or smell and are not connected in the way the visual and olfactory systems are in the intact animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Procedure 2 will involve a maximum of 12000 fish, calculated as 8 scientists using an average of 7.5 fish per week for 40 weeks per year over 5 years.

Procedure 1 will involve a maximum of 30000 fish, based on 40% (12000) proceeding to Procedure 2. About 60% of larvae grown beyond 5 days post-fertilization (when they come under the Act) do not proceed to Procedure 2 because of the limited number of experiments that a single scientist can do per week and the fact that we cannot control how many eggs are layed and fertilized and cannot use fish beyond 9 days post-fertilization.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the design phase we have carefully chosen the lines of zebrafish so that they can be used by the largest number of scientists working on this project (see below). We will collect multiple data from each animal, thus minimising the number of animals required. For example, in vivo imaging data of neuronal and synaptic activity will be collected from many hundreds of neurons in the one animal, from several regions of the cortex or hippocampus. The numbers of animals to be tested will be the minimum number required to obtain statistically reliable results, based on previous experience in the laboratory, and from published findings. Where appropriate, power calculations will be used to estimate the appropriate numbers of animals on the basis of expected variability, and anticipated effect sizes. Where possible, we will use within-subject comparisons to increase the statistical power of the experiments, and to minimise the numbers of animals that are used (e.g. when injecting a drug into the eye).

Cryopreservation will be used to preserve important lines and remove the necessity to hold stock for extended periods.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Scientists will breed a particular line of fish to be shared with others. A "good" breeding in Procedure 2 might produce 40 larvae of a particular type on a particular week. Two scientists will share these fish, so that an average of 15 are used per breeding rather than an average of 7.5.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Larval zebrafish will be used, which are generally considered less sentient than juveniles or adults because their nervous system is still developing. They will be bred from adults kept in well-maintained aquaria and when used for experiments they will usually be under terminal anaesthesia. For embryos at motile stages of development before they are protected by the Act, we still use anaesthetic for all operations and embryonic surgery. MS222 (also known as tricaine) is currently the anaesthetic of choice but we will also investigate the utility of etomidate, which has been reported to produce less obvious aversive effects. The anaesthetic regimen is similar for fish used after they are protected by the Act: the anaesthetic is added (with antibiotics) to the sterile water bathing the fish at appropriate concentrations (2 parts per thousand for MS222 applied to fish at 5-9 dpf). The animals quickly become insensible, and so analgesics are not used.

Why can’t you use animals that are less sentient?

We have to use a vertebrate species because the structural plan of the visual system is very different in invertebrates.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

For embryos at motile stages of development before they are protected by the Act, we still use anaesthetic for all operations and embryonic surgery. MS222 (also known as tricaine) is currently the anaesthetic of choice but we will also investigate the utility of etomidate, which has been reported to produce less obvious aversive effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow "responsibility in the use of animals in bioscience research", produced by the National Centre for the replacement, refinement and reduction of animals in research (NC3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by:

Using the National Centre for replacement, refinement and reduction (NC3Rs) as source of help, especially regular e-mail bulletins (NC3Rs News) that are forwarded to us by our NACWO.

Good communication with staff in the Biomedical Research Facility (BRF) who attend industry conferences and are in regular contact with staff in other facilities in the UK, as well as our Home Office Inspector and Named Veterinary Surgeon.

Meetings of BRF staff and users.

Implementation of advances will occur in consultation with our NACWO, Home Office Inspector and Named Veterinary Surgeon. All members of the lab working under this license will be involved.

35. The neurobiological bases of mental health across the life span

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neuroscience, Mental Health, Neurodegeneration, Alzheimer's disease, Behaviour

Animal types	Life stages
Mice	neonate, juvenile, adult, aged, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To study the neurobiological mechanisms underlying both normal brain function and disorders, and how risk/resilience factors interplay to drive changes in neural processing and behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The World Health Organisation has estimated that a quarter of the world's population will suffer from mental or neurological disorders in their lifetime. There are key points in the lifespan when people are especially susceptible, for example in adolescence (mental health conditions account for 16% of the global burden of disease and injury in 10-19 year

olds) and our ageing population (the risk of dementia increases with every decade). There are many factors, both environmental and genetic that can increase risk or resilience to mental health disorders. Studying the neurobiological mechanisms underlying both normal brain function and disorders, and how risk/resilience factors interplay to drive changes in neural processing and behaviour, will provide insight into the burdens placed on the human brain and strategies both pharmacological or behavioural that could be used to mitigate damage and build resilience to mental health disorders and disease.

What outputs do you think you will see at the end of this project?

This project will output academic publications which will help other researchers to understand the mechanisms of disease to eventually lead to the new therapeutic strategies. As we develop new behavioural protocols and tests we will publish these, both in academic journals and as an open access resource to give other researcher free access to new techniques. Through establishing how genetic and environmental factors impact mouse behaviours (associated with mental health disorders) , and understanding the neurobiological mechansims driving these differences we will help to develop understanding of mental health disorders across the lifespan, which can be presented to the public and other research groups in publication or presentation formats.

Who or what will benefit from these outputs, and how?

Academic publications: Publications are crucial to allow sharing of our techniques with other researchers. This will improve reproducibility of science between laboratories and help grow the evidence base.

There are multiple levels of benefits to this. For example, with the proposed work on APOE and Alzheimer’s disease:

Short term (2-3 years): We aim to establish a time course for how APOE increases AD risk to find targetable timepoints for treatment. We also aim to establish some of the mechanisms involved in this risk at different levels of study (i.e. from whole brain to individual cells)

Medium term (3-5 years): We aim to identify and test new methods to alter APOE genotype or alter APOE-associated changes at different levels of study (i.e. how to target APOE in the whole brain vs effects on individual cells).

Long term (10+ years): Alzheimer’s Disease and other dementias are becoming an increasing health burden as life expectancy has increased. Recent statistics suggest that a third of people born in 2015 will suffer from dementia. A treatment that might prevent the onset of dementia by 5 years would reduce this number by a third. Up to 30% of the population carry an APOE4 allele and thus their risk of AD is doubled. If we could reduce/eliminate this risk it could have a large effect both on individual suffering and the economic burden of AD. This project seeks to establish the mechanism by which APOE4 confers this risk and develop and test strategies / treatments to prevent or reverse it, with the long-term potential of a new effective therapeutic strategy for Alzheimer’s Disease.

How will you look to maximise the outputs of this work?

- Using multiple avenues of dissemination so it reaches a wide range of audiences. As well as academic publications, present the data in different forums, to demonstrate the significance to all stakeholders, from academic researchers to drug discovery and clinical researchers, policy makers and the educated public.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are going to be used in this project because of their comparability to humans as a model for behaviour and brain structure/function. The biological markers of ageing have been, to some extent, mapped between mice and humans. This, in addition to the fact that mice have a much shorter lifespan than humans and can therefore be studied more quickly, provides good motivation for using mice in biological research. Finally, we are taking a lifelong approach to try to get the most information from individual animals as possible, minimising the number of animals and giving us insight into the lifespan ageing process.

Typically, what will be done to an animal used in your project?

The majority of animals used in this project will undergo repeated mild stressors such as handling, participation in behavioural procedures (e.g. tests of memory and attention) for periods of several months. Some animals will also be administered with substances which may cause mild discomfort and experience stress related to the substance.

Other animals may undergo a combination of the above-mentioned procedures in addition to surgical procedures. All surgical procedures are carried out under anaesthesia with best practice including post- operative care and pain management. Any suffering exceeding that which is set out in the protocol for these procedures will be monitored and necessary interventions (such as treatment, or in severe cases, culling) will be performed.

What are the expected impacts and/or adverse effects for the animals during your project?

Protocol 1: we do not expect any adverse harms to the animals in protocol 1, as this simply involves maintenance and breeding as standard procedure.

Protocol 2; Animals in protocol 2 may experience mild weight loss and acute stress due to the procedures carried out. However, the distress caused is expected to be mild and transient.

Protocol 3; Animals in protocol 3 will be exposed to mild handling and testing stress due to repeated human contact and placement in testing apparatus. The cumulative effect of

this is expected to be mild as, for the most part, animals are exposed to appetitive cognitive tasks which may be considered environmentally enriching. Animals may experience mild weight loss due to food restriction. Animals may also experience cumulative moderate stress due to repeated administration of drug substances. However, animals will be regularly monitored for signs of distress and will be culled if exceeding the set severity limit for protocol 3.

Protocol 4; Animals may experience the stressors and harm outlined in protocol 3, in addition to exposure to invasive surgery. While it is unlikely, animals may experience post-surgical complications such as infection, pain, or adverse behaviour. These events will be monitored for and animals will be treated as appropriate (e.g. provided post-operative pain relief). The expected severity outcome for animals in protocol 4 is moderate, and animals will be monitored for signs of exceeding this severity limit with repeat testing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Subthreshold - 30%

Mild - 30%

Moderate - 40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no non-animal alternative for behavioural studies to study cognition and behaviour. Study of genetic changes in humans is difficult due to high variability between individuals, and difficult to control lifestyle factors. Using mice allows us to control for these issues and test hypotheses across the lifespan. In addition, use of mice provides us with invaluable tissue (e.g. brain) at different times across the lifespan, which would otherwise be inaccessible. With access to this tissue, it is possible to test the mechanisms of disease that would otherwise be impossible in humans. Finally, mice are a good model system for human genetics and, to some extent, disease processes. Mice share a higher similarity in genetic structure and brain circuits to humans than lower organisms such as zebrafish or other model animals.

Which non-animal alternatives did you consider for use in this project?

For behavioural studies there are no non-animal alternatives. For development of new genetic tools, we will begin in vitro and only transition to in vivo when we are confident that we are able to effectively manipulate or express the genes in question.

Why were they not suitable?

In vitro methods cannot substitute for live animal research where we analyse behavioural outcomes and the interaction of neurobiological mechanisms at a circuit level.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been estimated from both previous experience and future planning for breeding mice with relatively complex genotypes and a calculation of numbers of experiments and numbers of mice within experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We perform statistical tests to assess how many animals we need to achieve reliable results. This is also based on prior experience in our and other laboratories as well as the scientific literature. We use repeated comparisons within individual mice where possible, as this can reduce the total number of mice needed and help us understand the within-individual effects we are researching. In our establishment we have access to statistical consultants to ensure decisions made about experiment size are appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use efficient breeding strategies to breed specifically for the numbers of animals needed for given experiments. This allows us to reduce our numbers to a minimum. In addition, we perform ‘pilot’ studies to test whether the number of animals we have is enough for statistically meaningful data. Where possible we use archived data for re-analysis, which does not require the use of further animals. We aim to align our experiments to extract a range of data from a given animal, which further increases the power of these experiments. Finally, we have a policy to collect potentially valuable tissue from all animals where appropriate, post-mortem. This allows us to share our resources with other laboratories and act as a source for new experiments without use of further animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mice in our project due to their genetic and systemic comparability to the human condition. Namely, mice share more in common genetically, behaviourally, and structurally (i.e. circuits within the brain) with humans than other lower species (e.g. zebrafish). Mice are also excellent subjects for genetic manipulation owing to their well characterised genetics. This project therefore will use mice as our animal model, with genetic manipulations as a primary method for creating models for experimentation.

Our project aims can be achieved by using behavioural tests in mice that assess the effect of various genetic and environmental alterations on mental-health associated behaviours. The majority of these tests are appetitive (involving performing simple tasks for a food reward) and provide environmental enrichment for the animals. Surgical procedures are performed under anaesthesia, and we use a common system to maintain a record of the severity of post-surgical outcomes. We use these systems to identify future refinements to our protocols to further reduce any animal suffering. The use of invasive surgical procedures is crucial to help us establish how certain genetic and environmental risk factors affect brain function in alive subjects. This increases our ability to draw conclusions about direct effects of such factors and how potential interventions may be effective.

Both the behavioural and surgical aspects of this project are collaborative between laboratories to ensure best practice is always being used to minimise animal distress and the number of animals required to achieve the project aims.

Why can’t you use animals that are less sentient?

We are interested in effects across the life span and so a number of our animals will be maintained until old age. Less complex organisms than mice become more tangentially related to the human condition, therefore mice serve as an excellent middle ground for complexity but maintaining relevance to human physiology.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Example: The five-choice serial reaction time task (to measure attention) requires mice to be motivated to work for food reward, and the traditional methodology required animals to be food deprived for several months at a time. We have adopted and are piloting a new technique, were the mice have continuous access to the testing cage and are able to learn and perform the task in 5 days compared with 5 months, and because their food source is

provided by performing the task, it is only necessary to food deprive for a few days at a time, when doing probe trials.

We are also developing a new spatial maze, the appetitive dry maze, which should provide similar information to the Morris Water Maze, but without the necessity for the mice to be repeatedly exposed to water, instead they search a dry maze for a food reward.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow LASA guidelines for Aseptic Surgery, and the PREPARE guidelines for designing experiments (https://norecopa.no/prepare).

We will also investigate and use where appropriate new open science initiatives including preregistration of studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use the NC3Rs website for latest information and resources (including e-learning training), user meetings and information from the Named Information Officer to stay updated with current guidance and areas of best practice.

In addition, European best practice and guidelines (via NORECOPA resources) will be applied where applicable, such as the PREPARE guidelines and NORECOPA newsletters.

We will also stay updated through the British Neuroscience Association's 'Credibility in Neuroscience' initiative and other 'open science' initiatives and adopt new methods of good practice where appropriate.

36. The Symptoms and Pathogenesis of Lung Diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Respiratory, Chronic Obstructive Pulmonary Disease, Asthma, Inflammation, Cough

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify new abnormal biological processes that are involved in causing airway diseases such as asthma, chronic obstructive pulmonary disease (COPD) & idiopathic pulmonary fibrosis (IPF) and the symptom of cough. Subsequently to identify if returning these processes to there normal state will help ease the symptoms and also make patients feel better and live longer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Respiratory diseases such as asthma, chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) are a significant cause of illness and death across the

world. Currently approximately 5.4 million people in the UK are currently receiving treatment for asthma, that is 1.1 million children and 4.3 million adults (Asthma UK). Although a large number of asthmatics have their symptoms controlled, many of the medications used have side effects which cause high blood pressure and increased risk of diabetes. There are also around 200,000 people in the UK who have severe asthma, this form of the disease does not respond to the usual treatments and can cause people to frequently require hospital attention. Approximately 1300 die each year in the UK from asthma.

For COPD, approximately 2% of the whole UK population – 4.5% of all people aged over 40 – live with the disease. Symptoms include a shortness of breath, a persistent cough and wheezing especially in cold weather. There is no cure for COPD and although several medications can help relieve some of the symptoms they do not stop the decrease in how well the lungs work or slow the development of the disease.

Over 6000 people are diagnosed with IPF every year in the UK and almost half of those will die within 3 years of diagnosis. Symptoms include a persistent cough and extreme tiredness, both of which are extremely distressing. There are currently no real treatments capable of halting the ongoing stiffening of the lungs or reducing the symptoms.

In healthy people coughing is protective reflex designed to expel foreign material from the lungs. However, a persistent cough, when the person has coughed for more than 8 weeks, can occur as a symptom of a number of diseases including asthma, COPD and IPF or it can have an unknown cause. Approximately 7% of the world's population suffer from a persistent cough and this symptom has a significant negative impact on the quality of the persons life. Although cough medicines are readily available from pharmacies, there is little evidence to support that they really help and therefore new and effective medicines are urgently required. If we can identify new abnormal biological processes that cause cough and then we can investigate if returning these irregular systems to normal would reduce the coughing and help the patient have a better quality of life.

It is quite likely that some of the abnormal processes that drive the respiratory diseases described above will be common across all of them. For example coughing is observed in asthmatics, COPD and IPF patients and structural changes in the airways are also common across all three of the diseases.

Many patients suffer from disease that includes aspects of both asthma and COPD. Therefore, understanding a biological pathway that is responsible for causing cough, structural changes or inflammation of the lungs may have benefits for many respiratory diseases, including those mentioned earlier.

At the time of writing this application there is a global respiratory viral pandemic resulting in severe disease and loss of life. The work described in the project will enable us to gain a greater understanding of the processes that cause respiratory diseases. This in turn should enable us to potentially target any processes which show promise with new therapeutic agents. If these agents work effectively in returning the abnormal processes to their normal state and therefore reducing the severity and/or frequency of symptoms then

data obtained will hopefully form part of the portfolio of work required to enable new medicines to be tested in human clinical trials.

What outputs do you think you will see at the end of this project?

Based on our achievements over the term of our previous project, we can expect that at the expiry of this licence we will have identified a number of new pathophysiological mechanisms involved in the most common respiratory diseases. The experiments will give raise to a significant amount of original and new information and much of this work will be presented at international conferences of professional and learned societies and then submitted for publication to peer reviewed scientific journals. We will also publish negative data and experiments where we have been unable to confirm other laboratories results with the aim of reducing unnecessary in vivo experiments. A great number of animal tissue samples will also be generated and these will be shared with other scientists and collaborators that work with us.

We also aim to assist in the progress of a number of projects and novel candidate molecules through pre-clinical research into human clinical trials.

Who or what will benefit from these outputs, and how?

The new knowledge that we will discover will be published in scientific journals and presented at conferences of learned societies. This greater understanding of respiratory diseases will enable other research groups, working in both universities and in the pharmaceutical industry, to hopefully make more informed decisions regarding their animal research and potentially lead to a reduction in numbers and also refinements.

We aim to publish our findings throughout the 5 year term of the project.

It is expected that we will be successful in progressing a number of candidate drugs through into human clinical trials. These potential new medicines may take up to 5-10 years to make it as a successful new drug. However if they are successful we expect them to have a significant positive impact on the lives of patients, their families and society as whole.

How will you look to maximise the outputs of this work?

The new scientific knowledge that we discover will be published in books, on websites and in scientific journals and presented at both internal meetings and external international conferences. We have a large network of scientists working in universities and for pharmaceutical companies with whom we share our findings with and benefit from the discussion of our research. We are very aware that there is a need to share the findings when new medicines are not successful and we will continue to talk and discuss with other scientists and researchers in the community to share ways that will reduce the number of animals that we use and refine them so that animals will suffer less.

Species and numbers of animals expected to be used

- Mice: 14130

- Rats: 10700
- Guinea pigs: 7600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures...

Explain why you are using these types of animals and your choice of Life stages.

Adult mice, rats and guinea pigs are appropriate animals to study diseases of the lungs as they have many similarities in the way their lungs work when compared to humans. For example we are particularly interested in helping people who have a persistent cough and we can use guinea pigs who also cough in response to certain chemicals to help us find new medicines to treat this distressing symptom. We intend to use adult animals as their lungs are fully formed and also their immune system and circulation system is sufficiently matured and again is similar to that observed in humans.

Typically, what will be done to an animal used in your project?

A typical study may involve up to 6 groups, with 6 animals in each group. At least 7 days after delivery, animals will be given a protein, on up to 3 occasions, by either an injection of a small volume of liquid into the lungs (for this they are anesthetised) or by an injection into the cavity containing the intestines and stomach etc. A few weeks later we put the animals in a chamber and expose them to a fine mist containing the same protein. This causes them to have an allergic reaction similar to an asthma attack. Before, during and/or after this the animals would receive a number of doses of a potential new medicine either given into the lungs in a very small volume of liquid (under anaesthesia) or dosed into their stomach. By placing the animals in a special chamber to measure changes in the way they breath, where they are free to walk around, we can work out how effective our new medicine is at reducing the intensity of the asthma attack. Animals would then be returned to their home cage and closely observed to ensure they are now acting normal and not experiencing symptoms. They would be checked again at the end of the working day and then left overnight. Animals are then checked first thing in the morning and killed by an overdose of anaesthetic. We would then take blood samples and also take samples of the lung and other tissues to look for evidence that our new potential medicine has worked.

For some studies where we are trying to model diseases that take a long time to develop, such as emphysema or chronic bronchitis, the experiments may take longer. For example we know that the cause of most cases of chronic bronchitis is cigarette smoking and therefore to model this disease we expose animals to tobacco smoke over a number of weeks. This ensures that the animal model resembles chronic bronchitis as closely as possible.

More recently we have observed that some chemicals (e.g. salt solutions) that are known to cause cough in humans , do not cause cough in the guinea pig. It is important to be able to model coughing to substances like salt solutions because it is believed that these may be more relevant. We think that one reason why this might happen is that whilst humans

breath the salt solution via the mouth, guinea pigs who breath mostly through their noses, filter out the solution so that it us unable to reach the lungs and cause cough. Therefore we are performing studies where we block the noses of guinea pigs to see if they then cough to salt solutions.

We have been working on a new drug that shows great promise as a medicine for cough. However it appears that it may affect peoples ability to taste food properly. Therefore we are performing experiments investigating if the animals ability to taste sweet and sour substances is affect by the group of medicines that we are investigating.

What are the expected impacts and/or adverse effects for the animals during your project?

Causing lung diseases such as asthma and symptoms such as cough will likely cause the animals to feel similar to a human when they have an asthma attack or an irritating cough. Typically signs that we would see in our animals would be an increase in how quickly they breath, erect fur and looking scruffy. However, these signs normally disappear completely within a few hours. Most of the studies that we conduct are short (typically less than 4 days in duration) although some experiments where we study diseases that take a long time to develop, like chronic bronchitis, could last could last for approximately twelve weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For mice, rats and guinea pigs, we expect approximately 50% of animals to be classified as moderate and the remaining 50% being classified as mild or sub-threshold. This will depend on the specific studies but in many cases we will have animals who are not given a respiratory disease or are humanely killed and their tissues used for experiments. A significant number of animals who we make experience asthma or are made to cough will be treated with new experimental medicines which we expect to reduce the symptoms for them and thereby make them feel better.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Respiratory diseases occur through a complicated process involving the immune system, your genes and the environmental. The cells in our lungs, the blood vessels and the nerves and white blood cells all interact in ways which we currently cannot replicate

without using animals. This is especially true when we are trying to understand the way a potential new medicine might work.

Which non-animal alternatives did you consider for use in this project?

Using human cells and animal cells that we grow in the laboratory and also using human tissue that we obtain from operations is an important part of our research programmes. We only use animal studies when we gather enough scientific information from those experiments to justify their use.

Why were they not suitable?

The cells and tissues that we use, although very useful, are not able to reproduce the same conditions that the human lung works in such as a working blood supply, nervous system and immune system.

We also use human lung tissue as often as we can source it, however even this is not a complete alterative to using animals as it lacks an intact circulation system and thus no white blood cells and also a complete nervous system and many other components.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates are based on the anticipated number of studies and knowing the typical numbers used in previous experiments to produce meaning full results. Over a 5 year period, animal usage may vary across protocols as the demand from as yet unknown research projects emerges. Rather than just stating the potential maximum of animals we will use across all protocols we have kept numbers within the range of recent experience so it is possible that future amendments may be required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines were used for planning of all the experiments using animals. The guidelines for planning animal experiments complement reporting guidelines such as ARRIVE and ensure the quality, reproducibility and translatability of animal studies, enabling the minimum number of animals are used but still producing meaning full results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A significant amount of in vitro experiments, using human and animal cells and human tissue, is performed prior to any animal work and this significantly reduces animal usage. We actively source human lung tissue from both the UK and abroad and this ensures we can revise and amend animal experiments when tissue is sourced. When animals are killed at the end of a study, multiple samples of lung tissue, blood and other organs are collected and stored either deep frozen or prepared and preserved for future microscopic examination. These samples are then shared with research colleagues both within universities and with collaborating pharmaceutical companies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse, rat and guinea pig models which enable us to study the processes involved in human lung diseases such as asthma, COPD and IPF as well as the clinical symptom of cough. We need to cause inflammation to the lungs and cause symptoms such as cough as this reflects what happens in human diseases of the lungs. It is likely that animals will experience respiratory changes and discomfort similar to those observed in patients with asthma, bronchitis and fibrosis. However, as we are seeking to find and develop new medicines, many animals would be likely to have this suffering reduced by our new treatments. We have selected airway models that are well tolerated by the mice, rats and guinea pigs and over the years we have reduced the lung inflammation that we cause to the them and thus this reduces the welfare impact on the animals, but still enables us to use them as models of lung diseases.

Why can’t you use animals that are less sentient?

We are seeking to identify and develop new treatments for human respiratory diseases and therefore although there may be some similar biology in lower species such as flies or fish we would generally not expect potential new medicines, which have been developed using on animal experiments such as human and animal cells, to work. These lower species also do not accurately reflect the human circulation and immune systems and also the structures that they use to breath are very different. This licence application does include a protocol for purely non-recovery studies (except for compound administration) where all steps are performed under terminal anaesthesia and we use this extensively.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

During procedures all animals are monitored continuously so that any adverse effects can be acted upon immediately. Any clinical signs that are observed normally disappear within a few hours. Animals displaying clinical signs longer than this will be assessed more frequently and additional support offered such as warming or wet mash given as needed. Advice will also be sort from either the Named Veterinary Surgeon or the Named Animal Care & Welfare Officer or both. In general animals are closely monitored and are kept in modern, purpose built facilities with highly trained and motivated technical staff. We put in place many systems to improve animal welfare, including stress-reducing handling (i.e. tunnel handling or cupping for mice), environmental enrichment such as tunnels, nesting materials and chew sticks, as well as cage floor level access to food for animals displaying reduced activity or mobility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice, for example the use of analgesics after surgical procedures will be employed to minimise suffering. LASA best practice guidelines will be consulted as required. We follow the PREPARE ((Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for planning animal experiments and we will also adhere to the ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments) to improve the reporting of our research involving animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My team and I are in regular contact with other scientists who work with animals and with teams of animal welfare specialists across both universities and pharmaceutical companies. Members of my team regularly attend seminars and conferences organised by organisations such as the RSPCA and the NC3Rs. We also subscribe to email newsletters from the aforementioned organisations and also from professional societies such as the Royal Society of Biology, British Pharmacological Society and Institute of Animal Technology.

37. Physiopathology and therapeutic approaches for neuromuscular diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

neuromuscular disorders, therapeutic strategies, pathological mechanisms

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to develop therapeutic approaches (treatments) for several neuromuscular diseases such as Duchenne Muscular Dystrophy (DMD). Indeed, many of these diseases reduce life expectancy and dramatically impact the quality of life. 70,000 people have MD or related condition in UK and an estimated 7 million people worldwide. The cost per patient varies between £30,000 and

£60,000 / year depending on the disease. So far, there is no preventive or curative treatment for most of these diseases and our aim is to develop new treatments for the patients (either small molecules or viral vector coding the missing gene or allowing the expression of the altered gene (in Duchenne muscular dystrophy for instance) or inhibiting the expression of a deleterious gene (in facioscapulohumeral dystrophy)).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Findings of this project will pave the way for new treatments and pre-clinical studies for several neuromuscular diseases. They will also increase our knowledge on the malfunctioning biological processes leading to these genetic diseases. We will create new animal models because there is a critical needs for more robust animal models.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

- We use mice. Approximatively 2000 over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Some of our mouse models of neuromuscular disease develop symptoms of the disease, particularly as they get older, the major symptom being a weakness in the legs but the mice are able to walk around.

We perform surgical techniques under general anaesthesia and carefully monitor the mice postoperatively, being particularly careful to keep them warm and well-hydrated. All animals undergoing surgery will be given appropriate analgesia to minimise pain during the procedure and in the recovery period. All recovery surgery will be done aseptically. Animal undergoing local irradiation may show skin lesions (redness). Immunodeficient mice are prone to infections, so are kept in individually-ventilated cages in barrier conditions, to minimize risk of infection. We will perform treadmill running to test endurance and the experiment is stopped when a mouse remains in the fatigue zone for 5 continuous seconds. The majority of the procedures are of moderate severity. At the end of the experiments, mice will be humanely culled.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Our therapeutic approaches are or have been first evaluated in vitro in a cellular model of the disease. However, as a next step towards a clinical trial, in vivo testing of potential therapeutics is unavoidable. Indeed, tissue culture is far away from recapitulating what happens in vivo, in an animal. For example, skeletal muscle stem cells do not achieve their full differentiative capacity unless they are in an innervated, vascularized setting with other cellular and non-cellular components such as connective tissue and immunological cells.

Moreover a crucial point in the development of a drug is to determine which organs are targeted and with which efficacy. In our case, we want to be sure that the muscles are massively targeted whereas other organs are spared. This cannot be assessed in vitro.

It is thus essential to evaluate our potential treatments in mice.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use the minimum number of mice per experiment to achieve statistically-significant results and minimize the size of breeding colonies to produce the required numbers of mice. From our previous experiments we know that groups of 6-12 animals are sufficient to have statistically significant results. However, advice on the proposed experimental designs and methods of analysis of the results will be taken from a statistician. Moreover, when different experimental groups are realized, we will try to minimize the number of mice by sharing the controls across the different experiments.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We use mice, as normal, immunodeficient and genetically-altered strains and models of neuromuscular conditions are available for us to perform the proposed experiments. Our breeding programme is also directed at developing animal models that reflect the condition more accurately. Animals will be closely monitored for the 1st week and every 3-4 days thereafter. As a palliative measure, dampened food may be placed on the floor of the cage post-operatively. Any animal not fully recovered from the surgical procedure within 24 hrs (eating, drinking and return to normal behaviour) will be humanely killed.

If an animal shows compromised limb function beyond 4 days after surgery, it will be killed.

All our work will be performed in the context of the emerging literature. We will take on new ideas and discard those shown to be unsuccessful.

When testing pharmacological agents, only innocuous substances would be of interest for administering to human patients suffering from muscular dystrophy.

We will obtain guidance on doses from existing studies on humans or mice and use doses shown not to have toxic side effects. If the agent being tested is likely to have any overt toxicity, a small pilot study will be performed first. Although we cannot absolutely predict toxic effects, our checking regime will ensure that any agents causing deleterious effects will be rapidly identified.

The added values of a xenograft model (in which human cells or very small human muscle biopsy are grafted into a one muscle of a mouse) are numerous. Indeed, transgenic mouse models are useful to understand the mechanisms leading to the pathology and to

develop therapeutic approaches, but they may not fully mimic the human pathology. However, to graft human muscle biopsies or cells into immunodeficient mice may better mimic the human features.

38. Understanding the womb in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Menstruation, Implantation, Hypoxia, Inflammation, Vasculature

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how the uterus (womb) functions normally and how this changes to cause problematic menstrual bleeding or implantation disorders. Our work aims to develop preventative and therapeutic strategies for those with problematic periods and implantation disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heavy menstrual bleeding (HMB) affects a quarter of women of reproductive age in the UK, i.e. approximately 4 million women. HMB has a significant negative impact on quality of life and is a huge socio-economic burden for women, their families, the NHS and society. Side effects of current medical treatments mean up to 60% of women seeking

treatment resort to risky, fertility-ending surgery. There is a clear unmet need for acceptable, effective, fertility-preserving medical treatments for HMB, yet this common, debilitating condition remains under-researched. Understanding how the uterus functions normally and what changes to cause HMB is necessary to enable development of personalised, effective medical treatments.

Up to 25% of pregnancies result in miscarriage, i.e. loss of a pregnancy before 24 weeks gestation (Practice Committee of the American Society for Reproductive Medicine, 2012). Many of these losses occur before 12 weeks and are associated with chromosomal errors in the embryo/fetus. In contrast, recurrent miscarriage occurs with normal embryos and may indicate a disorder of the womb lining (endometrium). Identification and correction of this endometrial pathology will improve the psychological and physical impact of recurrent pregnancy loss.

What outputs do you think you will see at the end of this project?

Publications: we aim to produce a minimum of four primary research papers from the work described herein.

Presentations: we aim to present these findings at scientific and public conferences, e.g. society for reproductive investigation international conference, endometriosis UK patient information days.

Clinical applications: findings from this work may inform clinical guidelines for abnormal uterine bleeding. In addition, it may identify new therapeutic targets for the treatment of period problems.

Who or what will benefit from these outputs, and how?

This project will study the normal mechanisms involved in the womb at menstruation. In addition, we will study the aberrations that lead to abnormal menstrual bleeding. Defining menstrual physiology will greatly advance our knowledge of womb function, specifically (1) the role of hypoxia (low oxygen levels) in the endometrium (womb lining) and (2) the inflammatory response at menstruation. As the endometrium repairs without scarring or loss of function during each menstrual cycle, the knowledge obtained from this project may also have more widespread benefits for other tissue sites where inflammation and scarring is problematic (e.g. lung/liver). Furthermore, these studies may identify new medications for women with problematic periods. Our models will enable proof of concept studies for new treatments. Study of the effects of diet/obesity on menstrual function will enable evidence-based lifestyle advice for women suffering from these disorders, supporting patient autonomy during clinical management.

The scientific community, patients, their relatives and society will benefit from this project. In the short term, these animal studies will benefit the scientific community due by determining how the womb works normally. In particular, the role of hypoxia in menstruation has been the source of intense debate for over 70 years. Experiments outlined here will allow us to increase or decrease hypoxia at menstruation and provide answers to this key question in reproductive biology. We will disseminate our findings

through annual presentation at national and international meetings and publication in peer reviewed journals.

More long term, it would be our intention that the outputs from this research will benefit women with problematic periods by contributing to the development of new therapies for their debilitating disorder. There is a clear unmet clinical need for new medical treatments that are effective and acceptable to women and allow surgery to be avoided. The studies performed during this project may lead to phase I clinical trials, hopefully within 5 years. A major strength of the mouse studies described herein is that they are based on our previous observational studies in human tissue, increasing the probability of translational benefits for women. Effective medical treatments for periods problems will have significant future benefits not only for those suffering from these conditions, but their families and for society. The economic cost of menstrual disorders, including surgical intervention and work absence, is significant. These mouse studies are the first step towards significant cost benefits for society.

How will you look to maximise the outputs of this work?

Collaboration: We have strong collaborations already in place with both local and international laboratories that work on hypoxia in the lung and tumour microenvironment. These collaborations are essential for sharing knowledge, protocols, resources and expertise. This will maximise outputs from this project. In addition, we are developing a new collaboration with epidemiology colleagues, who will analyse human data to inform these studies and optimise their translational benefits. Our strong track record of studies in human endometrial tissue will inform and direct this project to ensure maximal benefits for patients.

Dissemination: We plan to present our findings at national and international conferences to ensure maximal dissemination of our findings to inform the global research effort in this important area. We have developed a patient information website, where major results from studies in menstrual function can be disseminated quickly and accurately to the public. Our research institute runs regular public lectures that have received excellent feedback. We have actively participated in these in the past and will continue to do so in the future. Unbiased publication: Our aim is to publish our findings from this project, regardless of outcome. This will inform the global research effort in this area.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The human womb is important for implantation of a pregnancy. If pregnancy does not occur, menstruation (a period) occurs. Many women suffer from common, devastating

disorders of implantation and/or menstruation. Our understanding of these conditions is limited as studying human tissue disrupts the organised structure of the womb, including the blood supply and inflammatory cells, meaning interpretation of experimental results is difficult.

The mouse uterus functions in a similar manner to that of humans during pregnancy. When not pregnant, mice do not naturally menstruate. However, by administering hormones in a similar pattern to those experienced by women during a menstrual cycle, we can induce menstruation in mice. This allows the study of uterine function in health and disease without disruption of the normal uterine architecture. We only use mice greater than 6 weeks old, to make sure their reproductive system is mature enough to respond.

Typically, what will be done to an animal used in your project?

To induce menstruation in mice, we remove the ovaries of female mice under general anaesthetic before giving them estrogen for 1 week. Mice then have a progesterone implant inserted for a few days (much like a mini version of the contraceptive implant used by many women). We insert some oil through the vagina and remove the progesterone implant to trigger menstruation.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice may experience pain or infection following ovary removal or progesterone implant insertion/removal. We minimise these by giving mice a general anaesthetic for surgery and painkillers during and/or after the operation. Mice do not show any signs of distress during menstruation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice will experience moderate severities due to surgery. This is minimised by anaesthetic, painkillers and careful post operative monitoring.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Inducing menstruation in mice is necessary as the lining of the womb (endometrium) is a dynamic, hormone responsive organ made up of numerous cell types. The complex and

sophisticated control of the womb by hormones from the ovary results in changes in womb function. These include changes to the blood vessels and influx of cells from the blood, e.g. immune cells. This means that an intact uterus in a whole animal is required to carry out focused, incisive experiments to determine womb function.

These are not possible if cells or parts of tissue are removed and studied in the laboratory as tissue interactions are disturbed. Lower organisms such as flies and frogs do not have a uterus. Experiments carried out in animal models will be limited to those questions that are not possible to answer with other methods.

Previous work from our laboratory has used human cells, tissue and data analysis to generate preliminary findings on how the human womb functions in health and disease. The results of this work have allowed us to develop focused experiments using mice. For example, we have identified that the womb becomes hypoxic (low oxygen levels) during menstruation in women with normal periods.

Women with heavy periods appear to lack this menstrual hypoxia. Therefore, we seek to manipulate the hypoxia system genetically and pharmacologically to determine impact on menstrual function.

Which non-animal alternatives did you consider for use in this project?

Hysterectomy specimens/womb biopsies

Human womb cells

Why were they not suitable?

Hysterectomy specimens/womb biopsies from women with objectively measured heavy and normal menstrual bleeding. These samples have been used to identify differences in the womb between those with heavy and normal periods. However, the endometrial architecture is disturbed with tissue removal making study of blood vessels and immune cell influx very difficult. In addition, these samples cannot be used to see if these differences are a cause or consequence of heavy menstrual bleeding. In addition, it is difficult to collect the large numbers of samples required to normalise for the inevitable variability between different women.

Study of human womb cells. This will be used where possible, but does not allow the study of the interactions between different cell types and influx of cells from outside the womb.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is estimated based on the number of mice required in our experimental and comparator groups to examine the impact of hypoxia, inflammation and obesity on womb function. These numbers are required to provide meaningful results to inform future development of preventative and therapeutic strategies for women with problematic menstruation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have searched the available literature and on line databases to ensure our experiments do not unnecessarily duplicate published work.

We have arranged sharing of resources with other researchers and close control of our breeding strategies to ensure minimal animal use.

Statistical advice has been sought to increase the precision of our experimental data and limit the number of animals used. Careful experimental design will limit numbers of mice used, utilising NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use efficient breeding strategies to optimise the number of animals used. Pilot studies will be performed where appropriate to optimise experimental protocols. Our carefully managed mouse tissue database facilitates reuse of the mouse tissue collected for multiple laboratory experiments, reducing numbers of mice needed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice do not naturally menstruate but we can simulate menstruation in mice with a protocol optimised in our laboratory to closely resemble the changes seen in the human womb. Mice will be used in our experiments as they are amenable to pharmacological and genetic manipulation with the preservation of cell and tissue structure. Mice will be at least 6 weeks old to ensure appropriate reproductive maturity and decrease unsuccessful induction of menstruation.

All surgery will be performed with aseptic technique, appropriate anaesthesia (e.g. isofluorane in 100% oxygen) and analgesia given routinely at the time of surgery. Post-operative analgesia will be administered as required (buprenorphine 0.05-0.1mg/kg s.c. or in diet). In our experience, surgeries are well tolerated with a recovery time of less than an hour. Post-surgical complications are unusual but we will monitor mice closely post-operatively to aid early detection and treatment. We will maintain close relationships with the NVS/NACWO to continually refine our behavioural and health monitoring procedures.

Mice will be housed in groups, including following surgery. Group numbers will be in line with the code of practice. Appropriate environmental enrichment will be supplied.

Why can't you use animals that are less sentient?

Lower organisms, such as flies and frogs, do not have a uterus. Menstruation is limited to women, old world primates, fruit bats and the elephant shrew. Simulated menstruation in mice limits experimentation on primates, such as the rhesus macaque.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Menstruation is a feature of normal reproductive function in women and higher primates. A mouse model of simulated menses was reported in 1984 and has undergone subsequent refinement.

Introduction of oil to the womb via the vagina/cervix has been established in our laboratory and this is used wherever possible to reduce the number of surgeries.

For implantation studies, we will aim to optimise a transcervical method of embryo transfer to reduce the number of surgeries required in our experimental design.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where more refined approaches become available during the course of this licence either through personal communication, publications or veterinary advice, we will investigate their use following discussion with the NVS and Home Office Inspector.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Where more refined approaches become available during the course of this licence through personal communication, publications or veterinary advice, we will investigate their use following discussion with the NVS and Home Office Inspector.

39. Innate antimicrobials in defence against infection

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Infection, Virus, Bacteria, Antimicrobial, Immunology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand the mechanisms by which antimicrobials, produced naturally by mammals, can prevent and combat infections and the harmful responses to infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infectious diseases are a major cause of death and illness around the world. The growing problems of antimicrobial resistant bacteria, and harmful viruses for which we have no vaccine or effective treatments, demonstrate the need for new approaches to prevent and treat infections. Understanding the most effective mechanisms by which antimicrobials, produced naturally by mammals, can effectively combat infectious diseases and modify the body's responses to them, will help to develop urgently required new therapeutic and preventative strategies.

What outputs do you think you will see at the end of this project?

This project is expected to lead to a range of outputs, including advancement of scientific knowledge with clear translational potential to impact upon novel interventions for infectious diseases, publications, presentations, funding applications, public engagement resources/events and press releases as appropriate.

Who or what will benefit from these outputs, and how?

Infectious diseases are a major cause of morbidity and mortality. Despite a golden era of antibiotics, respiratory infections alone account for 1 in 15 deaths in the UK, and ~18% of mortality in children under 5 years of age globally. Bacterial pathogens resistant to antibiotics now represent an ever increasing challenge, prompting international fears of an “antibiotic apocalypse”. In addition, new viruses, and the recently demonstrated ease of their rapid global spread, represent a threat for which vaccine development can be too slow, and effective therapeutics for viral infections are rare. Finding new approaches is an urgent international priority.

Targeting the most effective components of our naturally-occurring defence systems, promises new preventative and therapeutic approaches for infectious and inflammatory diseases. However, a greater understanding of these natural protective mechanisms is required; from microbicidal properties to the mechanisms of modulation of immune responses, the role of the microbiome, and the effects of aging.

The short term benefits of this project will be to advance our mechanistic understanding of Host Defence Peptides in protection against infection/inflammation. This advancement of scientific knowledge, with clear translational potential to impact upon novel interventions for infectious diseases, is expected within a 5 year period. Successful discoveries, with the potential to lead to the develop of new treatments (most likely to be for viral lung infections) could then be developed over the following 5 - 10 years.

How will you look to maximise the outputs of this work?

The impacts and outputs of this research will be maximised by early dissemination, publication and presentation of findings in open access formats, and by optimising local and international collaborative approaches (including with biotech industry if appropriate) and data sharing to advance the work in the most rapid and effective manner.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

To complement studies performed with cells in the laboratory, and human clinical studies, mice will be used; studied at neonatal, adult and aged Life stages to evaluate the Life

stages at which specific infections are found to occur in humans, and related to well known changes in the immune systems of mice and humans with age. Mice have been shown to closely share key features of the immune system with humans, and to be good models for understanding effective responses to infection in the lungs, using the microbes of interest in this proposal. In particular, their natural "antimicrobial host defence peptides" (the major system studied by this proposal), are very similar to humans. The availability of mice in which these defences have been genetically altered, and demonstration that this leads to less effective defence against these lung infections, makes this the ideal animal in which to understand how new approaches can be developed, targeting these systems, in humans.

Typically, what will be done to an animal used in your project?

Typically mice will sniff a small droplet into their lungs, to introduce a viral infection, and will also inhale substances designed to boost their defences to that infection (up to once a day, typically for one week). Some of these mice will be the offspring of genetically-modified mice, with specific elements of their defence to infection targeted to work less well. The mice will be observed and weighed, before being humanely killed to study the effectiveness of the infection and the treatments.

What are the expected impacts and/or adverse effects for the animals during your project?

The main impacts expected in mice with lung infections are weight loss and some decreased activity, typically over one week. Where a small minority of mice have more substantial responses to the early phases of infection, they may have loss of body temperature, significantly decreased activity and shortness of breath for a few hours maximum.

Expected severity categories and the proportion of animals in each category, per species. What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals (~75%) used on this licence are expected to be subthreshold, used only for breeding of genetically-modified mice with not harmful characteristics. Of the remaining 25% of animals, the majority (~70% of these) are expected to have only mild signs, associated with mild infections that are well controlled, cleared and boosted by treatments, with the remaining (estimated at less than 30%) having experiences of moderate severity (principally in relation to weight loss).

What will happen to animals at the end of this project?

- Humanely killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding the body's natural defences to infection, and then using that information to develop new approaches to preventing and treating infections, is of ever greater global importance. Projects, such as this, with those aims, need to combine studies using the best approaches to studying cells in the laboratory, with clinical studies characterising the outcomes in humans. However, that combination still cannot provide all the answers and needs to be complemented with studies in animals. These studies allow the researchers to examine all the biological components of the response to infection, and to actively modify it, from the initiation to the recovery, in a living system that is greater than the sum of its parts.

Which non-animal alternatives did you consider for use in this project?

This project has considered, and is undertaking, studies using bacteria and viruses alone, studies using cells grown in the laboratory, studies using materials from humans (both healthy volunteers and infected patients), and studies characterising relevant aspects of human health and responses to naturally occurring infections, as alternatives to the use of animals, to address some of the key components of this project.

Why were they not suitable?

Studies using bacteria and viruses alone, studies using cells grown in the laboratory, studies using materials from humans (both healthy volunteers and infected patients), and studies characterising relevant aspects of human health and responses to naturally occurring infections, are all suitable to answer some the questions required to meet our aims. However, testing the hypotheses that we can create from these studies ultimately also requires the use of live animals. These complementary studies in animals then enable researchers to modify the biological responses to an active infection (to block and/or boost them) at different defined stages and observe the consequences for protection against infection in all the multitude of components of a living system that is great then the sum of its parts. This is not possible to do using non-animal alternatives alone and is essential for the development of new preventative and therapeutic approaches to infection.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice necessary for this project have been estimated based both on records from previous related research, to determine the scale of breeding colonies required, and using mathematical approaches to estimate the numbers of mice required for individual experiments to provide reliable levels of data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Extensive use of studies using cells grown in the laboratory, and use of human samples, to precede and complement studies using animals, means that mouse numbers used in experiments will be significantly reduced.

In designing experiments for this project, approaches have included consulting experts in experimental design and statistics, using experimental design training from FRAME (an independent charity, working to promote alternatives to animal testing), and using the NC3R's (National Centre for the replacement, refinement and reduction of animals in Research) Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In addition to good experimental design, this project will optimise the number of animals required by using efficient breeding protocols, small, targeted pilot studies to focus experimental approaches, approaches that maximise the number of scientific questions that than can addressed in each animal, and via the sharing of tissues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use models of lung infections of particular global health importance, such as using viruses for which we have no effective treatment or vaccine, or bacteria with high levels of antibiotic resistance, for which new preventative and therapeutic approaches are urgently needed. Lung infections will be initiated and allowed to develop in the least harmful manner possible while still causing targetable natural defence systems to be activated; achieved by using well documented previous studies, pilot studies, careful clinical monitoring and appropriate further responsive-mode refinement of approaches. At different phases of disease, from initiation to recovery, researchers will intervene to boost or to block the natural defence systems to clearly identify promising interventions. This may be through administration of drugs or cells, or the use of genetically-modified mice (in which host defences are automatically disrupted without further active procedures or harmful characteristics). Suffering during periods of infection will be minimised by using the lowest dose of infection and the shortest time course of infection possible while still make valid use of the study to answer the specific questions, in addition to support measures (such as active maintenance of body temperature) to minimise the severity of symptoms

that cannot be avoided. In any cases where clinical monitoring identifies an unexpectedly higher level of severity, the experimental animal will be humanely killed.

Why can't you use animals that are less sentient?

Animals that are less sentient (such as drosophila and zebrafish) can be used to examine certain aspects of defence against infection. However, for these specific studies, mice are the least sentient animals in which all the major components of the natural defences against infection are characterised as sufficiently similar to those of human to enable valid evaluations of their relative importance and interplay within a living organism. This level of complexity is required at this stage in the experimental scientific research and development of novel preventative and therapeutic approaches for future human use.

Conducting infection time-course studies over the required timeframe cannot be conducted under terminal anesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To refine the procedures being used, to minimise the harm to animals, the research team have developed and use a clinical scoring system for infected animals. This is used hourly in acute phase of infections, and daily in less severe, longer infection periods, to ensure that harm is minimal, and to enable further refinement of protocols where any deviation is observed, particularly when using animals that are potentially more susceptible than usual. Using this system, the approaches can be refined to use lung infections that develop in the least harmful manner possible while still causing targetable natural defence systems to be activated, and over the shortest periods possible to answer the specific questions. Additional refinements, already in place, include support measures, such as active maintenance of body temperature, during the early acute phase of bacterial infection, developed to minimise the severity of responses to infection.

Our team, in particular animal technicians (who can conduct, train and supervise procedures), are experienced in handling and conducting experimental work on animals, which will reduce stress and suffering of the animals. The unit in which the animals are kept is large, well-resourced and well- equipped. Throughout all work, advice is sought from the animal technicians and from veterinary staff. Every experiment is submitted first to a vet for review, advice and scrutiny of procedures. Prior to and during experiments, animal health will be maintained using good breeding and handling techniques and housing in individually ventilated cages.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE 2.0 guidelines will be used to ensure that experiments are conducted and reported in a valid and appropriate manner, and the Experimental Design Assistant from the National Centre for the replacement, refinement and reduction of Animals in Research (NC3Rs) will be used to ensure the most refined experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The team will stay informed about the 3Rs during this project, and implement appropriate advances. This will be achieved by reading relevant publications, and attending appropriate presentations / conferences. In addition to those disseminating the relevant scientific advances, these will include information from the local Animal Welfare Ethical Review Body, local Annual Refresher Training, local annual 3Rs day of presentations, and output from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs)

40. Presynaptic function and dysfunction in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Brain cells, Epilepsy, Neurodevelopmental Disorders, Neurodegeneration, Therapy

Animal types	Life stages
Rats	neonate, juvenile, adult, pregnant, embryo, aged
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine the role of presynaptic function and dysfunction in health and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important since an understanding of how the brain cells communicate in both health and disease is critical to sustain efficient neuronal communication if it is disrupted. Many brain molecules have poorly defined functions, and many communication processes are not understood at the molecular level.

Furthermore, how these processes contribute to higher brain function is still unclear. The work outlined in this project addresses these points, and will use the information acquired to understand how dysfunction in brain communication culminates in human disease. By determining where dysfunction exists at multiple levels of complexity, and critically, how this dysfunction may be corrected, is of the highest urgency and importance.

What outputs do you think you will see at the end of this project?

The output from this programme of work will primarily provide new information, specifically a more sophisticated and accurate understanding of the key molecular steps that underpin brain communication. This is important for two major reasons 1) an in-depth knowledge of the function of specific molecules required for brain communication will allow a focused study of genes (and mutations in these genes) identified as being linked or causal to human disease and 2) a determination of which aspects of brain communication are disrupted in models of human disease. Importantly, our research strategy allows the convergence of a future therapeutic programme of work at the level of brain processes, rather than individual molecules. This should allow a greater diversity of interventions in pathways that occur either in parallel to, or are integrated with, the affected brain processes.

Another output is the generation of new models of human disease. A demonstration that the disruption of specific neuronal processes can translate into an easily measurable outcome in animals will be of high value for researchers in academic and commercial settings. This is because it will increase the possibility of translating progress from basic to applied research, by providing a means to screen for future drugs using simple measures.

The aim is that by the end of this 5 year project we will have identified key targets for future intervention in a number of neurodevelopmental disorders and neurodegenerative conditions and may have identified potential new drugs to combat these disorders.

Who or what will benefit from these outputs, and how?

Scientists studying brain communication will benefit, since this group will be able to exploit this new knowledge in their own research. This may provide novel and hitherto unexplored avenues of research for a number of academic and/or research groups.

Research funders such as UK Research Councils and various charities devoted to the treatment of neurodevelopmental disorders and neurodegenerative conditions will benefit from the results of this project as it will validate the value of the scientific research that they support.

Other beneficiaries will be companies that investigate disorders of the brain, such as autism, intellectual disability, epilepsy and neurodegenerative conditions. The identification of specific molecules and processes required for correct brain communication and critically interventions that can correct brain dysfunction, will provide new drug targets and therapeutic interventions respectively. The benefits to this group will be longer term, however if specific drugs can be used that are already approved for human use, this could allow drug trails in companies to commence immediately.

How will you look to maximise the outputs of this work?

The results from this work will primarily be reported in scientific publications in specialist journals. It will also be presented at international conferences focussed on brain communication and human neuronal disorders. Furthermore, the work will be publicised to a wider lay audience through scientific communication events and via social networking sites such as Twitter.

Importantly, we will also publish the outcomes of unsuccessful approaches, in terms of failure of specific interventions to correct observed defects in brain communication, and also where testing of specific hypothesises regarding such communication were disproven.

If outputs indicate that the project would benefit from collaboration with other scientific groups or companies that possess specific expertise, this would be enthusiastically followed.

Research funders will publicise the outputs, especially high-impact work, since this provides proof of benefit of their financial support.

Species and numbers of animals expected to be used

- Mice: 16250
- Rats: 7250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Rodents are the most appropriate species for our work, not only because they are amenable to genetic manipulation, but studies have identified that the key molecules that will be the subject of investigation are highly conserved between both rodents and humans. The great majority of the work outlined will be performed using tissue from embryonic or neonatal rodents. Adult rodents will only be used in specific instances to obtain brain tissue to investigate the composition or circuitry of specific brain region. The only time living rodents will be used in a procedure will be to assess their seizure susceptibility or the impact of their aging. These experiments are essential, since they allow the effect of drug interventions to be tested.

Typically, what will be done to an animal used in your project?

As stated above, the vast majority of animals will be culled simply to utilise their brain tissue. Culling will be either by schedule 1 procedures or other procedures that are occasionally required to maintain the functionality of the tissue. A small fraction of experiments (less than 5%) will involve the delivery of virus particles to the rodent brain via surgery and injection. Another fraction (less than 5%) will be performed in living animals, this will involve on occasion the delivery of drugs either orally or via injection. The seizure susceptibility experiments are very brief (lasting 2 minutes), whereas the aging studies, by definition, last longer. If any animal displays distress for these two procedures they will be immediately culled.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no expected adverse effects in any of the genetically modified rodents we plan to use. The adverse effects arising from surgery and injection of virus particles will be minimised by best practice in pre and postoperative care and appropriate analgesia. In seizure susceptibility experiments rodents may progress through to full seizure within the 2 minute experiential period. These rodents will be humanely culled immediately. Rodents that are part of an aging study will be closely monitored for adverse effects such as weight loss or abnormal gait. Animals that continue to lose weight will be humanely culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for the majority of the procedures under this licence is anticipated to be sub- threshold (approximately 80 %). Breeding and maintenance of genetically-modified rodents will occasionally reach mild severity (5 %). Culling for CNS tissue (approx 5%) and aging studies (approx

2.5 %) will be mild. Both seizure susceptibility to audiogenic stimuli (2.5 %) and surgery and delivery of virus (5 %) will be moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project studies the role of molecules in brain communication and how alterations in this communication result in neurological disease. For this study an experimental system of appropriate complexity must be used in relation to the cross-talk within individual brain cells, how they communicate with other brain cells and ultimately how this translates into altered behaviour. The only appropriate experimental system that allows the study of such processes through increasing complexity are vertebrate animals.

Which non-animal alternatives did you consider for use in this project?

As the field currently stands there is no alternative to using brain cells from animals. We investigated the possibility of using "transformed" cell lines to mimic the communication inside brain cells. These cells can grow and multiply on their own in a dish, negating the requirement for animal brain cells.

We also investigated establishing measurements of brain cell function in stem cells taken from patients with neurodevelopmental / neurodegenerative disorders. These can be induced to behave in a manner similar to mammalian brain cells.

Why were they not suitable?

Transformed cell lines cannot currently mimic the intricate series of molecular events observed in brain cells. In most cases they also require a series of interventions to make them “neuronal”. Therefore it is unlikely that this system will faithfully reproduce the events that occurring inside human brain cells.

Human stem cells that are induced to appear "neuronal" are a promising avenue for the future. However as the field currently stands, these cells appear to be highly "immature" and do not produce the same molecules or communication pathways currently observed in brain cells taken from embryonic rodents. Therefore the ability to investigate the complex communication within and between mammalian brain cells is still not possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Power analysis calculations will determine how many animals will be used for specific experiments. These calculations will be guided using established statistical methods that we have applied to these types of data over the past 10 years, and that have been subject to scrutiny during peer-review. Brain cells grown in culture are a reproducible system, meaning we can reduce the number of animals required to reach statistical significance (usually less than 6 animals). This number is slightly higher for experiments using brain tissue (normally 8–10 animals are required for each experiment). Also there is a chance that altering the genetic makeup of the animal may lead to greater variance in a particular phenotype. Power analysis calculations can be performed to accurately estimate the number of animals required to complete the aims with statistical significance in this regard.

For experiments that require observation of animal behaviour, these may require the use separate experimental groups (i.e., control minus drug, genetically-altered minus drug, control with drug, genetically altered with drug). Previous Power analyses suggest that group sizes of at least 15-20 will likely be necessary.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments will be performed according to the ARRIVE guidelines. As such, genetically altered animals (or experiments using brain tissue) will always be tested alongside unaltered wild type animals (or brain tissue) that are matched for age and gender, and treated groups will always be compared to vehicle controls. Furthermore, experiments will be performed blind to genetic makeup by using a code (e.g., A or B) to identify each animal. This code will be kept by a person who is not involved in the experiment. Groups will be assigned in a randomised fashion.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cultures of brain cells will be shared among the research group to permit as many experiments as possible to be performed per animal. This is also the case for experiments using brain tissue.

Researchers can and often do use material from one animal for multiple experiments. In many cases, two researchers prepare tissue from the same animal to perform their experiments.

Finally, all of the systems and behavioural experiments in the application are extremely well characterised by both ourselves and other research groups, meaning that almost all animals will be utilised in a productive manner. Wherever possible both male and female animals will be used in our experiments, again reducing the number of unnecessary deaths.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents are the most appropriate species for our work. One reason is that they are amenable to genetic manipulation and numerous studies have identified that the key molecules we are investigating are very similar in both rodents and humans. Furthermore some aspects of the research programme require investigation of region-specific effects in mammalian brain (e,g, striatum loss in Huntington's Disease). Therefore having an experimental system that is built in the same general manner to humans is key to this programme. Also, genetically modified rodents accurately recapitulate the genetic disease state in individual brain cells, providing a refinement not possible with other alternatives, such as destroying brain regions.

Why can't you use animals that are less sentient?

Cultures of brain cells (where the majority of the work is focussed) are derived from rodent embryos or pups within their first week of life. Therefore we are already using an immature life stage for this work. The study of brain circuits requires greater complexity, therefore brain tissue has to be obtained from older rodents. Animal behaviour has to be observed in conscious rodents by definition, therefore there is no alternative in this instance. Less sentient species are not appropriate for these studies, since we require the complex behaviours observed in rodent models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In most cases culling of animals will be performed using schedule 1 approaches. The genetically modified (GM) mice we plan to use initially display only mild phenotypes. For any known age-dependent adverse effects of genetic makeup animals will be culled before any distress is known to occur. Novel GM animals that may become the subject of investigation will have their health monitored closely.

Where required, principles of good practice for surgery will be followed (e.g. establishment guidelines for 'Anaesthesia in Rodents' and 'Surgical Procedures on Experimental Rodents'). Pain will be controlled during surgery by general anaesthesia and pre- and post-surgery by analgesics. Risk of infection will be minimised by good surgical and aseptic techniques. Surgical sites will monitored for signs of inflammation and infection.

For audiogenic seizure experiments, we will follow published methodology but with important refinements. In the published methodology seizure is graded on a 4 point scale (wild running, clonic seizure, tonic seizure and death). In our protocol we will test only one

GM animal at a time (paired with a control); this will allow us to stop the experiment and humanely kill an animal should a tonic seizure occur. Thus, we will assess audiogenic seizure on a 3 point (rather than a 4 point scale) in order that death is not an endpoint of the seizure. In order to compare our data with that of other laboratories who have conducted such experiments we need to carry out this protocol on awake animals to assess any behaviour that the auditory stimulus initiates – using anaesthetized animals and recording brain activity, for example, is not possible with our proposed protocol nor is it practical in terms of the age of animals being studied.

Another further refinement is the expertise and experience of care and research staff within the laboratory and animal facility. Rodents will have access to a well-resourced and well-equipped modern facility with individually ventilated cages and barrier systems in use for maintaining “Specific Pathogen-Free” (SPF) status/health. Where appropriate to animal health and wellbeing colonies will be provided with environmental enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on the Operations of ASPA - https://www.nc3rs.org.uk/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will visit the 3Rs webpage regularly to keep abreast of the latest developments. Myself and my research group will also attend 3Rs seminars and webinars where available. Where an obvious advance in 3Rs is apparent, we will move to quickly adapt our protocols to conform with the new guidance.

41. Investigating cardiovascular disease using the zebrafish

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

zebrafish, Cardiovascular, Heart, Regeneration

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Identifying novel molecular pathways that regulate cardiomyocyte proliferation and regeneration following cardiac injury.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are millions of people living and dying due to heart and circulatory diseases in the UK every year. While survival rates are improving, an ageing population will ultimately lead to more heart disease in the future. Loss of heart tissue can result from common conditions such as heart attacks or high blood pressure leading to decreased heart function and heart failure. Replacing lost heart tissue could restore heart function in damaged hearts. One potential way to achieve this would be to stimulate the heart to regrow new tissue. However, while the zebrafish can do this, the human heart cannot. This project seeks to better understand the specific molecular pathways and mechanisms that permit the zebrafish to achieve this and to explore whether they can be harnessed for human benefit.

What outputs do you think you will see at the end of this project?

All work will be published in peer reviewed journals in a timely fashion. Data will also be used in grant applications to generate further funding for ongoing research.

We anticipate a future grant to then take current projects forward into mouse regenerative models and provide further evidence in humans and understand the importance of underlying regenerative molecular mechanisms in CM vs other cell types.

The findings are expected to lead to novel pathways that could be targeted for drug treatments for human cardiovascular disease.

Who or what will benefit from these outputs, and how?

In the short term, 3-8 years, new pathways and mechanisms will be elucidated. This will benefit of the scientific community investigating potential molecular pathways that play a role in myocardial regeneration. In the longer term, possibly 10 or more years, nitrosylated proteins and LncRNA-Carmen could be of benefit in animal models such that both molecules could be targeted as candidates for novel treatments for heart disease.

How will you look to maximise the outputs of this work?

The work involves collaborations with other molecular scientists across the University campus and internationally. The work will be shared with key funding bodies such as the BHF and MRC and also shared across various publication and web platforms thus ensuring a wide distribution and sharing of the knowledge and ideas arising from the proposed work.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The zebrafish is unique in that it can regrow new heart muscle tissue following injury. Studying this will allow us to seek new mechanisms that might allow human hearts to undergo a similar form of self-repair after a heart attack for example. The adult zebrafish, 90-120 days after fertilisation will be used as this is the key time when the zebrafish heart has a strong capacity to regrow.

Typically, what will be done to an animal used in your project?

The adult zebrafish will undergo an operation to cause heart injury either by surgically removing a small portion of the heart muscle or injury caused by freezing a small portion of the heart using liquid nitrogen. Both types of injury will be done by an experienced operator under a full general anaesthetic. The animal will then recover from the operation for a period of up to 60 days before being killed for investigation. We add morphine to the bathing water routinely in the post-operative period to address pain relief.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals recover from the operation fairly quickly, typically within 24 hours. There is occasionally some bleeding from the wound. The fish start swimming around the fish tank within 4-6 hours after surgery and appear to show no major adverse effects. Fish are monitored throughout the surgery and the 24 hour period thereafter and euthanased if showing signs of distress or are unlikely to recover. Despite this we still find that we have a 5% mortality within the first 24 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Both types of heart injury operations using either surgical resection or cryo-injury represent moderate severity, any animals showing severe distress during the operation are not allowed to recover from the initial general anaesthesia and are euthanased using an overdose of anaesthetic.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tissue culture experiments cannot provide the in-situ, mixed-cell, whole organ environment required to study cardiac regeneration. The zebrafish whole heart regeneration model permits the study of multicellular tissue incorporating intrinsic tissue remodelling and an acute and inflammatory response to injury all of which can be studied in this model and could not be readily studied in other replacement models such as tissue culture. We do however perform similar experiments in larvae at much earlier developmental stages whenever possible to minimise suffering to older adult fish.

Which non-animal alternatives did you consider for use in this project?

Tissue culture models of cardiomyocytes have been considered but these are limited by the issues highlighted in the section above. Larval models of heart injury have been extensively used in my laboratory but the immature heart does not contain the same complex mixture of cell types such as fibroblasts, mature immune cells and vascular smooth muscle cells that are present in the regenerating adult heart.

Why were they not suitable?

Adult cardiomyocytes do not grow well in in tissue culture and the mixed cellular components, and their associated extracellular milieu, cannot be replicated in tissue culture setting. In addition, as described above, the adult zebrafish heart produces a modest fibrotic scar in response to cryo-injury which does not arise in the larval animal and is difficult to reproduce in tissue culture. This scar formation creates a model that is very similar to that found in mammalian model systems and in humans after myocardial infarction. This makes the adult zebrafish models described in this application highly relevant for human disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimated numbers take into account a set of experiments from two specific, funded projects addressing key issues regarding the molecular pathways of cardiac regeneration. The numbers are based on previous experience in our Lab and in other labs in our institute. The numbers are also based on the protocols described in each of the funded projects. However, the majority of the adult fish used under this license will be utilised for breeding and maintenance which has a maximal severity limit of mild.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used a number of approaches including - advice from our local responsible veterinary officer, the NC3R's design assistant and we took advice from other colleagues performing similar experiments using zebrafish.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible, we will share tissue across different members of our lab group and other members of our centre. We have a very pro-active team in our aquatic facility that monitors and streamlines all fish lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Two Adult Zebrafish heart injury models will be used in this project: heart resection and heart cryoinjury. Most of the experiments will be done using the cryoinjury model which is technically less demanding, and which produces a myocardial scar similar to that seen in mammalian models of myocardial infarction. In our experience of using these models, once recovered from surgery the vast majority of animals survive to the end of protocol at 60 days. Suffering is minimised by carefully observing them in the immediate 2 hours following surgery, allowing them to recover in a dark area, if they show any signs of distress based on monitoring protocol and scoring system then they are killed quickly by overdose of anaesthetic. Once they are over this 2 hour post-surgery time point, we typically observe good recovery with severity not exceeding moderate.

Why can’t you use animals that are less sentient?

We do currently use a model of heart laser injury in larval zebrafish but this model has limitations from a scientific viewpoint in that the heart is very immature, the cellular response to injury is driven mostly by usual-embryonic growth and the heart is very small and thus much more difficult to extract, stain and analyse histologically.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

All members of my research group will continue to seek new ways to minimise harm caused to our animals by attending regular, appropriate training courses, liaising closely with our local animal care staff and veterinary services, reading appropriate literature and remaining vigilant for the welfare of our animals on a day to day basis by maintaining good communication and relations with colleagues in our aquatic facility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use online material at zfin: https://zfin.org/zf_info/zfbook/cont.html

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will remain continuously engaged with updates from NCR3's via email updates and web-posts, we will continue to maintain and develop our training and skills with regard to animal welfare. We will remain engaged fully with our local animal care staff and veterinary services.

42. Breeding and Maintenance of Genetically Altered Rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Breeding , Genetically altered

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to create, breed and maintain mice with genetic alterations and supply them to investigators to carry out research into the study of biological and physiological processes and/or the control of disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically altered (GA) rodents are widely used in the fields of biological, medical and veterinary science, and are considered to be of great value in dissecting the function of genes and pathways in physiological and pathological processes. GA animals also provide us with models for many human diseases.

The application of GA mice is well established at our establishment to study biological and physiological processes and/or the control of disease. The data generated from these studies are essential to provide new knowledge at the cellular and molecular level, and to validate new prophylactic or therapeutic approaches for disease.

What outputs do you think you will see at the end of this project?

This project aims to breed, maintain and supply GA mice to our research teams and to those at other establishments working in collaboration with us. The outputs at the end of the project will be in the form of new information and publications from the investigators and research groups that we have provided animals to.

Who or what will benefit from these outputs, and how?

Scientists working on projects using GA animals at our establishment will all benefit from an efficient supply of animals for their research. Outputs and advancements in these scientific areas will be published and benefit the wider scientific community and advance medical knowledge. Where practical, animals will also be available for collaborators at other institutions. Overall, this may result in less numbers of animals bred and used.

How will you look to maximise the outputs of this work?

Many Project Licence holders collaborate with other establishments in many research areas and publish scientific data and findings observed throughout the studies conducted.

Species and numbers of animals expected to be used

- Mice: 25000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

This project aims to breed, maintain and supply adult GA mice to our research teams and to those at other establishments working in collaboration with us.

The types of mice bred and maintained will be determined by our Project Licence holders' requirements for their Home Office-approved research projects.

Typically, what will be done to an animal used in your project?

Mice will be placed in pairs or trios and bred to produce GA animals.

For certain breeding schemes, a small tissue sample (drop of blood or ear notch) may be collected at weaning to examine if the offspring is of the correct GA status.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no adverse effects expected for the animals in this project, as the GA strains bred under this licence are not expected to show any harmful phenotypes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity for 100% of the animals is expected

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to breed, maintain and supply GA mice to investigators to carry out Home office-approved research into the study of biological and physiological processes and/or the control of disease.

To date, there are no in vitro assays that adequately model the molecular, cellular and physiological interactions that take place in an intact animal. Nor is it possible to perform studies in which immune/pathological responses to infection of human subjects are manipulated or examined in a controlled manner. Therefore it is necessary to use a whole-animal model.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each Home Office-authorized Project Licence at our establishment has numbers of animals to be used specified in their licence. These animal numbers are added up, and this figure is used to determine how many animals will be produced on the GA production licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animals will only be bred if a user requirement has been established, and the breeding programme will be subject to regular review to optimise production in line with anticipated demand. Breeding will be optimised, wherever possible, to produce only the genotype required.

Unnecessary breeding of GA animals will be avoided by searching cryobanks and databases (e.g. from the National Centre for the replacement, refinement and reduction of Animals in Research, the Jackson Laboratory, and the Federation of International Mouse Resources).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use the “traffic light system” for all our mouse breedings. This is a standardised system to determine the quality and efficiency of breeding colonies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The purpose of this project is to breed, maintain and supply GA mice to other investigators. Animals are not expected to display pain, suffering or distress.

Access to the breeding room is limited to ensure animals are housed in quiet areas with minimal disturbance.

For some mice, a small sample of tissue (drop of blood or ear notch) will be taken at weaning for genotyping to examine the genetic status. Published guidelines for current best practice will be followed to minimise animal suffering

Why can’t you use animals that are less sentient?

N/A

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Breeding animals are checked twice daily by a competent person. Breeding colonies are maintained by staff who are licensed and trained to the highest standard, including how to recognize any signs of ill health, pain or distress.

All animals are handled using the cupping or tunnelling technique in order to minimise stress.

All animals bred under this licence are subject to a rolling programme of environmental enrichment to ensure they do not exhibit any adverse effects due to boredom and lack of stimulation. This enrichment programme includes, tubes, tunnels, mouse houses, sunflower seeds and other available enrichment item

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The "Advice on Severity Assessment of GA animals" published in 2014 will be used, along with published articles from the NC3Rs, Understanding Animal Research, and RSPCA on GA animal breeding.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The licence holder keeps up to date with any advancements in the industry. The licence holder is also a member of a number of networks that share best practice and advances in the 3Rs, and regularly and actively seeks out new information and updates regarding breeding practices. This knowledge is shared with staff involved in mouse colony care and maintenance.

43. Discovery of new anti-cancer therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Metastasis, Pharmacokinetics, Therapeutic efficacy

Animal types	Life stages
Mice	adult, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The work performed under this licence aims to develop novel agents that can then be assessed clinically as potential treatments for cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Around one in four of all deaths in the UK are caused by cancer, highlighting the urgent need for improved cancer treatments. Many novel molecularly-targeted anti-cancer agents have been developed, and some show significant benefit in subsets of cancer patients.

However, the duration of drug-induced tumour responses is often short-lived due to the emergence of drug resistance, and for many patients there is currently no beneficial treatment.

What outputs do you think you will see at the end of this project?

This project will contribute to evaluation and progression towards clinical trials of potential novel anti- cancer agents targeting key features of cancer such as metastasis, resistance to standard of care drugs, drugs, regrowth after regression/treatment, that are unresolved issues in current cancer treatment and the cause of many cancer-driven fatalities.

Who or what will benefit from these outputs, and how?

Ultimately, cancer patients may benefit from these outputs if drug candidates progress to clinical trials. Deeper biological understanding of cancer biology will be acquired and therapeutic hypotheses will be confirmed or refined based on this work.

How will you look to maximise the outputs of this work?

We have close collaborations with colleagues from the Establishment and we collaborate with them to discover inhibitors for their targets and assess our inhibitors in vivo in their models. The results of this work will be published and/or disseminated through presentations at scientific conferences when appropriate and will therefore inform other cancer researchers worldwide.

Species and numbers of animals expected to be used

- Mice: 10650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages

Cancer development is dependent not only on the changes occurring within the transformed cells, but also on the interactions of the cells with their microenvironment. Mice are more comparable to humans than less sentient model systems (fish, invertebrates) in pathophysiology and show higher levels of conservation in nucleotide and amino acid sequences. This is important as we intend to use reagents such as small molecule inhibitors and antibodies that have been developed to target human proteins.

While cell-based research has elucidated many changes in cancer cells, it provides little information about the local environmental factors influencing early-stage cancer development in life. Also certain hallmarks of cancer, such as spread of cancer and blood vessel formation, are impossible to study in vitro (cell culture). Therefore, mouse models are important for studying the in life aspects of human cancer development. Mouse models have been engineered to develop tissue-specific cancers, which accurately mimic their human counterparts, and have potential applications to test the effectiveness of novel

cancer therapeutics. Moreover, non-protected species and less sentient species do not have specific organs such as lungs, so we would be unable to use them for animal models of lung cancer involving the injection of cancer cells in the organ where they are found in man.

Typically, what will be done to an animal used in your project?

Normal and genetically altered mice will be used to investigate the efficacy of modulating certain specific molecular pathways to suppress induction, progression and metastatic spread of cancer cells.

Most mice used, will experience only administration of agents by either mouth or injection into a vein, under the skin or in the abdomen and taking very small blood samples as we determine the concentration of drugs (up to 24hr) and tolerability studies (up to 28 days) with gradual increments in doses given.

The mice may have tumours grown in them initiated through either use of cancer prone genetically modified mice or by the implantation / injection of existing tumour cells / tumour pieces. Surgical procedures requiring general anaesthesia and pain relief are tumour implantation (most commonly subcutaneously) and tumour biopsy (a gold standard method used clinically).

A combination of methods will be used to monitor tumour growth: the use of calipers (for subcutaneous implanted tumours) and imaging under light general anaesthesia will be performed on a number of occasions. The effect of potential new therapeutics upon tumour growth will be investigated either alone or in combination with existing agents to determine their potential future utility in patients.

On occasions it will also be necessary to inject, by one of several possible different routes, chemical agents that will allow better imaging of the internal tumours. The majority of animals are not expected to show signs of adverse effects that impact on their general well-being. Very rarely the severity of these signs may be such that the humane end points may be reached (i.e. 20% loss in bodyweight) and the mice killed humanely. The majority of the procedures will result in no more than transient discomfort and no lasting harm.

All the mice will be humanely culled at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Novel agents that will be used may not have a history of being used in mouse models. There is potential therefore for acute adverse effects of intolerability. The body weight and other signs of discomfort will be monitored daily; transient weight-loss is common with many anti-cancer therapeutics. Mice will be observed more frequently during the first two hours after novel agent administration.

Lethality resulting from drug toxicity is anticipated to be very rare; furthermore, in our experience not more than 2% of mice should experience a level of toxicity that

necessitates humane culling of the animal. Regular observations of the animals should ensure wherever possible that mice are culled prior to drug-induced deaths.

The impact of tumourigenic mutations are not expected to cause any adverse effects per se as these in most cases only manifest following administration of inducing agents. It is possible that the tumour growth might affect normal physiological functions (such as eating, locomotion or breathing). However, mice will be observed daily and any side effect that cannot be managed satisfactorily will result in humane culling of the animal.

Injections would only cause very transient pain.

After surgical procedures we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of mice used in drug exposure / tolerability studies are expected to experience no clinical symptoms due to the administration of novel agents before they are humanely killed. We will use very small does and only two animals per group initially when the first administration of a new agent is used. Additionally, some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery with a specialist tube. We will aim to utilise the least stressful route of administration wherever possible.

The vast majority of mice used in tumour / efficacy studies are only expected to experience the mildest clinical symptoms due to tumour growth before they are humanely culled. Some mice may experience a degree of skin ulceration. Dry ulceration is considered a sign of healing and are not considered harmful. Mice that develop ulcers that impact adversely on their well-being will be killed humanely.

A minority of mice will undergo surgery and these will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing this is not painful.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are necessary to test concepts in tissue settings under physiological conditions that resemble those in humans. Treatment of organisms with anti-cancer agents induces complex responses involving interactions between different types of tissues and organs.

In order to test the activity of cancer drugs, it is necessary to use models of cancer grown in an appropriate environment. Immuno-incompetent (nude or SCID) mice are routinely used for these studies because they can support the growth of human cancer cells as a non-mouse tumour.

Furthermore, in this proposal, we will examine the effects of drugs on the subcutaneous growth of human tumours and this can only be achieved in a complete organism that has a fully functional circulatory system.

Additionally, it is a legal requirement that any drug for human cancer use is assessed in at least one mammalian species before entry into clinical trials. Finally, mice are also routinely utilised in cancer research for the assessment of drug exposure, tolerability and therapeutic efficacy.

The research plan follows well recognised international guidelines, which aim to facilitate and accelerate the development of anticancer pharmaceuticals and protect patients from unnecessary adverse effects, whilst avoiding unnecessary use of animals, in accordance with the 3R principles (reduce/refine/replace).

Which non-animal alternatives did you consider for use in this project?

- Mammalian cell cultures.

Why were they not suitable?

These responses cannot be recapitulated using in vitro methods alone or with simple organisms (e.g., Mammalian cell cultures) that lack the differentiated system of an animal. Multiple pathways that together determine the fate of a drug in human, such as adsorption, metabolism, distribution, excretion, and pharmacological and toxicologic effects cannot be mimicked by an in vitro system. It is established that treatments in humans have comparable biological and biochemical activities in animals.

Conclusions from animal experiments are therefore relevant in understanding human disease and therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume or tumour incidence following manipulation of a gene of interest or treatment with a drug can be determined using the minimal number of animals.

Data available from the literature or from pilot studies are used to perform power analysis to determine an appropriate sample size for the definitive experiment. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.

Based on past experience, group sizes of between 6 and 12 animals (dependent on the readout) per experimental group suffice. However, we may use several doses of a drug, or several different drugs or treatment combinations to test a hypothesis. The number of experiments and groups per experiment is estimated based on the stage of the projects and the estimated number of compounds that following progression through the screening cascade will be appropriate for in vivo evaluation. This is based on our experience of bringing multiple drug discovery projects from hit identification to candidate nomination and clinical trials.

Considering power, the number of experimental groups, and the number of drug targets we are interested in, we have then estimated the total number of mice to be used over the licence lifetime.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to any large scale experimentation, initial pilot studies will be conducted to characterise models. This will allow us to better estimate take rates after cell implantation, observe recovery rates from surgery, and observe how the mice cope with the tumour burden and any clinical observations that may indicate complications. Further standard experimental procedures will also be assessed for applicability, for example, the measurement of tumour growth, inter- and intra-tumour variability, and the measurement technique employed. The information gathered will help to establish the numbers needed to power larger studies for statistical significance, in parallel with the best processes for the monitoring and care for the animals during these experiments. Experiments are designed using the principles outlined in the experimental design tool on https://eda.nc3rs.org.uk/ and reported according to ARRIVE guidelines. Power analyses will be performed, ideally with the support of a biostatistician or mathematician, to ensure that we use the minimum number of mice to generate statistically validated results.

As a result of advances in blood biochemistry analysis (e.g. highly sensitive high performance liquid chromatography mass spectrometry HPLCMS/MS technology coupled with ‘micro-capillary bleeds’), it is possible to analyse circulating drug levels from very small blood samples (~10µL blood volume). The small sample volume allows serial samples to be collected from the same animal, thereby reducing the total number of animals required for pharmacokinetic studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of animals will be minimised by (i) making use of in vitro model systems (e.g. tumour cells in the presence of drugs) to test specific hypothesis wherever scientifically justified, (ii) use of in vivo bioimaging to follow disease development and response in real time (rather than culling cohorts of mice at defined time points), (iii) the use of pilot experiments to test for the extent of an expected phenotype prior to a full scale confirmatory experiment (thus avoiding full scale experiments that may lack sufficient statistical power), and (iv) making use of a screening cascade to limit the number of compounds and therefore the number of mice required for the in vivo investigation stage.

Experiments will be appropriately controlled and mice of the same age, genetic background and source used to reduce the variability of results and to produce highly consistent data. Wherever possible and appropriate, a single group of animals will serve as a control for duplicate experimental group. The proposed experimental designs and methods of analysis of the results will follow statistical guidelines and involve discussion with our bioinformatician or mathematician scientist to provide sufficiently powered studies, minimizing the number of animals used in each experiment. The design of individual experiments will generally involve factorial designs, which maximise the information obtained from the minimum resource.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and humans share significant similarities in genome structure and gene complexity, in comparison with other less sentient model systems. Moreover, the mouse is well understood and is an adequate model to use for this work. Previous studies have used the mouse, thus use of this model avoids the need to repeat earlier studies in a new species.

Initial pilot studies and consultation with industry experts will aid in identifying the ideal mouse strain as well as to characterise the model, as detailed above. Experience within the Establishment with PD studies has helped refine treatment scheduling. This has led to a reduction in animal numbers and improved inter-animal variability. Such investigations and improvements are continuous within the institute and will be implemented where appropriate.

As a result of advances in blood biochemistry analysis (e.g. highly sensitive HPLCMS/MS technology), it is possible to analyse drug levels from very small blood samples. The small sample volume is a refinement, because warming time prior to sampling can be reduced as well as quicker/simpler sampling method reducing procedural handling. The use of these serial micro-sampling methods has been implemented for all dose

escalation/toleration studies and provides additional exposure data without the need to run an additional study. In mice we usually use 6 animals per route, due to limitations in blood volume that can be taken, with a staggered blood sampling over an 8 hours period. This is also a refinement to the traditional method of using an animal per sample time point, and reducing inter-animal variability, providing 3 values per time-point for improved statistical significance whilst greatly reducing the total number of mice required per study.

Targeting pro-drug delivery to specific tumours offers a Refinement for the systemic exposure of active compound since the conversion from the administered pro-drug is concentrated within the tumour cells expressing the viral transfection.

Why can’t you use animals that are less sentient?

Only a mammalian lung cancer model system has the potential to accurately mimic both the anatomy and complex cell biology, including microenvironmental interactions, of human normal and tumoural lung. Furthermore, there is considerable experience in the wider scientific community regarding the use of mice as a model system for human malignancies and many reagents exist for the phenotypic characterisation of mouse cells.

Mice are the lowest sentient species that are appropriate for in vivo drug development studies and are widely used for this purpose. Most of our work is carried out using well-characterised human tumour cells, grown in the appropriate anatomical site in naturally immunodeficient adult mice to avoid tissue rejection. This enables us to study human cancers in the correct tissue microenvironment.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Suffering is minimised by keeping tumour sizes within tolerable and acceptable limits and according to recognised guidelines. Compounds are delivered using previously determined well-tolerated doses and schedules, and are generally of low toxicity (e.g. agents targeted to molecules selectively overexpressed or mutated in human cancers). We will make the most of non-invasive methods such as optical imaging, bioluminescence, CT-Scan, radiography, optoacoustic, ultrasound.

The conditions under which the experimental animals are kept and used for the proposed procedures are designed for the least possible disruption of natural behaviour and quality of life. The animals are maintained in individually ventilated cages using sterile food and bedding with enrichment of the cage environment and all procedures are carried out in special cabinets using strict aseptic techniques to avoid infections. We constantly work to improve husbandry and procedures to minimize actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare in situations where the use of animals is unavoidable. As detailed in each protocol, there is provision for the appropriate anaesthetic and analgesic regimes as well as appropriate culling methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).

We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)] administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.

For monitoring the aged mice we will follow the guidelines of Wilkinson et al (2020) Laboratory Animals, Vol. 54(3) 225–238.

Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23].

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature and participating in 3Rs workshops / activities locally. Through discussing refinements with our NACWO, NVS and HO inspector..

44. Mapping and controlling neural circuits

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neuroengineering, Neuroscience

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main aim is to develop new tools and techniques that help us understand how the brain is altered in disease and help to correct those alterations. Ultimately, these tools can eventually be applied to diagnose and treat brain disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The most important discoveries that have been made recently in neuroscience have relied on new tools for analyzing and controlling the nervous system. For example, most of the neuroscientists at our institution rely on optogenetics, a system for controlling the activity of brain cells, in order to understand the effects that individual brain cells have on animal

behavior. Most neuroscientists also rely on the use of specialized proteins called calcium indicators, which can tell neuroscientists when individual brain cells are active. These tools (calcium indicators and optogenetics) were both developed by neuroengineers like myself. In contrast to most areas of neuroscience, neuroengineers do not typically seek to understand how the brain works, but instead seek to build tools that will help other neuroscientists understand how the brain works. The tools that we develop lay the groundwork for the next generation of neuroscience.

In all cases, we thoroughly test new tools in cultured cells or in computational systems before using them on animals. However, our goal is to develop tools that can be used by neuroscientists to better understand the mammalian brain, or that can be used in humans for therapeutic purposes. For that reason, it is critically important that new tools be tested on animals to determine whether or not they work for their intended purpose. The protocols described in this license application are intended to allow us to test new tools in animals, before deploying them widely for other neurosciencists to use.

In the long run, the experiments we are doing will have a major impact on neuroscience and the treatment of neuropsychiatric disease. Some of the tools we are developing will enable neuroscientists to study the brain at a higher level of detail, revealing new aspects of how diseases affect the brain. In addition, we are also developing tools for controlling brain activity, which may eventually be used directly for therapeutic purposes. For example, we are exploring new ways to diagnose neurodegenerative diseases such as Alzheimer's disease, and are building new gene therapies for debilitating psychiatric and neurological disorders such as epilepsy. The use of animal models allows us to evaluate the safety and efficacy of these tools before they would ever be used in humans.

What outputs do you think you will see at the end of this project?

This project will advance our understanding of how networks of neurons are organized within the brain, how cell types are distributed throughout the brain, and how neuronal activity is organized within the brain. Moreover, this project will produce new technologies aimed at controlling the organization and activity of brains. This knowledge will be disseminated through presentations at scientific conferences and peer-reviewed publications. In addition, any new techniques, reagents, or software tools generated as a part of this project that have potential to impact clinical or broader scientific practice will be disseminated either freely, through partnership with an appropriate company, or through commercialization in a startup company.

Who or what will benefit from these outputs, and how?

Our goal is to produce new technologies that lead to major advances in the diagnosis and treatment of brain disorders, including psychological disorders such as schizophrenia and depression; neurological disorders such as epilepsy; and neurodegenerative disorders such as Parkinson's and Alzheimer's. We will achieve impact in these areas both directly, through the creation of technologies that can be applied for therapeutic purposes in humans; and indirectly, through the creation of technologies that allow researchers to better understand the effect of these diseases on the brain, thereby allowing them to develop newer therapies.

The methods we develop with direct therapeutic potential will include new techniques for delivering gene therapies to the brain as a way of producing gene-replacement therapies for debilitating diseases such as Fragile X. In addition, we will produce new methods for inhibiting gene expression in specific cell-types, for example to allow us to knockdown expression of genes that cause disease such as the Huntingtin gene in Huntington's disease.

On the other hand, some of the indirect methods we will generate will include methods for characterizing brain circuits and the distribution of cell types throughout the brain, thus allowing us to observe how tissues are affected by disease.

Our goal is ultimately to make our technologies available as widely as possible, so scientists, doctors, and patients can all benefit from them.

How will you look to maximise the outputs of this work?

Whenever possible, we will seek to maximise the utility of data and tools generated as a part of this project through collaboration with other experimental or theoretical groups, and online distribution of raw data and software tools. We will also make use of preprint platforms, such as bioRxiv, to rapidly disseminate our findings to a broad audience.

Species and numbers of animals expected to be used

- Mice: 27150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We are developing many different kinds of tools, all aimed at recording or manipulating different properties of the nervous system. The overall organization of the brain and the function of cells in the brain is similar across mammals. Therefore, insights gained through studying the effect of molecular tools on the structure and function of the mouse brain will help understand what effects these tools would have on the human brain. In addition, the availability of genetically altered mice makes it possible to measure and manipulate neural circuits with unprecedented precision.

Most experiments will be conducted in adult mice. In the case of some tools that are aimed at recording properties of the nervous system during development, or that are aimed at manipulating neural development (e.g., gene therapies that could be used as interventions for neurodevelopmental disorders), we will use neonatal animals. In addition, mouse embryos or oocytes will be used when required for the development and maintenance of genetically altered mouse lines.

Typically, what will be done to an animal used in your project?

Typically, animals will be subjected to a single surgery under suitable anesthesia and analgesia with post-operative follow-up. During the surgery, a molecular tool we have developed (such as a gene therapy) will be injected into the brain, but these tools are not expected to have adverse effects. Animals will typically then be allowed to recover for an extended period of time, unless they exhibit adverse effects requiring early termination, or must be terminated early for scientific reasons. Rarely, animals will be subjected to a second procedure, under appropriate anesthetic and analgesia, in which a chemical will be injected to stimulate neural activity or changes in neural connectivity. Finally, animals will be terminated and tissue will be collected for further investigation.

What are the expected impacts and/or adverse effects for the animals during your project?

Pain resulting from surgical procedures may reach moderate severity for short periods of time immediately following surgery. Animals will be closely monitored for signs of pain after surgery and appropriate analgesia will be provided.

Head fixation is expected to result in only mild stress during initial habituation to the experimental apparatus.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

16350 mice at mild severity. 10800 mice at moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are still far from understanding the effects of different neuroscientific research tools on the brain. For example, we have previously tried to develop research tools in cell culture, and have found that the levels of gene expression in cultured cells can be very different from the levels of gene expression in the mouse brain. Many other features of biology cannot be satisfactorily replicated in in vitro systems: for example, the blood-brain-barrier is a major barrier to the development of brain therapies, and despite several advances there are not yet satisfactory models for the blood-brain-barrier in vitro. Since our ultimate goal is to create tools that can be used to develop new therapies and diagnostics for use in humans, it is important that we use model systems that are as close as possible to human biology, hence the need for animals.

We will focus on mice, which are genetically tractable allowing highly precise measurements and manipulations of neural circuits and the development of disease models, and whose brains are organized according to similar principles to humans.

Which non-animal alternatives did you consider for use in this project?

Computer simulations Brain organoids

Stem-cell-derived model systems

Why were they not suitable?

Often, when tools fail, they fail because of some element of the underlying biology that is not yet understood. Elements of biology that are not understood cannot be modeled in computer simulations. This is why, for example, even simple organisms such as worms and flies still cannot be simulated in the computer faithfully.

Organoids can reproduce many of the aspects of the brain, but still differ in ways that are important and often unknown. Moreover, brain organoids lack normal sensory inputs or outputs, and as a result the connectivity and activity of neural networks present in organoids may differ substantially from the networks present in animal brains.

Finally, stem-cell-derived model systems are excellent for studying aspects of cellular biology, and we expect to use such systems widely. However, they are not effective for studying aspects of the nervous system such as connectivity or activity for the same reason as organoids.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals are estimated based on our prior experience breeding genetically altered mouse lines and with experimental approaches used in the project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will always ensure that we use the minimum number of animals possible to achieve our research goals. We will conduct pilot studies and adopt new methods as they become available, to ensure that we are always extracting the most information possible from any particular experiment or animal. In addition, we will develop better analysis methods and experimental design to ensure that we achieve maximal power and minimal variability.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always conduct pilot studies to test the efficiency and applicability of new tools and techniques before employing them broadly to pursue the scientific objectives of the project. We will use computer modeling and first-principles modeling to refine engineering designs and hypotheses. Whenever possible, brain tissue and experimental data will be shared between researchers or will be used for multiple experiments or analyses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will exclusively use mice. Surgical procedures will be conducted under deep anaesthesia following aseptic technique and mice will be carefully monitored following surgery to ensure complete and uneventful recovery.

Why can’t you use animals that are less sentient?

For projects that have direct clinical application, it is very important to use models that are as close to humans as possible: for example, the adeno-associated viruses that we are experimenting with only infect mammals, and previous studies involving adeno-associated viruses have been found to be invalid because they were used in animals that were not sufficiently similar to humans. Carrying out experiments in this project solely in terminally anaesthetized animals is not feasible since many of our experiments require gene expression, which takes place over the course of several weeks.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

We will ensure always to use appropriate analgesia and anesthesia, with close monitoring following surgery. We will habituate mice gradually to any new apparatus in order to minimize stress, for example in the case of head fixation.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines set out in LASA Guiding Principles on Preparing for and Undertaking Aseptic Surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will utilize online resources such as the NC3RS and RSPCA, and will work with the staff of the biological research facility, such as the NIO, NACWO, and NVS, in order to improve and refine our procedures and adopt new techniques as they become available.

45. Tumour targeting of novel anti-cancer immunotherapies

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cell-based therapy, nanomedicine, immunotherapy, Cancer, macrophages

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project involves the testing of novel cancer immunotherapies alone or in combination with traditional cancer treatments in preclinical mouse models of cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Curing cancer is one of the big challenges of the 21st century. The global cancer burden is estimated to have risen to 18.1 million new cases and 9.6 million deaths in 2018. Our knowledge of cancer has greatly improved, and this has revealed the huge variability that can be found between not only different types of cancer, but also between patients with the same type of cancer. Cancer is responsible for over one quarter of deaths in the UK. Many conventional drugs like chemotherapy and radiotherapy are good at killing cancer cells, but they also kill normal healthy cells. New targeted therapies are urgently needed. Immunotherapies that activate the immune system to identify and attack tumours have now become a clinically validated treatment for some cancers. The research we are undertaking seeks to improve the tumour targeting of immunotherapies alone or in combination with current cancer treatments. If successful this could make a big difference in the way cancer is treated, taking us closer to being able to 'cure' this disease.

What outputs do you think you will see at the end of this project?

The major outcome of this work will be identifying a clinical strategy for translation of novel cancer therapeutics into patients and will directly influence phase I clinical trials as a mono or combination therapy. This work will be published in frontline journals and will provide valuable insights and new information about these targets and their role in cancer. Once we have published our findings and protected our new drugs (e.g. through patents) the drugs developed in this work programme will be shared with other researchers who think they may be useful for the treatment of other diseases.

Who or what will benefit from these outputs, and how?

In the short-term, this work will benefit the scientific community by providing valuable knowledge on new targeted drugs for cancer and the response of the immune system to these drugs. It is likely that the drugs investigated here will also be useful in other cancer types, and the novel compounds will be made available to other researchers for further exploration.

In the mid-long term, the ultimate benefit of this work will be to cancer patients. During this project we also predict sensitivity and resistance to the compounds, for identification of patients who are likely to respond to the treatment.

How will you look to maximise the outputs of this work?

We will collaborate with industry and academic partners for the safety and toxicity testing of these drugs, who are better equipped to perform these experiments. This will streamline the process of taking new drugs through pre-clinical testing, allowing us to more quickly move forward promising compounds into clinical trials. We will disseminate our findings at conferences and in frontline journals and where possible include negative data in these.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We will use mouse models of cancer as these are well established, reproducible and reliably mimic much of the disease in patients. Many studies will use human tumour cells, to most reliably replicate the human disease. However, implantation of human tumour cells must be done in mice with a deficient immune system. For some studies it will be important to have a fully functioning immune system, for example for drugs targeting the immune system, in this case mouse tumours will be used.

For each experiment, the model used will be guided by studies in cells and patient screening. In each circumstance, the advantages and disadvantages of each mouse model will be weighed and the model that most appropriately addresses the experimental aims, while adhering to the 3Rs, will be used.

Where possible we will use tumour cells genetically altered to allow specialised imaging of tumours that allows for tracking of tumour growth over time, to reduce the number of mice needed in each study. We will use mice of an appropriate age for each model that allows for effective engraftment and tumour growth, this is typically a young adult mouse.

We will perform as many experiments as possible in cells and/or organ cultures and screen patient samples (where possible) before we do any experiments in animals. Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but not as effective when treating a whole animal. This is because of the complex environments and signalling networks within animals that may prevent the therapy from working, as yet this cannot be modelled in a dish or by a computer. For example, sometimes drugs do not get through the body to the cancer very effectively, or the body might remove the drug before it can do its job.

We will use cell/organoid culture and screening of patient samples to identify sensitive cancer types and effective drug combinations. We will combine this with computer modelling to understand as much as possible about how the drugs work before treating animals, e.g. how drug resistance may develop. Studies in mice will only be performed

after this to show that the treatments are effective in a whole animal model, and also to identify which new or approved drugs should be used in combination.

Studies will be designed in line with the NCRI Guidelines for the welfare and use of animals in cancer research (Workman et al. 2010). Throughout the study we will re-evaluate the models used in line withthe 3Rs (replace, reduce, refine), to ensure we are using the best and most ethical animal models and where possible use non-whole animal models.

Typically, what will be done to an animal used in your project?

Some animals will be injected or implanted with cancer cells. Where possible, this will be done in the way that most accurately mimics with disease in patients (e.g. injected into the blood for blood cancers, or into mammary tissue for breast cancer), sometimes this will require a surgery under general anaesthesia. In some cases, tumour cells will be injected under the skin as this provides easy access and monitoring of the tumour and avoids complex surgical procedures.

Some animals may be fed a modified diet for a part or throughout the study as this can improve how effective some therapies are in reducing tumour. Some animals will be fed or injected with compounds that we are developing to treat cancer, or a placebo, this is usually once a day or up to 3 times a week. Animals may also be treated with other cancer therapies including radiotherapy. Animals will be weighed at appropriate intervals to monitor weight loss, as this is a sign that they are unwell.

To monitor tumour, animals will be put under general anaesthesia for specialised imaging, this is usually once a week. We will also take a small amount of blood from a vein in the tail once a week to measure markers of response which can be detected in blood. For some tumours, other specialised techniques may be used to monitor the disease. For example, for cancers which cause bone disease we will use micro-computed tomography to scan an affected bone under general anaesthesia. or if magnetic therapies are administered we may use MRI to track delivery as well as monitor tumour size.

The duration of each study will depend on the model used, studies using more aggressive tumours may only last 3 weeks, whereas less aggressive tumours can develop over several months. Experiments to study the effect of compounds on normal biology without tumours present, will last for a defined treatment period, usually this will not be more than 2 months. Humane endpoints will be used to define the end of each study, such as tumour size, detection of relapse or metastasis, or after a period of treatment.

Animals will be humanely killed at the end of the study or when they show signs of becoming significantly unwell, whichever is first.

What are the expected impacts and/or adverse effects for the animals during your project?

Occasionally some mice will experience adverse effects, but provisions will be made to minimise these. For example, the cancer may make some animals feel sick and they may stop eating or drinking resulting in weight loss, their activity may change, or they may look

scruffy. We will weigh and check the mice regularly to carefully monitor for signs that they may be unwell. We will also measure the tumour regularly, and not allow the tumours to grow beyond reasonable limits. If the mice lose too much weight and don't recover within 24 hours, seem unwell or if their tumour gets too large, they will be humanely killed.

When blood samples are taken, if too much blood is taken the mice can become anaemic. To make sure we do not take too much blood mice will be weighed and only an appropriate amount of blood willbe taken from each mouse on each occasion (https://www.nc3rs.org.uk/mouse-decision-tree-blood- sampling).

The drugs and compounds we will treat the mice with are not expected to have any adverse effects at the doses we will use. The injection or feeding of these drugs will not cause any more than a short discomfort at the time of administration.

General anaesthesia for imaging or tumour implantation is not expected to have any adverse effects. Mice will be closely monitored during anaesthesia and if breathing becomes irregular then mice will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Animals will experience a maximum of a moderate severity level. It is expected that 99% of animals will experience a moderate severity, some animals in which tumours fail to grow will only experience a mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our overarching goal is to develop new treatment combinations for cancer. To achieve our aim of validating novel compounds for the treatment of cancer, and find effective therapeutic combinations, we will take a range of approaches. We will perform experiments in 2D and 3D (e.g. spheroid and organoid) cell cultures, fluid flow systems, perform screening in primary patient samples, use computer modelling of large complex data sets and use mouse models of cancer. While non-animal models of cancer are very helpful in understanding aspects of biology and response to therapeutics, unfortunately they do not as yet model the response of a whole organism. However, as much as possible we will replace animal models with non-animal models and we will continue to investigate non-animal alternatives throughout the duration of this licence.

We will perform as many experiments as possible in 2D and/or 3D cell cultures and where possible screen patient samples before we do experiments in mice. Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but not as effective when treating a whole animal. This is because of the complex environments and signalling networks within animals that may prevent thetherapy from working, as yet this cannot be modelled entirely in a dish or by a computer. For example, sometimes drugs do not get through the body to the cancer very effectively, or the body might remove the drug before it can do its job.

To understand cancer biology and therapeutic response, mice provide reliable and robust models. To study both human and mouse tumours, we will use mouse models of cancer to validate our findings in non-animal models in a whole organism model of cancer. Findings from these studies will then influence translation to clinical trials.

Which non-animal alternatives did you consider for use in this project?

Animal experiments are one key part of this work programme required to achieve our aims, which we will also combine with non-animal models.

We will use 2D and 3D (e.g. spheroid and organoid) cell culture and fluid flow models to study the biology of new targets and to test novel compounds. This will include understanding tumour response and the mechanisms that govern these responses. By screening in cells from a wide range of cancers we will be able to identify sensitive cancer types and potentially biomarkers that predict sensitivity or resistance. We will also test our compounds in combination with other potential cancer therapies, including novel therapies and those already in the clinic. The most promising cancer indications, and drug combinations will be validated in mouse models. We will also screen primary patient samples with our compounds to identify sensitive cancer types. Finally, some experiments performed in cells will generate large sets of data. To understand this data in a meaningful way we will use computer modelling. This will help us understand why some cancers are sensitive to our compounds and why some cancers have existing resistance or develop resistance after prolonged treatment.

Throughout the study we will continue to investigate non-animal alternatives through resources such as the NC3Rs. Alternatives will be implemented when relevant.

Why were they not suitable?

The non-animal experiments are all suitable models for early investigation of new drugs for cancer treatment, and we will use these to complement studies in mice. However, experiments in a dish or computer are unfortunately not capable of reproducing the effects in a whole organism e.g. do not have a complete vascular system to study drug delivery.

Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but either do not work or are less effective when treating a whole animal. A whole animal has many natural barriers that can prevent a drug from working the way it would on an individual cell. After entering the body, the drug may never reach the tumour or the drug may be metabolised and removed from too quickly to have an effect. Even if the drug

reaches the tumour, the tumour microenvironment for most cancers is much more diverse than that which can be modelled in a dish, and this can also influence drug responses. Finally, there can also be systemic effects that may change the response to the drug.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used quantitative data from previous studies for statistical analysis as well as online tools and specialised software to estimate the numbers of animals we will use. In particular we have used the NC3Rs Experimental Design Assistant, PREPARE guidelines (Norecopa) and G*Power software.

Where appropriate, we will perform pilot studies on small numbers of mice to determine the optimal number of mice for each cancer model to use the lowest number of mice required to achieve statistical power

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have planned to use a number of non-animal models (e.g. cell models and screening of patient samples) prior to experiments in animals to reduc the number of animals required.

Experiments were planned using the NC3Rs Experimental Design Assistant and the Norecopa PREPARE guidelines, G* Power Software was used for power calculations and experiments were planning in line with the National Cancer Research Institute's Guidelines for the welfare and use of animals in cancer research (Workman et al. 2010 Brit J Cancer).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When required we will use pilot studies to identify optimal compound doses and mouse numbers to use for each model. We will continue to use the NC3Rs Experimental Design Assistant, Norecopa PREPARE guidelines and G* Power Software. For complex experiments, we will seek advice from specialist statisticians to help in experimental design.

We will use mouse models of cancer as these reliably and reproducibly mimic many aspects of tumour growth and metastasis in humans and can be manipulated for use of specialised techniques, like tumour imaging. We will also use inbred mice because this minimises variation between mice, thereby reducing the number of animals required.

Where possible we will use labelled tumour cells that allow tracking of tumour over time with specialised tumour imaging. We will also use other specialised monitoring techniques for specific cancers, e.g. micro computed tomography for cancers that cause bone disease. This will reduce the number of mice required for experiments, by performing measurements over time in the same animal rather than requiring multiple groups to investigate different timepoints.

In some instances, we may use multiple treatment groups with one control group. For instance, if we want to test more than one compound in one cancer model and the compounds can be administered on the same schedule. This will reduce the number of studies and hence reduce the number of animals used.

Where possible we will store tissue that may be of interest to investigate in the future, even if analysis is not planned in the original design. This will minimise the risk of having to repeat a study to obtain more tissue/data. We will also make this tissue available to other researchers upon reasonable request.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use two general types of mouse models of cancer to study the effects of new potential cancer therapies. The first uses human tumour cells or tissue implanted into mice that lack part of their immune system. This is required so that the body does not reject the human tumour cells. The second model, uses mouse tumours implanted into mice with a fully functioning immune system. This is also important as the immune system can influence tumour growth and response to therapy. These models have been extensively used by us and others, so there is a wealth on information available on these models and they are considered to be reliable and reproducible. We will plan experiments to not let tumours grow to a size where they cause the animal to become significantly unwell, we will use earlier timepoints at which the animals will be humanely killed.

To minimise harm to animals, we previously developed refined mouse models of prostate cancer, that have minimised harm, stress, suffering and pain to mice by identifying earlier endpoints that to not rely on the animals showing signs of being unwell. This was made possible through specialised imaging techniques that can detect the disease at much earlier stages. This also made monitoring therapeutic intervention more accurate and allowed further refinement of one model to mimic a specific disease state that occurs in many myeloma patients. This is something that we implement as much as possible in models of other types of cancer. We will use specialised, non-invasive tumour imaging

techniques under anaesthesia, which allow us to identify and implement study endpoints that do not rely on animals showing signs of being sick, in distress or in pain, while also reducing the numbers of mice required.

Only animals deemed to be in good health will be used in experiments. Animals with a compromised immune system will be housed in ventilated cages through a biosecurity barrier to minimise their risk of infection. Any techniques that may be painful or distressing to animals will be performed with anaesthesia and appropriate pain relief will be given to minimise pain (e.g. after surgery). All surgeries will be performed under sterile conditions following best practice guidelines (e.g. LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery). Animals will be regularly monitored for possible adverse effects that may occur in response to the tumour, procedures or treatments. We will seek advice from the NVS and/or NACWO where appropriate (e.g. for administration of an antibiotic if an infection is suspected. Optimal treatment regimens (e.g. dose, frequency and route of administration) will be identified in small pilot studies before use in larger scale studies.

We will also use general practices that minimise stress, harm and pain to animals. This includes non- aversive methods for handling mice (e.g. not picking up by the tail), the use of single-use needles to avoid pain from dulled needles and NC3R guidelines on blood sampling.

Why can’t you use animals that are less sentient?

To study effect of treatments on tumour growth, metastasis and relapse requires a whole organism model. Mouse models have been extensively used by us and others, so there is a wealth on information available on these models and they are considered to be reliable and reproducible. Mice are also very similar to humans genetically, and many processes in relation to development and growth of cancer are conserved between these species. Mice that lack part of the immune system can also grow human tumours, allowing us to study the effect of new treatments on human tumours.

Some less-sentient species, such as zebrafish, can be used to study specific tumorigenic processes. However, these models cannot be used for studying the effects on intervention on processes like metastasis. They also do not provide the ability to model treatment strategies that are used for patients. For our studies, in order to determine whether our new treatments are effective at treating growth of primary tumours and/or metastasis, mice are the most reliable model and we cannot currently perform these experiments in a less-sentient species. We find mouse models of cancer are most reliable and representative in adult mice and they cannot be used at a life stage where mice are less-sentient.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

Tumours will be regularly monitored through non-invasive methods. Mice will also be weighed to check for signs of weight loss that may occur in response to the tumour or treatments. Mice will be regularly checked for signs of being unwell, for example changes

to the coat condition, behaviour and movement. We will also continually attempt to identify earlier endpoints for studies, to minimise harm to animals.

Invasive surgeries will be performed under general anaesthesia. Mice will be given pain-relief to manage post-operative pain and kept warm while they recover. Mice will be monitored following surgery and any procedures that may have immediate adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgeries will be performed under sterile conditions following best practice guidelines, e.g. LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Procedures for establishment and monitoring of tumour growth, metastasis and animal welfare will follow best practice guidelines (e.g. NCRI Guidelines for the welfare and use of animals in cancer research, Workman et al. 2010 Br. J. Cancer). We will also consult the NC3Rs website and Norecopa for information on the 3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the NC3Rs websites, NC3Rs regional programme manager, the literature and colleagues/collaborators for information on the 3Rs. Any relevant advancements that can be implemented will be used.

46. Cell-Matrix interaction in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Skeletal muscle, Muscle stem cells, Integrins, Extracellular matrix, Muscle regeneration

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to further our understanding of the interplay of cells with their specific extracellular environment, with a focus on skeletal muscle.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Loss of muscle mass during muscle wasting diseases and in ageing is compensated by increased fat and fibrotic tissue. Moreover, muscle loss may lead to diabetes because the most insulin-sensitive tissue in the body is lost. It is estimated that the health service costs just due to age-related muscle loss due to frailty and subsequent falls are £1.7 billion per year. These figures are likely underestimated as they do not take into account secondary

implications of muscle loss such as diabetes and heart disease. Moreover, muscle loss has a devastating effect on the quality of life, especially of the elderly, including reduced motility and eventually loss of independence.

Recent evidence suggests the extracellular environment, or “niche”, of the muscle endogenous stem cell, changes with continued muscle repair or with age and limits its regeneration. This study therefore seeks to determine mechanisms for impaired muscle stem cell functionality in a mouse model in which interaction of the stem cell with its niche is compromised. Although this project is primarily directed at identifying underlying basic mechanisms that are leading to muscle loss, any outcome may be valuable in the future to develop therapeutic strategies to slow down muscle loss.

What outputs do you think you will see at the end of this project?

We expect to generate several publications in well-respected academic journals on how the muscle stem cell is regulated by the extracellular interaction with a long-term understanding of potential methods to maintain muscle mass in ageing and muscle wasting diseases. We in addition plan to communicate our findings to the public, either by press statements or in local science festivals.

Who or what will benefit from these outputs, and how?

We hope to further our understanding of the role the local environment of muscle stem cells plays in development and disease progression and/or prevention. The primary aim of the project is to unravel fundamental basic mechanisms of skeletal muscle regeneration, which have not been studied so far. This information will in the short to medium term mainly benefit researchers in the skeletal muscle field. In the longer term, there is a potential benefit that new drugs and/or new therapeutic strategies based on this work can be developed to combat muscle wasting in disease and in ageing.

How will you look to maximise the outputs of this work?

We collaborate with researchers with expertise in similar areas both locally, nationally and internationally. We will also attend national and international scientific meetings to present our unpublished work, through which we expect to obtain feed-back and advice from the scientific community.

Species and numbers of animals expected to be used

- Mice: 9925

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The exact regulation of muscle development and regeneration can only be achieved in vivo. While we do use in vitro cell culture models, these have major limitations as such

models do not reflect the mechanical forces exerted on the tissue and lack the interactions with other cell types and the environment. Mice are the optimum model as they are similar to human in many aspects and so muscle regeneration can be easily followed in a local muscle of the hindlimb and allow genetic manipulation. For the majority of work adult mice will be used (>2months of age). However, it may be necessary to follow a specific cell fate during late foetal or post-natal development in a small number of mice.

Typically, what will be done to an animal used in your project?

The majority animals (>95%) used in this project will receive injection of substances either via the intraperitoneal route and/or locally administered into a superficial muscle. These are short-term procedures and mice are not expected to exhibit any harmful phenotype.

Insulin and glucose tolerance testing requires that the animals are starved for up to 16hrs, after which insulin or glucose will be injected intraperitoneally. Glucose levels are then measured in the following in a small blood drop obtained from the end of the tail. The mice are not expected to exhibit any harmful phenotype.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible adverse effects that may happen to a small percentage of animals are Some offspring may lose weight due to muscle wasting.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity for this project is moderate, but it is expected that only a small minority of animals (<5%) will experience this severity. The majority of animals (>95%) are expected to make a rapid and unremarkable recovery from the procedures.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The function and regulation of adult stem cells in muscle tissue under normal and pathological conditions can only be unambiguously analysed in vivo. In vitro cell culture models do not reflect the mechanical forces exerted on the tissue and the interaction with

other cell types and the environment, do not assemble higher order structures such as basement membranes and cannot mimic metabolic changes like glucose or insulin sensitivity and effects on other organs of the body.

Which non-animal alternatives did you consider for use in this project?

Although our work is animal based due to the reasons given above, we are using several in vitro and ex vitro models to answer basic questions

- When possible in vitro culture models will be used for analysis of basic mechanisms (e.g. signalling cascades).
- Immortalized cell lines have been from several transgenic lines to test basic mechanisms (e.g. signalling cascades, effect of glucose).
- Ex vivo models for muscle regeneration are used for underpinning basic concepts of adult stem cell function.

Why were they not suitable?

Cell culture models are a good system to overall reduce animal number as candidates (e.g. signalling cascades) can be pre-tested before they are verified in cell directly isolated from mice. However, although the ex vivo regeneration model will deliver data, how well a muscle regenerates and how the organism reacts to high fat diet can only be achieved in an animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are estimated on our current usage and projected proposed studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use several measures to reduce animal numbers.

- The experiments are designed to use the minimum number of animals necessary. This includes the use of established immortalised cell lines as in vitro culture models for pre-screening studying basic mechanisms and ex vivo methods to analyse basic concepts of adult stem cell function and only bring the most likely candidates into in vivo studies.
- We have calculated the number of animals for each experiment together with a statistician to use the minimum number of mice whilst still receiving meaningful and statistically significant results.

- We will use the Experimental Design Assistant provided by NC3R to design experiments the most efficient way and put stops if necessary.
- When using genetically modified mice, we use homozygous mutant mice for mating wherever possible to minimise unrequired genotypes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- When using genetically modified mice, we use homozygous mutant mice for mating wherever possible to minimise unrequired genotypes.
- We use both male and female mice for our studies.
- We isolate tissue from animals from experimental animals and store it appropriately for later use in histological and immuno-histological analyses and/or share tissue when appropriate with collaborator and colleagues, thereby reducing the need to breed mice specifically for this purpose

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- The project uses the mouse as model organism, as it is easy to genetically manipulate. The strains required are available without the need to create new lines. There is also a plethora of information about dosing of substances available in the scientific literature, thereby reducing the need for pilot studies to determine appropriate dosages.
- We have experience of all the methods to be used in this application and they have been optimised to cause the least pain and distress to animals and will not cause any lasting harm to the animal other than transient.
- Animals will be humanely killed after the injection of gene deleting/inducing agents and used for in vitro and ex vivo studies of skeletal muscle regeneration.
- A short anaesthesia during which a superficially located muscle will be injected with a myotoxic agent will not cause any lasting harm to the animal other than transient.
- Glucose metabolism on a chow or high fat diet will be tested after starving for a maximum period of 16 hrs by injection of appropriate doses of glucose and insulin, what will not cause any lasting harm to the animal other than transient.

Why can’t you use animals that are less sentient?

Our research requires whole body systems in order to understand the complex physiological interactions of individual and multiple genes on multiple organs of the body.

The mouse is the least sentient animal that is both physiologically and genetically closely similar to human and allows both genetical and pharmaceutical manipulation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Welfare of the mice will be monitored after the administration of substances on multiple occasions by the experimenters and then inspected daily by qualified animal carers. Aseptic precautions will be taken to help prevent infections.
- Surgical procedures will be carried out according to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Analgesic agents will be administered as required after the surgery. In the event of post-operative complications, animals will be killed unless, in the opinion of the Named Veterinary Surgeon, such complications can be remedied promptly and successfully using no more than minor interventions.
- Altered food composition should cause no adverse effects to the animal. Weight will be controlled weekly and mice will be humanely killed if the weight gain restricts movement to reach food and water.
- Animals will be monitored constantly while on the treadmill or rotarod. Voluntary running of mice on the treadmill will be supported by covering the end of the treadmill with a black bin liner. When testing endurance animals will be removed from the treadmill or rotarod as soon as they avoid running voluntarily.
- Any animal will be humanely killed before signs of distress (e.g. loss of body weight, unkempt fur, abnormal posture, loss of muscle tone) become apparent.
- All procedures applied to animals under this licence are current best protocols and well validated and will not cause any lasting harm to the animal other than transient. We will follow the advice of NC3R in case the protocols will be adjusted to minimise harm.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All our studies follow the guidelines of NC3R which are widely accepted by the scientific community. In addition, we keep up-to-date, by following updates provided by the Laboratory Animal Science Association (LASA) which, together with NC3R constantly publish improved and refined animal procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All researchers involved in this project will be encouraged to subscribe to the NC3R newsletter and website and review current methods as soon as new guidelines will become available. All researchers are also encouraged to subscribe to the Experimental Design Assistant provided by NC3R to design experiments the most efficient way and put stops if necessary.

47. Roles for genomic instability in cancer and aging

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Ageing disease, Genomic instability, Phenotyping, Therapies

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to find genes that regulate genomic instability (GIN). The genes will be researched to find ways to prevent genomic instability beginning and building up.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

- Genome instability (GIN) contributes to many diseases which, if prevented, would lead to disease improvement. Discovering ways to prevent GIN could lead to better treatment of cancer and ageing.
- Our cells are exposed to factors that lead to DNA damage. The environment, such as UV light, radiation and chemicals, can cause the damage. Alternatively, damage can come from within the body during natural processes. For example, when the body uses

water or converts food to energy and other life sustaining components. When these processes go wrong in the body, bad chemicals or molecules can be created that cause DNA damage. The natural processes in the body may go wrong because of faulty genes.

- DNA can be damaged in a minor way but also in a major way. DNA can be damaged at different times when a cell is growing. How the body decides to fix damage to DNA depends on these circumstances and is called the DNA damage response (DDR).
- DDR senses DNA damage and triggers DNA repair, cell cycle arrest or cell death. Failure of these responses results in GIN and the start of disease. This includes developmental disorders such as progeria, an illness where people show signs of ageing and die early. Also, some forms of ataxia, which can affect co-ordination, balance and speech. Such diseases may affect the brain, the nervous system, muscle function and the immune system. They can affect people at different ages, young and old. They may cause degeneration that results in loss of movement, the senses, premature ageing and ultimately death. DDR failure resulting in GIN also leads to cancer and ageing related disease including dementia. A better understanding of how GIN works provides potential routes for disease prevention and treatment.
- There were 9.6 million deaths from cancer worldwide in 2018. Alzheimer's and other dementias led to
- 1.5 million deaths in 2017. As the world population ages the cases of cancer and age-related illness are set to increase. It is estimated that 47 million people live with dementia around the world. Finding suitable treatments for certain age-related disease has proven difficult. We believe that this area of research is crucial for discovering new ways to combat cancer and age-related illness.

What outputs do you think you will see at the end of this project?

Primary outputs:

- New genes of interest will be identified and described. Novel therapeutic strategies will be discovered.
- New mouse strains will be created and mouse strains created elsewhere will be investigated further, providing new information about those strains. New data will be created on the effect of novel therapeutic agents on the process of genomic instability (GIN).
- We will gain new knowledge of how certain genes work. We will also get information of how one or more genes work together. This information will allow us to make decisions on the best way to move forward in researching the many different genes involved with GIN. We will get new information on how certain genes and combinations of genes cause diseases to be worse. Importantly, we will discover gene combinations that will reduce illness and suffering. For example, we will find combinations of genes that will reduce the rate at which a cancer will grow. We will find combinations of genes that will stop or reduce the faulty development and ageing health issues associated with GIN. Biomarkers or gene targets will be identified. These secondary outputs will help us work toward our primary output to find particular drugs to combat the illnesses.

- New cell lines will be derived from the embryos of the mouse strains studied. Newly created mouse strains and materials originating from these mice, including cells and tissues, will be made available to the scientific community.
- Work will be published in peer reviewed journals.

Who or what will benefit from these outputs, and how?

- Mice and tissues produced will be supplied to other researchers. This will include new mouse models and novel genetic crosses with details of their phenotype. This will enhance and speed up the research for these investigators.
- Outputs such as biomarkers could be used in pre-clinical and selected clinical trials. A biomarker is something that can be measured to show what is happening in the body. Measuring biomarkers can indicate the presence of a disease. Cancers can produce biomarkers and so can the body's healthy cells in response to the cancer. Cancer varies between individual patients and using biomarkers can help show what is happening inside the body and identify the best approach for dealing with a particular case. Thus, finding new biomarkers improves our ability to both detect and treat cancer.
- GIN is a hallmark of cancer and ageing and there are millions of people in UK and throughout the world that are affected by GIN related disease. The approach we will employ in this project and the outputs generated will help find new therapies to fight illness in those affected. Our work will provide benefit for those suffering from neuro-developmental disorders such as ataxia. We will be contributing to finding ways to combat dementia, including Alzheimer's and Huntington's. Other specific illnesses targeted include Hutchinson Gilford Progeria and Cockayne syndrome. Ultimately, cancer sufferers and patients of these diseases will benefit along with their carers and society as a whole.

How will you look to maximise the outputs of this work?

All mouse lines we produce will be made freely available. Moreover, we will report all data that will be generated under this licence. Negative data is very informative but seldom published; following quality control and validation, all generated data, positive and negative will be published in open access databases or journals. We will collaborate with other researchers in the field and present findings through meetings and conferences.

Species and numbers of animals expected to be used

- Mice: It is expected that a maximum of 14,000 mice will be used over the course of 5 years, with 9,500 of these being used solely for breeding to generate mice for analysis.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

- Using mice is the best test against data gained in the lab. Using ageing and cancer mouse models is the only approach available for full investigation of the processes involved with DNA damage response (DDR).
- Using the mouse embryo allows us to make the mice we need for our work. The mouse embryo also allows us to do work without the need for live mice. Young mice are used because the genes we study may have an impact on development. Studying young mice is important when looking at illness relating to age because signs of illness can start earlier with age related disease. Much of our work will be done on adult mice since a lot of data can be gained at this stage.

Typically, what will be done to an animal used in your project?

- The mice on this licence will be used to understand the role of genomic instability (GIN) in the promotion or dampening of tumour formation and ageing.
- Some new mouse strains will be created. Different strains of mice will be bred together. Such strains will not have been bred together previously. We will study these new strains to see if they produce mice at the usual rate and whether they develop normally. We will look at the development at different life stages. Individual mice from these new strains may be examined over the first few weeks of their lives, have their weight, shape and size measured. Simple procedures may be carried out on these mice, such as a blood sample or x-ray image. Other mice from the new strains will be used to test behaviour. In these cases mice will undergo non-invasive behaviour tests carried out on several days over a three week period to examine how the brain is working.
- We will breed different strains of mice together to see if one strain stops the signs of disease in another.
- Mice will undergo procedures where tumour development can occur or they may be allowed to age. These mice may carry an altered gene and are monitored to see if they develop a developmental defect, tumour or age related change.
- Sometimes, mice will be injected with cells that produce tumours. All such mice are monitored daily for any signs of developing tumours. The mice will be checked to see if the tumours are making them ill and may be given drugs to reverse the tumour growth. Certain drugs can be given in food, a low harm route. Such mice will be studied for a few weeks.
- Mice will have blood samples taken. Images including x-rays may be taken. Sampling and imaging procedures are quickly carried out as a single event.
- If a mouse becomes sick unexpectedly it will be humanely killed and the mouse examined to see why it was displaying these symptoms. Samples will be collected for further analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

- Many mice will suffer no adverse effect during the project.
- Some mice will experience no more than a transient feeling of pain or suffering.

- Few mice will develop at a slower rate and/or have developmental abnormalities, for example curvature of the spine. These effects may develop gradually over weeks and will not be allowed to prevent the mouse from feeding and drinking.
- Some mice will form tumours. Tumours may last for a few weeks but will not be allowed to stop mice carrying on with normal behaviour. For short periods, the body weight of the mouse may increase or decrease in the presence of a tumour. Mice may move differently or have uncoordinated movement. Breathing may be more difficult. Skin could become more irritated in the presence of a tumour.
- Some mice may show signs of ageing earlier. There may be gradual weight loss, over several days, and loss of fat and muscle mass.
- Certain mice may experience loss of coordination or seizures. This is expected to be rare and for short periods.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- A large proportion of the mice, possibly more than 5000 mice and particularly on the breeding licence, are not expected to suffer any adverse effect (sub-threshold).
- About 30% of the mice we propose to use will experience pain or suffering that is classified as 'mild'. Particular mouse strains known to develop adverse effects or an illness because of their genetic alteration will not be allowed to develop more than short-term mild pain, suffering or distress. The genetic alteration in the mouse may result in a difference in growth rate, size or behaviour. However, these mice will have a normal lifespan and will be able to freely move and feed. These mice will have only one or a limited number of procedures carried out on them, which will result in no lasting adverse effect. Where these mice are used for more than one test, it will be ensured that the combined affect causes no more than slight or transitory pain or suffering.
- About 35% will be classified as 'moderate' severity. These mice may shows signs of disease but will not become severely ill or die as a result. Mice may lose more of their body weight, up to 15% weight loss. Some mice may have a more significant loss of normal movement or there may be more persistent evidence of an illness. Some mice will develop tumours. Growths will be monitored to ensure they do not go over a certain size and do not make the mouse severely ill or significantly impair movement.
- Surgical procedures, for establishing new mouse colonies, will result in pain for no more than a few hours and include administration of pain relief.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

- We can test in the laboratory without using animals to provide useful data on how diseases work in humans or animals. We can also run tests without using animals to see how different genes work together to make a disease better or worse.

- Particular cells from animals can be used to test the effect of drugs that could stop a disease. With cancer and ageing as studied in this project, we can only confirm that lab tests have worked well by testing further with mice. When mice are used to find genes that affect cancer or ageing or to prove a drug works against a disease, it provides an avenue for finding medicines for humans.

Which non-animal alternatives did you consider for use in this project?

- Extensive analysis without using mice is integral to the project and is always the first option considered when new biological areas of interest are identified. Organoids from both human and animal origin are our first alternative to using mice.

- Organoids are 3D organ-buds that can be grown in the lab. They can be made from the tumour and normal tissue of a patients cell. Organoids enable us to study how tumours develop and how they respond to treatments. Tests using organoids can reduce the number of mice needed for experiments and improve the chances of successful experiments using mice.

Why were they not suitable?

Accumulation of GIN is a multi-step, highly complex process involving cell and tissue interactions. GIN accumulation can act together with multiple genetic abnormalities. GIN associated disease including developmental disease, cancer and ageing affects all organ systems in a highly interconnected fashion. This means that GIN and the associated diseases cannot be fully modelled without a whole organism such as the mouse.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- This is based on previous experimental work for similar programmes of work done on licences held in other establishments whereby 15,000 mice were created and used over an 8 year period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Mouse experiments are not carried out until there is sufficient evidence from testing in the lab. Animal sample size calculations are made to ensure as few mice as possible are used whilst still achieving good results. Online resources from trusted and experienced organisations provide software and templates that help with this.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Where possible we shall import existing mouse lines rather than generating new ones. We will utilise the archive at our previous establishment, where our current colonies are cryopreserved, and will use wildtype mice that are surplus wherever available. In general, we will order lines in as frozen sperm or embryos for recovery. This will reduce the number of mice used for breeding between facilities as well as remove the harms related to the stress mice are under when in transit.

- For certain studies, such as when cells are injected into mice for cancer experiments, we will use commercially available mice. This will reduce the need to produce and breed mice at the facility.
- All mouse lines will be archived so that they may be distributed to other researchers worldwide. This will reduce the number of animals used globally, as fewer animals will be required to re-generate these archived lines.
- In some circumstances, such as when certain mouse lines have been only recently created, less published data will be available thus we propose to perform small pilot experiments to determine the final experimental design.
- Wherever possible, multiple experiments will be performed on the tissues collected from an individual mouse so as to maximise the use of the mouse.
- All data generated from our research on the mice will be published in scientific journals available to the whole scientific community, reducing duplication of production resources and phenotyping procedures elsewhere. Wherever possible, the results of experiments that involve large datasets will be made publically available to serve as a resource for other scientists and clinicians.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- Mouse models of cancer and ageing will be used during this project.

- Mice will only be bred if they are required for experimental analysis, distribution or archiving. Furthermore, the methods selected to analyse mice are all standard, robust, well validated tests that are commonly used in high throughput projects.

Why can't you use animals that are less sentient?

Mice and humans have the same basic organ systems, skeleton and reproductive cycles. These similarities, coupled with the technology available to manipulate the mouse genome, make the mouse the best to copy human diseases. There are no, less sentient animal models for tumour growth that can be used. Using non-mammalian species of lower neurophysiological sensitivity is not possible since they lack appropriate tissue physiology. Using mice at an immature life stage would not be possible as we need animals to be mature since we are often looking in to the effect of ageing.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Whenever guidance materials are updated with recommended refinements, we will strive to include them into our procedures. We will regularly review literature and discuss possible refinements with peers and experts.
- At all times, mice are handled calmly and following advice for best practice, for example tunnel handling.
- Where mice are imported in to the facility, they will always be given a minimum of one week for acclimatisation prior to use in procedures or further movement.
- Non-surgical methods of transferring embryos will be considered for mouse production. This will be assessed based on the ability to recover suitable numbers of live mice. All surgery will be undertaken in full compliance with Laboratory Animal Science Association aseptic technique guidance to minimise infection risk. Mice will always be provided with pain relief for surgical procedures, prior to commencement of surgery and, if required, following surgery. The group has over 10 years experience in refining surgical procedures, including the development of improved aseptic technique and rigorous analysis of surgery competency. We will continue to refine skills and techniques to improve surgical outcomes.
- When creating new lines we will use optimal methods for design and production. For example, it is our intention to create new GA mice using CRISPR technology, which significantly reduces the number of animals required for both surgery procedures and later during breeding.
- Mice which have had anaesthesia will have frequent monitoring until fully recovered and additional post recovery checks in animal holding rooms. When general anaesthetics are necessary, practicable combinations with the least adverse effects will be used. For example, gas anaesthetics will be used wherever possible.
- It is our intention to incorporate image recording technology for monitoring of some behaviour tests to improve our ability to successfully blind the experiments.

- Tumour growth experiments are carried out with extra monitoring of the mice involved. Mice will be checked using advanced welfare checks. These checks will be done more regularly than standard welfare checks and by staff trained to spot particular problems. Monitoring protocols can be changed or updated based on the particular mouse strains being looked at. For example, mice expected to experience adverse effects at an earlier age will have monitoring more regularly at an earlier stage of their life. Similarly, mice expected to develop tumours quickly will be monitored more regularly and at an earlier stage of the study.
- When dosing mice for treatment drugs via oral gavage, we will be using a refined dosing technique using plastic/silicone gavage tubes that reduce trauma and make visualising delivery easier.
- If there is a requirement to dose mice with treatment drugs beyond 30 days, usually administered via the intraperitoneal route, we will consider the option of mini-pumps for continuous dosing as an alternative.
- We have experiments where we are able to administer drugs via the mouse diet. Choosing this dose route is a refinement compared with other routes, such as in water or injection, where harms are known to be greater.
- Prior to recovering strains for breeding we will examine health observations previously recorded on a database that will allow us to accurately predict the onset of certain clinical signs of illness. We will then make notes on the database used by animal care staff so that they can quickly respond to welfare concerns. Furthermore, we will create a simple reference document listing all strains that will be used on this licence, including description and time of onset for particular health concerns.
- For all tests it is important that the animal has no additional stress, therefore mice are handled calmly and habituated to testing rooms as well as arenas if possible.
- Where mice are housed in modified cages for testing it will be for the minimum time needed to gather data. Mice will be removed from test scenarios if suffering from an adverse stress reaction, or other unexpected adverse effects.
- Technical refinements will be developed throughout the project and disseminated to other researchers and collaborating institutes.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The work in this project will be undertaken in accordance with the principles set out in the Guidelines for the Welfare and Use of Animals in Cancer Research: British Journal of Cancer (2010) 102, 1555- 1577 (referred to subsequently as the ‘NCRI Guidelines’) and in the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

We will be following ARRIVE and PREPARE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I, and delegates from the research team, will work together to adopt new developments in the 3Rs at the establishments the work will be carried out in. We will work closely with named persons and managers involved with promoting welfare, where possible, attending

events promoting the 3Rs hosted locally and through institutions such as NC3Rs, LASA and the IAT. The International Society for Transgenic Technologies (ISTT) provides additional contacts and materials for keeping up to date with production technologies emphasising the 3Rs.

Any new methodology, techniques or practical refinements will be tested against established techniques and where results are not compromised and animal welfare improved will be implemented accordingly.

48. The role of scavenger receptors in the development and progression of hepatocellular cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Liver cancer, Immunity, Scavenger receptors

Animal types	Life stages
Mice	juvenile, adult, pregnant, aged, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the role of scavenger receptors in the development and progression of primary liver tumours (also known as hepatocellular cancer) and whether they have an impact on the ability of the immune system to control cancer. To test whether the administration of therapies to block scavenger receptors can stop tumour growth in the context of liver disease and their potential as an immunotherapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The commonest form of primary liver cancer is known as Hepatocellular Cancer (HCC). HCC is rising dramatically around the world and it is now the second leading cause of cancer related deaths globally. Most patients present with incurable disease and have limited therapeutic options. The majority of patients with hepatocellular cancer (90%) have an underlying liver disease which leads to liver scarring. It is now clear that the cancer is protected from the immune system within the scarred liver.

We need better understanding of how HCC is protected from the immune system. If we can reverse the process, we can then activate the immune system to kill the cancer. Recent trials with immune therapies (checkpoint inhibitors) have proven that this approach could work, but are only effective in less than 20% of patients.

What outputs do you think you will see at the end of this project?

Hepatocellular cancer (HCC) is now classed as the second leading cause of cancer related deaths globally. The incidence is rising and the majority of patients present with advanced cancer and current therapies for these patients only prolong survival for a few months. My programme of work sets out to understand how the immune environment around liver cancer is regulated by scavenger receptors. The use of immunotherapy has shown promising results in early phase clinical trials but less than 20% of patients respond to this therapy. Our work will add significant knowledge to understanding how HCC evades the immune system and will be important for the scientific, medical and pharmaceutical industry. Specific outputs at the end of this work will be publications on how scavenger receptors play a role in the development and growth of hepatocellular cancer. The proposed work will identify mechanisms of cancer progression as well as new therapeutic targets and intellectual property (IP).

Who or what will benefit from these outputs, and how?

In the short term, the data will likely be used by basic scientists and clinician scientists to inform the design and outputs of their own experiments.

In the medium term The scientific community will benefit from these experiments because they should provide better understanding of the pathways that regulate cancer development in the context of inflammation and fibrosis, a major worldwide problem which is still poorly understood.

In the long term we also hope to identify scavenger receptors as new therapeutic targets for treating hepatocellular cancer. Blocking the action of these receptors may be effective in stopping and reversing tumour growth and may also improve the efficacy of current standard of care treatments. To facilitate this, we are skilled and have a strong track record of working with technologies based around the use of human material to interrogate

disease mechanisms, and our proposed animal investigations form an essential partnership to these studies to inform our understanding of cancer development in the setting of inflammation in several organs. We will have the potential of moving rapidly into early phase clinical trials, thus benefits of our work include transfer of knowledge, as well as improvements in treatment for UK patients and the healthcare industry.

How will you look to maximise the outputs of this work?

The data generated by these studies will be published in high impact journals conforming with ARRIVE guidelines provided by the NC3Rs, and presented at national and international meetings and conferences. The development of large datasets will be made available in open access data repositories for external investigators. Findings from this project will be shared with worldwide researchers through communication, including interdisciplinary collaborations, seminar engagements, and conferences. Regular local meetings provide a forum to communicate results to immediate colleagues including clinicians and members of the public attending local hospitals providing additional routes to communication at the local level. Communication of significant research findings will be enhanced with support from dedicated press teams. We also have international collaborations, the aims of these collaborations are to enable progress in translational cancer research through the development of tools, platforms and skills that form the foundations of such research.

These collaborations are therefore an ideal platform to maximise the output from this work.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

I have chosen this species as previous reports have demonstrated that murine models of liver cancer develop tumours which are pathologically similar to human disease. Several studies have shown that factors that drive the development of human liver cancer, especially underlying liver disease, can be reproduced in the mouse. This is vitally important to ensure the experimental findings have the

potential for translation to humans. The mice will be started on the experiments at an early stage so that the tumour development reflects the situation in humans, where tumours develop gradually on the background of liver disease, which occurs in 90% of patients with this type of tumour.

Typically, what will be done to an animal used in your project?

Some animals may receive injections or a gavage to induce genetic mutations. All animals will undergo a single injection into the abdomen at the start of the experiment with the majority then being started on a special diet. In combination, this will lead to mice developing liver tumours on a background of liver inflammation which reflects the development of liver cancer in humans. Animals will be kept for up to 12 months. During that time they may undergo blood sampling and receive further injections of potential treatments.

What are the expected impacts and/or adverse effects for the animals during your project?

Fundamentally, the animals will develop liver tumours, but these are not expected to cause any adverse effects over the planned experimental duration. Animals will however be closely monitored for adverse effects and if seen, animals will be humanely killed.

Where animals are receiving an altered diet, this should not cause any significant adverse effects; over a 12 months period the mice gain weight but it will not impinge on normal behaviour. Animals may develop a greasy coat leading to skin irritation, but steps are taken to minimise this. If it cannot be alleviated then animals will be humanely killed.

Most compounds to be used in this project have been successfully used in mice previously with no adverse effects, however we cannot rule out adverse effects from novel compounds being investigated as potential therapies. In this case, animals will be closely monitored for signs such as reduced mobility, shivering, hunched posture, piloerection, and failure to eat or drink. If such signs are detected the animal will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- The expected severity for all animals under this project licence is moderate. This is because the experimental diet will cause weight gain and gradually cause liver inflammation but will not be allowed to progress to liver failure. The liver tumours that develop during the 12 month period will not be allowed to grow large enough to cause significant discomfort or distress in the animals.
- Even in those animals where potential therapies are shown to be successful, they will have still received a combination of procedures that meet the moderate severity category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of an animal model is vital in order to mirror the multicellular environment of human cancer and its interaction with the whole immune system. We have studied scavenger receptors in human tissue but to demonstrate that they affect the growth of cancer and to confirm its mode of action requires animal models.

Which non-animal alternatives did you consider for use in this project?

Non-animal studies with human tumour cell lines and primary human immune cells were considered as an alternative.

Why were they not suitable?

Human liver cancer cell lines are available but the major criticisms with these experiments are that they do not take into account the multicellular environment and surrounding liver inflammation that is characteristic of human disease. Non-animal alternatives have however been used to inform project direction and replaced aspects of the work which otherwise would have required more animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used previous data from both our laboratory and that of our collaborators, plus published information, in order to inform our estimations. We also use pilot studies to help inform project design and the number of animals required to obtain statistically robust data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the published literature to estimate the number of tumours per mice using this model of liver cancer and utilised statistical tools for power calculations to ensure there are adequate numbers of

animal in each group to answer the research question. These calculations have followed guidelines outlined by the NC3Rs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have taken expert advice from our animal facility regarding the breeding of genetically altered lines and the minimal number required to maintain a colony. We will optimise the amount of information from each animal by studying changes in tumour growth,

metabolism and immunology. We also plan to run pilot studies to ensure the optimal duration and time points for treatments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Induction of liver tumours: This involves the injection of a carcinogen, diethylnitrosamine (DEN). DEN can be injected at various ages to induce liver cancer- we have chosen a time point that requires only a single injection as opposed to repeated procedures. The scientific endpoint is such that the mice should not develop significant adverse events, as the tumours do not grow to a size that causes distress. However, mice will be monitored throughout the study using a clinical score sheet which will include – weight, body condition, general health e.g. coat condition, palpation for evidence of liver tumours .

High fat choline deficient diet. There is a specific deficiency of choline incorporated into the diet which contributes to fatty liver inflammation and low grade scarring of the liver. We do not anticipate any significant adverse effects as the mice will not develop features of liver failure. This approach was selected as it achieves the required level of inflammation via the diet, rather than by administering multiple injections, unlike other methods.

Why can’t you use animals that are less sentient?

This project aims to understand how a family of molecules called scavenger receptors control the immune system in the setting of cancer. Mice have been chosen for these studies as the main components of their immune system are also found in humans; this is essential as the focus of the project is to understand how the immune system influences tumour development. Tumour development in less sentient animals does not incorporate the complex cellular cross talk between the tumour and the immune system that can be modelled in mice.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

We will closely monitor animal body weight, behaviours, and general condition to ensure that the animals do not undergo any undue suffering. This includes the use of welfare score sheets tailored to these models. Where animals may develop a greasy coat and skin irritation due to diet, we provide the diet on the floor to prevent it dropping onto their backs, and provide extra bedding. Where possible, animals are handled using the refined handling techniques promoted by the NC3Rs.

Where there is a choice of route of administration, we will always use the most refined whilst scientifically justified.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use LASA dosing guidelines and blood sampling recommendations.

Any publications resulting from our research will be reported in accordance to the ARRIVE2.0 guidelines and we will use the PREPARE guidelines when planning our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have already attended workshops by the NC3Rs and will continue to stay engaged with the NC3Rs through their website. We are also part of an international collaboration for liver cancer. One of the main aims of this collaboration are to develop new models of liver cancer to reduce animal experiments using laboratory methods with human tissue including organoid cultures and whole tissue specimens. I attend regular meetings and training workshops organised by this consortium, providing an opportunity to implement these techniques in my research. I will also be attending national and international scientific meetings to remain up to date in the latest non-animal techniques used to study liver cancer.

49. Exploring the role and function of fibroblast subsets in inflammatory arthritis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Arthritis, Therapy, Fibroblasts, Inflammation, Refractory

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the role of fibroblast subsets in the pathogenesis of inflammatory arthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Current treatments for inflammatory arthritis target immune cells or the substances they produce. Whilst this approach is effective, some patients do not respond adequately to current treatments and/or relapse following the withdrawal of therapy. As a result, there is a need to develop new therapies that target different disease pathways and particularly those driving disease persistence. We have examined the role of fibroblasts, a key cell type present in the lining of the joint and demonstrated the cellular heterogeneity of these cells in the joint. During inflammation, some of these fibroblast subtypes produce signals that attract immune cells to the joint resulting in persistent inflammation. These immune effector fibroblasts are highly enriched in the joints of patients with rheumatoid arthritis (RA) and therefore represent an attractive therapeutic target.

There are many questions that remain before we can translate these findings into clinical studies for patient benefit. Firstly, how do the types of fibroblast within the joint affect the outcome of inflammation and damage? How do the proportion and type of fibroblasts change over time and in response to treatment? What is the exact function of the individual fibroblast subtypes and what mechanisms regulate their phenotype? This proposal outlines a series of experiments to determine the type of fibroblasts associated with poor treatment response, the function of these fibroblasts and the mechanisms that regulate their behaviour and phenotype. The findings from this research will provide a clear rationale for the therapeutic targeting of specific subsets of fibroblasts in human disease.

In particular, our aim is to identify which subsets of fibroblasts are most important in the development of inflammatory arthritis and whether specific subsets of fibroblasts determine the response to therapy and underlie the development of treatment refractory RA. We aim to explore whether modulating fibroblast function improves disease and ultimately which of these specific fibroblast subsets to target therapeutically.

What outputs do you think you will see at the end of this project?

Project outputs will include:

- advances in scientific knowledge on the role of immune effector fibroblasts in treatment refractory rheumatoid arthritis.
- scientific and lay publications of our findings and methodology.
- presentation of our data and/or methodology to the wider scientific community through conference oral and poster presentations.
- identification of novel targets or agents that alter the behaviour and phenotype of fibroblasts in the joint, which can be taken forward to develop new therapies.

Who or what will benefit from these outputs, and how?

Short-medium term

Scientific developments and innovations leading to our enhanced understanding of the role of immune effector fibroblasts in inflammatory arthritis described in this licence will have an immediate impact on the ongoing projects at the host organisation, and also further afield upon dissemination. Moreover, the project aims to improve our understanding

of the processes driving pathology in chronic disease, specifically disease pathways mediating the persistence of joint inflammation that we anticipate will underpin the development of the next generation of anti-rheumatic therapies.

Medium-long term

We intend to invite external seminar speakers who have an interest in the role of fibroblasts in chronic inflammatory diseases to our organisation, with the view of fostering further collaborations based on the concepts and ideas incorporated in this proposal. We envisage that these collaborations will occur during and following the completion of this project, and therefore represent a medium to long-term impact of this work. Using these collaborations, we will develop the infrastructure needed to translate these findings into clinical trials and ultimately, clinical practice, therefore fully exploiting the translational potential of this work.

Long-term

Clinical academics, pharmaceutical companies and patients directly will benefit from advances in our understanding of disease pathology and particularly why some individuals with arthritis do not respond to currently available treatments, along with identification of novel targets, which can be taken forward to develop new therapies. We will develop collaborative networks to realise the translational potential of our findings over the subsequent 5-10 years following the completion of this project.

How will you look to maximise the outputs of this work? Dissemination of information

We will work with the relevant teams within our Establishment to facilitate communications and resulting impact. We plan to use several routes to disseminate our findings to the wider scientific community, industry and the public that will facilitate end-user engagement, namely:

Peer-reviewed publication: we aim to publish high impact papers based on the findings generated from this project licence. In addition, our group has a strong tradition of publishing methodology papers; and negative data to ensure that groups do not unnecessarily repeat experiments that either technically are flawed or biologically yield the null hypothesis.

Presentations: we and our collaborators will present data at internal seminars along with national and international conferences.

Dissemination via international societies: we and our collaborators are active members of various scientific societies, allowing our findings to be disseminated to the wider scientific community in societal magazines and training workshops.

Enhancement of public understanding and engagement with research

We will take advantage of several public engagement events organised by the Establishment and local charities to facilitate the public’s awareness of our research:

Science “pop-up” activities: we actively participate in “Meet the Scientist” tours and host stalls at local Science Festivals.

Lay Resources: we would develop lay resources, in collaboration with our patient/public research partners (PRP), for publication. Additionally, we will continue to involve patients and the public in the delivery and dissemination of research generated from this project.

I actively engage with our rheumatology patient research partners in all stages of our research including research strategy and planning, as well as dissemination to lay audiences. These partnerships are pivotal in developing our ongoing research strategy and ensuring our work is disseminated to lay audiences.

Clinical networks and translational collaborations

My team and I are active members of several multi-institute research centers and will be able to present our findings at least twice annually at ongoing Centre seminars. We will also attend clinical conferences in our field, where we will present our data and foster collaborative opportunities for translational research across the fields of rheumatology, ageing and chronic inflammatory diseases. As a team of both clinicians and scientists we have access to unique patient cohorts and therefore the expertise and ability to translate findings rapidly to early clinical studies.

Species and numbers of animals expected to be used

- Mice: Mouse ~6,000 over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Mice are the best model for the study of persistent inflammatory disease because:

The main components of their immune system are shared by humans; this is essential where immune responses as opposed to the function of individual genes is being studied and thus, will produce satisfactory results.
An extensive range of reagents are available for analysis of immune responses in mice and including genetically altered mice.

They are the most acceptable animal models that show the least degree of neurophysiological sensitivity and will suffer the least pain, suffering, distress, or lasting harm.

There are no other alternatives to this work. We are employing models that have been refined and streamlined as much as possible by our collaborators at our Establishment and beyond.

Typically, what will be done to an animal used in your project?

For arthritis models - the majority of animals (80%) will undergo general anaesthesia (up to 10 minutes), daily handling for scoring and calliper measurements of joints and limbs; administration of an agent or cells to determine cellular function or therapeutic efficacy and will be killed up to week 8 via schedule 1 method or non-schedule 1 for withdrawal of fluids (e.g. blood).

Each experimental model will be monitored daily following intervention and mice will be assessed for any signs of distress with supportive measures provided. Procedures will be undertaken using the most appropriate anaesthetic and analgesia will be given. The mode of substance administration will be chosen to cause the least harm and distress to the mouse. Any new substances or route of administration will be tested in a small pilot study and the mice monitored daily for signs of distress.

Humane endpoints will be strictly adhered to at all times.

What are the expected impacts and/or adverse effects for the animals during your project?

The maximum severity limit in this licence is moderate. Possible adverse effects include irritation from local injection, pain from joint inflammation, weight loss or mobility problems. Any animal showing deviation from normal behaviour as judged by; body weight, body condition, general and coat appearance, gait or behaviour will be treated with pain relief and we will administer food supplements such as gel and mash. Before pain and inflammation exceed a moderate severity level, animals will be killed to prevent any on-going pain or suffering. All animals will be killed at the end of the protocol with the exception of protocols 1 and 2 (Breeding and maintenance of genetically modified mice).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This project will run over 5 years and will use mice as the experimental animal. In this project, the majority of the mice used will be genetically modified with a non-harmful phenotype (protocol 1). These mice will be used to maintain breeding colonies or will be culled by a schedule 1 method for tissue collection. Over the duration of the project we expect ~30% of the mice will be used for this part of the project. A further ~30% of mice will be bred under protocol 2 - genetically modified with a harmful phenotype. The majority of these animals will be used to maintain the colony of which half will carry the harmful transgene. Over the 5-year period we expect that approximately ~10% mice will be used for cellular transfer experiments (moderate), ~10% for monoarthritis (moderate) and approximately ~20% for polyarthritis models (moderate).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to study the inflammatory response, three components need to be examined: time, place and cell type. While place (organ) and cell type (leucocyte or fibroblast) can be examined relatively easily in humans, it is difficult and, in some cases, unethical to perform multiple biopsies, and adoptive transfer experiments in humans with arthritis without underpinning preclinical data that support therapeutic utility. Furthermore, as manipulating fibroblast biology has the potential to affect systemic immune function, we will need to determine whether manipulating fibroblasts as a therapeutic target affects the innate and acquired immune response and this requires testing in different mouse models and those that most closely resemble aspects of human disease. This step is essential in order to ensure that the translation of our findings to humans passes through the appropriate clinical regulatory stages before use in patients with arthritis.

Which non-animal alternatives did you consider for use in this project?

Over the last decade we and our collaborators have pioneered a range of in vitro co-culture models that have furthered our understanding of leucocyte-fibroblast cell interactions in chronic inflammation.

However, we have now reached a point where we cannot proceed to test our ideas without resorting to animal models of arthritis and bone damage as our in vitro findings must be validated in licencing authority approved animal models before they enter clinical trials and are tested on patients. We also need to provide a clear rationale for the therapeutic targeting of these cell types in inflammatory arthritis and that requires a detailed understanding of their role in different aspects of disease.

Why were they not suitable?

Our in vitro models are unable to fully recapitulate the joint architecture in its entirety and how it is altered during disease and especially over time in different phases of disease. Moreover, our current findings must be validated in licensing authority approved animal models before they enter clinical trials and are tested on patients. In some cases, this work represents preclinical therapeutic (drug and/or cell) efficacy studies required prior to embarking on human clinical trials. There are no other in vitro or in vivo alternatives to this work. We will continue to collect as much in vitro evidence as possible before embarking on animal experiments, using it to inform and refine experimental design.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used specific mathematical calculations based upon previous studies and the likelihood of our interventions producing positive results, to estimate the number of animals we will use in our study. For all experimentation, the lowest possible number of animals will be tested whilst ensuring that the experimental result is robust.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A key strength of our work is that it combines both human and animal models so that each can be used to inform the other and therefore minimize an over reliance on mouse models of disease. This will give us the option to stop the line of research at any stage where our findings fail to show any significant increase in our understanding of chronic synovial inflammation. We are running these studies in parallel with studies that explore the same cell populations in immune mediated inflammatory diseases in humans.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have put in place careful breeding procedures and also, strategies to reduce the clinical symptoms of arthritis and inflammation in such mice by treating them with anti-TNF antibodies in the same way that therapy is given to humans with rheumatoid arthritis. By doing this, we will reduce unnecessary suffering for the mice and therefore, the number of mice needed in our breeding programme as litter mates can be bred for longer periods of time. Where possible, tissue will be archived for future use.

New interventions will first be tested for efficacy using in vitro models prior to use in vivo. Where new routes of administration or new interventions are being examined, pilot studies will first be established in 2-3 mice prior to full experiments. Subsequently these pilot data will be used in the specific mathematical calculations described above to ensure that we use the minimum number of animals needed to obtain statistically significant results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the best model for the study of persistent disease because:

The main components of their immune system are shared by humans; this is essential where immune responses as opposed to the function of individual genes is being studied and thus will produce satisfactory results.

A wide range of wild type and genetically manipulated strains of defined genetic makeup are available.

An extensive range of reagents are available for analysis of immune responses.

They are the most acceptable animal models that show the least degree of neurophysiological sensitivity and will suffer the least pain, suffering, distress or lasting harm.

There are no other alternatives to this work.

We have refined and streamlined as much as possible the models of arthritis that we use. Importantly we will use a research strategy that includes the use of different models of inflammatory arthritis to more accurately recapitulate a specific phase or aspect of joint disease, depending on the scientific questions of that particular experiment. This targeted approach will limit the use of persistent models of joint inflammation to only those experiments where it is needed to model that specific aspect of the disease.

Where necessary, males carrying the mutation will be used for breeding with WT females as this means the female does not have the burden of the effects of the mutation alongside pregnancy.

The maximum time a single mouse is likely to have arthritis is 5 weeks as the arthritis is self-limiting. We will give mice treatments that lessen pain and discomfort that might occur as part of the inflammatory response. This will include pre-emptive treatment with opiate analgesia. We have also adapted treatments used in patients with arthritis (e.g anti TNF biologic therapies) for use in mouse strains that have a genetic predisposition to develop arthritis. We have put in place mitigations as described below in the 3Rs to ensure that any suffering by an individual animal is minimized.

Why can’t you use animals that are less sentient?

Less sentient animals do not possess the same sort of skeletal structure that composes the joints, and often their vascular tree and immune system do not fully represent that of humans. Small rodents are the lowest mammals that can be used to recapitulate the human immune systems response to joint inflammation.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

We have refined a number of our protocols over the last five years.

We will use established reagents and protocols that we have developed and refined over the last 5 years to treat the mice. Therefore, we will not need to perform unnecessary toxicity studies and will be able to use the lowest doses of agents that are well tolerated.

We have refined and streamlined as much as possible the models of arthritis that we use. Importantly we have very clearly defined humane endpoints. We have refined procedures of cellular transfer, including by intra-articular injection so the smallest volumes can be injected.

Where necessary, male mice, transgenic for the gene of interest will be mated with wild type females in order to exclude indirect effects on the progeny derived from gene overexpression in the pregnant female.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animal welfare is a key consideration in all of our protocols, and we will be guided by our NACWOs and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from welfare standpoint to identify any potential for refinement.

We will also follow the published literature on arthritic models - for example the case for using different arthritis models to model the different aspects of inflammatory pathogenesis is extremely well made and described in Vincent et al. 2012. Moreover, refinement of the injections for the induction of collagen induced arthritis has been described in Hawkins et al. (2015) and we have implemented these in our work to date and will continue to do so in this project.

If undertaking a systematic review, we will use SyRF, the free online platform for researchers, to perform a systematic review and meta-analysis of animal studies. This will allow us to keep up to date with any improvements in protocols and techniques which may reduce or replace the use of animals.

Finally, we will follow the LASA guidelines Guiding Principles for Preparing for and Undertaking Aseptic Surgery (www.lasa.co.uk/wp-content/uploads/2018/05/Aseptic-Surgery.pdf) and by the Home Office Minimum Standards for Aseptic Surgery (www.procedureswithcare.org.uk/ASMS2012.pdf) when undertaking aseptic surgery and providing analgesia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I or a member of my research team will attend local 3Rs events and sign up to the NC3Rs newsletter. We will also be reviewing the literature on regular basis in our journal clubs and through this network we will discuss any refinements that could be applied to our own work.

50. Understanding the role of androgens in raised intracranial pressure in vivo

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

Androgens, Intracranial pressure microchip, Idiopathic intracranial hypertension, High-fat diet, Cerebrospinal fluid

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Test the effects of androgens (dihydrotestosterone) in the presence and absence of obesity on intracranial pressure (ICP) in a mouse model using minimally invasive intracranial pressure microchip monitoring.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Idiopathic intracranial hypertension (IIH) is characterised by raised intracranial pressure and causes headache and a considerable risk of blindness. It predominantly occurs in obese young women with disease burden rapidly rising in accordance with the epidemic of obesity, driving escalating healthcare costs (£450 Million/ year by 2030). Despite the incidence increasing, physiological mechanisms of idiopathic intracranial hypertension are unknown and therefore targeted treatments have not been established.

Our previous work demonstrated that idiopathic intracranial hypertension patients have a unique signature of androgen excess and provided evidence that androgens can modulate cerebrospinal fluid secretion via the choroid plexus. This work was carried out in vitro on rat choroid plexus cell lines and human serum and cerebrospinal fluid samples. These findings implicate androgen excess as a potential causal driver of raised intracranial pressure in idiopathic intracranial hypertension.

What outputs do you think you will see at the end of this project?

This basic research project will lead to better understanding of how androgens impact intracranial pressure regulation. Furthermore we will evaluate how androgens and obesity may synergistically impact intracranial pressure.

Knowledge gained from this project will have direct translational relevance to idiopathic intracranial hypertension patients by demonstrating whether androgens do or do not alter intracranial pressure. This will potentially lead to future therapeutics targeting androgen metabolism in idiopathic intracranial hypertension. Currently there are no targeted therapies for idiopathic intracranial hypertension. The current drugs available are off-licence and merely alleviate disease symptoms but do not address the underlying disease pathogenesis. There is consequently an unmet need to develop targeted therapies in idiopathic intracranial hypertension to help reduce the risk of blindness in this disabling disease.

Outputs of this information will be through sharing our findings at national and international conferences, through collaborations with other researchers, and by publishing in peer-reviewed journals.

Who or what will benefit from these outputs, and how?

The work will add to the knowledge of androgen effects on idiopathic intracranial hypertension. In the short term the outputs will accelerate scientific progress towards a greater understanding of the cause

of idiopathic intracranial hypertension as well as potential therapeutic approaches for the disease in the future.

In the medium term the impact of this project will open new avenues for developing therapeutic targets for idiopathic intracranial hypertension. Our evidence may thus accelerate trials and drug development. Ultimately, in the long term, the goal is to bring efficacious therapies into the clinical environment for idiopathic intracranial hypertension patients.

How will you look to maximise the outputs of this work?

To maximise the outputs we are collaborating with different groups internal and external to this establishment that will lend their expertise and knowledge to our work. We will publish our work in peer-reviewed journals and present at conferences to disseminate new knowledge including reporting of unsuccessful approaches. We will also share best practice of new techniques and protocols we have developed and validated to

collaborators. We will engage with the public through events organised by the establishment to showcase our research.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

We are using a mouse strain that has been previously used for androgen excess experiments as well as high-fat diet experiments and consequently we have an established expertise with this type of animal. We have chosen young adult mice as they will have grown sufficiently to allow implantation of an osmotic minipump and intracranial pressure microchip. Furthermore this mimics the human condition where disease onset is typically in young adulthood.

We will choose mice at a consistent age to ensure standardisation between experimental arms.

Typically, what will be done to an animal used in your project?

Intracranial pressure microchip monitoring has been established with our collaborators. We have noted that intracranial pressure can be monitored continuously whilst also continuously assessing animal movement thereby enabling analysis of intracranial pressure to be quantified both during activity and inactivity. In order to attach the microchip a small hole (0.5mm) is drilled through the skull (without piercing the dura) above the ventricle of the mouse brain. The intracranial pressure microchip is sealed in place using Epoxy resin (nothing penetrates the burr hole or goes into the mouse’s brain, the burr

hole acts as a fluid filled reservoir over which pressure can be measured). Mice will be allowed to recover for a minimum of 7 days following surgery.

To examine the impact of androgen excess on intracranial pressure, young adult mice will be implanted under the skin with a slow release device which will deliver DHT or placebo for up to 6 weeks. To enable monitoring of intracranial pressure the same mice will also have an intracranial pressure microchip implanted a minimum of 7 days prior to androgen device implantation.

Intracranial pressure will then be monitored in freely moving mice twice a week for three hours by attaching the chip to a wire attached to a computer, this will allow the mice to behave normally during the recording period. To confirm the androgen phenotype longitudinal monitoring will be conducted over the 6 weeks including oestrus cycle monitoring until cycle arrest is confirmed, glucose tolerance testing for diabetic function and blood collection for steroid hormone levels. For the glucose tolerance test mice will be

fasted up to 6 hours and no more than two procedures will be performed on any individual animal. The effects of androgens on appetite and bioenergetics will be evaluated using metabolic home-cage monitoring for one week prior to microchip implantation as well as the final week of the experiment. At the end of the protocol cerebrospinal fluid will be collected for steroid analysis under deep non recovery anaesthesia. Androgen sensitive tissues (fat, ovary, choroid plexus and muscle) will be weighed and collected for analysis post mortem.

In addition we wish to explore the synergistic role of androgen excess and obesity in modulating intracranial pressure in mice. Therefore an additional cohort of mice will be raised on a high-fat diet (up to 60% kcal from fat).

What are the expected impacts and/or adverse effects for the animals during your project?

Home cage metabolic energy expenditure will be monitored at week -2 and week 6 for a duration of up to 7 days each. During the acclimatisation phase, animals have to settle into new surroundings, and get used to the food hoppers and water bottles in the system. Animals display cautious behaviour and may feed and drink slightly less than normal leading to weight loss <5% (incidence 100%).

Glucose tolerance test will take place at week -2, for a duration of 3 hours. Administration of glucose is unlikely to result in any adverse effects and is well tolerated.

At week -1 animals will be anaesthetised for a surgical procedure that will approximately take 60 minutes. This would entail implantation of an intracranial pressure microchip. This procedure should not result in adverse effects and is well tolerated. Animals will experience transient discomfort following the implantation after waking from anaesthesia (100% incidence) but will receive analgesia. The animals will be allowed to recover for a minimum time of 7 days.

At week 0, under anaesthesia, animals will undergo a second surgical procedure that will takes up to 30 minutes. This will involve the implantation of an androgen minipump. This procedure is also unlikely to result in adverse effects and is well tolerated. Animals will experience transient discomfort following the implantation after waking from anaesthesia (100% incidence) but will receive analgesia.

Blood collection from a superficial vessel should result in only subtle signs of adverse effects indicative of transient pain and stress due to pin-prick and handling.

A group of mice will be fed a high-fat diet for 6 weeks. Animals receiving high fat commercially available laboratory chow have not been associated with any physical or behavioural abnormality, but the coats of the animals will become greasy and excessive grooming may occur, resulting in skin irritation.

Oestrus cycle monitoring will take place one week following androgen and microchip implantation surgery and will take 5 minutes per swab (swabs will occur on three days during this week). Animals will be weighed weekly. An assessment of intracranial pressure

will take place twice weekly in freely moving mice for 3 hours for up to 6 weeks. Animals will experience stress due to initial restraint.

Cerebrospinal fluid collection will occur at the end of the experiment under non recovery anaesthesia before humane killing and tissue collection post mortem.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Expected severities of procedures include: Metabolic monitoring (mild); glucose tolerance test (mild);Implantation of intracranial pressure microchip (moderate), insertion of minipump (moderate); blood sampling (mild); administration of a high-fat diet (mild); oestrus cycle and weight monitoring (mild); intracranial pressure monitoring (mild).
- When summarising the expected severities of all procedures, the cumulative severity will be moderate for 100% of the mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Raised intracranial pressure occurs only in the intact living brain due to increased cerebrospinal fluid secretion from the choroid plexuses in vivo within the brain ventricles with intact cellular and vascular architecture. Intracranial pressure cannot be reproduced in vitro, and not enough is known about idiopathic intracranial hypertension to construct computer models.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

Which non-animal alternatives did you consider for use in this project?

Our existing in vitro data obtained from cell culture approaches has guided the proposed in vivo studies. We always conduct cell culture based experiments to justify the need to use animals. These systems include culturing cells in monolayer as a homogeneous population on plastic or mouse/human derived tissue as organoids.

Why were they not suitable?

There are significant limitations of basic culture conditions using cells gown in isolation as a monolayer on a piece of plastic as this is not an accurate representation of what occurs within a patient. There is an inability to fully recapitulate the in vivo environment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

When possible we will always use power calculations to determine estimated numbers of animals that should be used. For most quantitative experiments, animal cohort size will be calculated via power analysis. Expected effect size will be determined through consultation of the literature, cell culture based in vitro analysis or through small pilot experiments when possible (have been previously conducted by our collaborators).

We have used statistical methods to calculate how many animals we need to get meaningful data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs' Experimental Design Assistant to design experiments and taken advice from researchers who have performed similar research projects in the past.

We aim to reduce animal numbers, apply methods to reduce subjective bias, and undertake appropriate statistical analysis without compromising the scientific objectives. When possible, experiments will involve a factorial design that will maximise the information obtained from a minimal number of animals.

For example, we will only conduct the experiments in one species (mice). Mice raised on a normal diet with androgens and a further group without androgens will serve as a control for mice raised on a high- fat diet.

We have also been able to accurately assess the variability of intracranial pressure measurements and thus the standard deviation used in the power calculation using our existing data collected with our collaborators.

By using a minimally invasive technique the procedure is less severe with less harm to the animal compared to an invasive intracranial pressure monitor. This will enable fewer mice to be used per experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have used previous pilot studies to estimate variability and perform power calculations to calculate sample sizes.

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.

All tissue surplus to requirement will be stored and made available to collaborators within the institution and beyond.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used for implantation of the microchips. Subcutaneous implantation of androgen minipump for prolonged release of dihydrotestosterone during the course of the experiment will be undertaken after a minimum of 7 days post microchip surgery. The intracranial pressure will be recorded in freely moving mice for a total of 6 weeks.

The androgen minipump implantation is a well-known technique and an established skill set within the animal facility. Previous studies have shown no known prolonged discomfort in these animals. This is a refinement to a daily injection of androgens which has been conducted in the past.

The intracranial pressure microchip implantation is minimally invasive compared to traditional intracranial pressure monitoring using a probe into the brain. This is a significant refinement as this technique involves drilling a smaller burr hole (0.5mm diameter) without penetrating the dura, therefore reducing the pain, suffering and distress to the animals whilst also delivering highly accurate data.

To measure the energy metabolism of mice in vivo we employ metabolic home cage monitoring. Unlike other metabolic cage systems, this approach allows mice to live in their home cages, and so CO2 production, O2 consumption as well as food and drink intake can be monitored without any disturbance to the animals.

Why can’t you use animals that are less sentient?

Mice are the least sentient species that will allow us to achieve our objectives.

We have chosen to use mice over other less sentient species as mice and humans share 97.5% of their coding DNA sequences. Moreover they are the ideal size due to the nature of the experiments in terms of implantation and assessment of responses.

In vitro studies cannot fully provide essential information about raised intracranial pressure that is obtained from in vivo studies, because the complete physiological response to raised intracranial pressure involves a closed system of pressure build, such that valid treatment testing requires the study of intracranial pressure in vivo.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare Animal welfare is a key consideration in all of our protocols and we will be guided by our experienced technical and veterinary staff in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local animal welfare and ethical review committee. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.

Analgesic will be administered at the time of each separate surgery for intracranial pressure microchip and androgen minipump implantation both during the procedure and approximately 24 hours later for post-operative analgesia. The mice will be observed closely for any evidence of discomfort, and should we observe such evidence they will be humanely killed.

We will make every effort to group house the mice in between procedures.

We are fortunate to have excellent colleagues with extensive, relevant animal procedure experience, from whom we can learn refined techniques from.

Examples: The home cage metabolic monitoring system allows the quantification of energy metabolism by measuring O2 and CO2 concentrations, food and drink intake while the animal is living in an individually ventilated cage without any disturbance. For glucose tolerance testing a single incision will be made on the tail to take small sequential blood samples rather than sequential cutting for blood sampling from tail vein. We use ultrasensitive ELISA assays for hormone measurements to reduce the blood volume that has to be taken. Refined handling techniques are used wherever possible and body condition charts for humane endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the literature for experimental design, best practice, and humane endpoints for research in animals.

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The data will be published in Open Access journals that support the ARRIVE guidelines, published by the NC3R's, and conduct our experiments with advice from the PREPARE publication (PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Literature searches, attendance at vendor's information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.

We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), an NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.

We will consult the NC3Rs social media platforms to help us keep up with advances in the 3Rs which will be discussed an implemented through our lab meetings.

51. Understanding glaucoma pathology and the development of new therapeutic strategies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neuroprotection, Retinal disease, Glaucoma, Fibrosis, Drug delivery

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this programme of work is to understand how and why glaucoma develops and to investigate if we can treat the underlying causes of glaucoma with new experimental therapies.

Glaucoma is a complex disease that leads to blindness and currently there are no curative therapies. In this programme of work we aim to understand and treat the causes of glaucoma by investigating cells, fluids and tissues within the front and back of the eye.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

Glaucoma is a neurodegenerative disease and is the leading cause of irreversible blindness worldwide. There are approximately 80 million people affected by glaucoma with

11 million people worldwide being bilaterally blind from the disease (https://www.iapb.org/wsd14-case-glaucoma/).

Currently there are no curative therapies available for glaucoma and patients lose their sight over time.

What outputs do you think you will see at the end of this project?

The main outputs from this project will be:

Improvements in understanding how glaucoma develops and cellular and extracellular disease processes that occur within the front and the back of the eye. Furthermore, we will have gained knowledge in understanding the role(s) of fibrosis in the development of glaucoma.

The development and assessment of novel therapies to treat disease at the front and back of the eye in glaucoma.

The development and assessment of ocular drug delivery technologies in order to treat front and back of the eye pathology in glaucoma.

The knowledge and data generated through this project will be disseminated through patient and public events, conferences, high impact peer reviewed publications and/or future grant applications.

Who or what will benefit from these outputs, and how?

Being able to demonstrate preclinical efficacy of potential therapeutic agents will enhance their translation into the clinic, and therefore this research has the potential to significantly reduce patient, clinical and economic burdens associated with glaucoma. In the UK over 2% of people over 40 years of age have glaucoma. Sight loss due to glaucoma poses significant emotional and physical burdens on patients.

Short-term (during the project): within the five year programme, beneficiaries will be the local, national and international research communities involved in glaucoma, fibrosis and drug delivery research. Benefits will include both scientific discovery and technical expertise, which can be shared through social media, conferences, meetings and publications. Also in the shorter term, patients will be made aware of the work through glaucoma and ocular disease patient groups (for which our team is already part of).

Long-term (after this project): Through knowledge acquisition and therapeutic discovery, patients and clinicians will be the most likely beneficiaries to this research. For patients, it will be the development of a treatment which offers anti-scarring, pro-regenerative and neuroprotective therapies, administered in a way that is patient acceptable and reduces side effects of current IOP lowering medications. For clinicians, the development of disease modifying therapies would be revolutionary for glaucoma.

Furthermore, being able to administer therapies in a manner suitable to ensure patient adherence to treatment regimens would be of benefit to the clinical community and patients.

How will you look to maximise the outputs of this work?

The outputs of this research will be maximised at an Establishment level by the sharing of surplus animal tissue, and at national and international levels by promoting collaborations, the dissemination of new knowledge, and the publication of results and methods to inform the scientific community.

Surplus animal tissue: given that a lot of the research will be based on the eye and central nervous system, other surplus animal tissues from these experiments will be freely available to other researchers.

Collaborations: we have recently set up collaborations to investigate mechanisms of TM/SC dynamics. This project would permit knowledge sharing and allow us to develop improved ex vivo modelling to further reduce the need for in vivo experiments.

Knowledge sharing of positive and negative results and approaches: results from this project will be important for advancing our knowledge of glaucoma pathology, new disease targets and any new treatments. The results of the models, the techniques and data will be published in peer reviewed journals (ophthalmology, general medical, drug delivery and method journals) in order to reach a wider audience. Furthermore, social media will be used to promote the research and its results. It is important that any research pitfalls or challenges be addressed and described in order to allow others to learn and optimise methods.

Species and numbers of animals expected to be used

- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Rat models of glaucoma have been extensively investigated and routinely used for vision research. Their ocular anatomy and functioning is very comparable to the human eye, and therefore is an ideal surrogate to model the human disease. Glaucoma typically effects adults and therefore adult rats have been chosen for this project.

Typically, what will be done to an animal used in your project?

Typically, under a general anaesthetic, rats will have their eye pressure non-invasively measured (using a probe that gently touches the cornea to calculate the pressure inside the eye) and then have glaucoma induced by a small injection into the front of their eye under a general anaesthetic. These injections are given twice a week for 1 month. Usually at around two weeks from the start of the experiment, rats will be given a treatment, either as an eye drop or as injections into the eye to treat their glaucoma. All of the methods used here are routinely performed on humans with glaucoma in a clinical setting (although

humans receive a local rather than general anaesthetic). Rats may also have non-invasive imaging of their eyes performed at the end of the experiment using optical coherence tomography (the same type of imaging which people receive at the opticians). The experiments will typically last for 1 month and rats will have a maximum of 9 anaesthetic interventions.

What are the expected impacts and/or adverse effects for the animals during your project?

Glaucoma doesn't present with symptoms in humans, and it's one of the main reasons why the irreversible sight loss is so profound. It is also one of the main reasons why patients forget to administer their own eye drop treatments. As with humans, the overall presence of glaucoma in the rats will not induce any adverse effects or pain for the animal. The rats will experience transient adverse effects from the multiple intraocular injections which could lead to some discomfort of the eye, however given that the rat will be under a general anaesthetic, any eye irritation will have likely worn off when the animal recovers. Topical analgesia may however be given as a precautionary measure if required.

Typically the injections take 3-5 minutes each. For the treatments, although unlikely, there may be intolerance to the therapeutic agent, however, as most agents will be given locally to the eye, this is not expected to reach the systemic system and therefore the risk of toxicity or intolerance will be very low. For the assessment of new therapies, all rats will be closely monitored for any weight loss or abnormal behaviours. Additionally, all new therapeutic agents will have undergone extensive testing via other methods prior to use in living animals to minimise any risk of adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The protocols have been classified as moderate due to the repeated injections into the eye and the repeated use of anaesthetics.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no substitute for the in vivo models we plan to use. We need a living system in which to accurately mimic the human condition of glaucoma so we can understand and study the complex interactions and functioning of the fluid systems and drainage tissues

within the eye and how they control internal eye pressure. We also need a fully functioning living system to provide a scenario in which we can manipulate eye pressure and investigate the downstream complex signalling and release of factors which lead to retinal and optic nerve degeneration - the cardinal features of glaucoma in humans. Without the in vivo system, we would also be unable to investigate and identify treatments that interact with the multiple responsive cell types involved in glaucoma, together with the immune and inflammatory response signals which cannot be modelled in vitro. Whilst it is unethical to experiment on human subjects to model glaucoma, we will also be using waste tissue from human surgeries to help inform the project.

Which non-animal alternatives did you consider for use in this project?

We have and continue to use the culture models of the particular cell types involved and these can give us a good idea of how those cell types behave in certain contexts, however, they are unable to model the complex interactions between the fluid production, drainage and pressure in the eye, and how all of this can lead to retinal and optic nerve damage. Furthermore we have considered the use of porcine (waste tissue) and human donor eyes as surrogates to try and understand how we can deliver drugs into the eye.

Why were they not suitable?

Culture models or ex vivo eyes are unsuitable for modelling glaucoma. Cultures are not currently complex cell systems which can interact with all the cell types involved in glaucoma. Ex vivo porcine or human eyes are not living tissues, and as such they cannot be used as glaucoma models because they cannot be maintained for the length of time required to develop glaucoma and assess the therapeutic potential of new treatments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers estimated in this project are based upon 8 years of experience of experimental design and from previous experience of using this same model. Most of the experiments have quantitative end points, and previous experiments have demonstrated that we require around 8-9 animals per treatment group in order to develop statistically sound results. Although we reduce the variability as much as possible, some rats have innate differences in their eye pressures and/or may not develop glaucoma. We know from past experiments that generally >6 out of 10 rats will respond to the induction of glaucoma, therefore, this has been taken into account when deciding on the total numbers for the project. In addition, reduction in animal numbers will be achieved through the use of both eyes to induce glaucoma, therefore if only one eye develops high intraocular pressure then that animal can still be used in the experiment reducing the need to use more

animals. The use of both eyes also enables eye tissues and fluids to be pooled for analysis where needed. For qualitative end points less animal numbers will be used, typically 3-6 animals per treatment group.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Based on previous studies, randomised designs are used for most experiments where animals are randomly assigned to a treatment arm. Studies will usually monitor the effects of therapies to lower eye pressure throughout the experiment. Most of the experiments are hypothesis driven with clear end points to help aid the design. Study designs are checked against the ARRIVE2.0 guidelines and the EDA tool will be used in order to minimise any error in design or bias and to ensure we report the study results comprehensively. Furthermore, we often consult statisticians to help derive the correct powering of the study or to review our experimental designs before the study starts.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Initially studies (modelling the disease and doses of therapies) will be designed based on previous experiments. Given that we have over 8 years' experience of using this model, we are confident in the experimental design for the induction of glaucoma. The key optimisation steps are therefore around testing of the therapeutics. Most of our therapies have been administered by topical or injectable routes. So for similar compounds our experimental design protocols are already in place. However, we are developing novel ways in which to enhance drug delivery (use of hydrogels, cell penetrating agents) and so we would perform pilot studies for the new compounds to enable us to establish a therapeutic window in which to use these compounds in the larger glaucoma studies.

We will optimise the data and information from all animals in all experiments. Furthermore, unused tissues from experimental or control animals will be made freely available to other scientists within the University.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experiments detailed here will be carried out in rats. They have been rigorously characterised and are suitable for use in glaucoma as they possess comparable eye and visual systems, develop the same clinical signs (e.g. ocular hypertension, trabecular

meshwork scarring and retinal degeneration) and have the same molecular and cellular signalling cascades that lead to glaucoma in humans. This glaucoma model has been further refined from the previously used optic nerve crush model. In the optic nerve crush model over 95% of retinal neurons are damaged, in this more refined model, there is only between 30-40% loss of retinal neurons and it is more representative of the human condition.

Furthermore, although the rat eye and visual system are identical to humans, rats do not rely on sight as their primary sense. Generally, the injections take less than 10 minutes to perform under general anaesthetic and the rats demonstrate a full return to normal behaviour within a few minutes of waking.

Additionally, whilst this procedure is not thought to cause postoperative pain, where appropriate topical analgesia will be applied at the time of the injection as a cautionary measure. We have taken care to develop the models to have minimal adverse effects on the rats and all the techniques employed in this project are routinely performed in humans in the clinic.

Why can’t you use animals that are less sentient?

Although mice also possess a similar eye structure and function to rats, they are not feasible for these experiments due to the very small size of the eye, making intraocular injections challenging. If mice were to be used, it would likely result in the use of more animals due to technical failures. Less sentient animals such as fish are not suitable for modelling human neurodegenerative diseases as, unlike mammals, they are able to regenerate their injured central nervous system.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

The animals will be allowed to acclimatise to their surroundings for 5 days and get used to being handled. Monitoring forms will be used for the rats and daily monitoring will be conducted especially for any new therapeutic interventions which could have unexpected effects on the animals. All experimental time points will be kept to a minimum and multiple analyses will be conducted from each animal during and after the experiment. The number of interventions will be kept to a minimum and the minimal drug volumes will be used. Topical analgesia will be used where appropriate as a cautionary measure. We are also putting refinements in place by determining the most efficient way to deliver drugs into the eye in the least invasive manner. These refinement steps, and those still in progress, will streamline experiments and reduce the use and suffering of animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE2.0 and PREPARE guidelines will be used to help plan, design and report on the experiments in order to ensure our studies are conducted in the most refined way possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will use the NC3Rs website to stay informed of latest developments, together with newsletters from our animal facility. I have previously attended courses provided by the Animals in Science Regulation Unit, United Kingdom and attended workshops on the ARRIVE guidelines (2017) and NC3Rs best practice in experimental design (2019). I have also attended online seminars including the NC3Rs' "improving the quality of funding applications using animals" in 2020. I intend to stay informed by attending local workshops and engaging in seminars and events given by the NC3Rs.

52. Engineering plant ion channels and receptors

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

plant physiology, ion channels, molecular engineering

Animal types	Life stages
Xenopus laevis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall goal of this project is to understand how ion channels work in plants in order to develop strategies for improving crops. Ion channels are proteins that facilitate the movement of ions across cell membranes and are vital for many functions in plants, including photosynthesis, resistance to pathogens, and environmental hardiness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ion channels are important targets for research because of their potential for improving crops. Pioneering studies from research groups around the world over the past few years have provided proof-of-principle for enhancing crop biomass yields and water use efficiencies. For example, by accelerating ion fluxes, it has been possible to improve photosynthetic carbon fixation. These advances are important, because they demonstrate the potential to greatly increase crop production and, at the same time, to do so with a reduced cost to the environment.

We know a great deal about how the plant ion channels work, and we have knowledge sufficient to begin engineering their protein structure in order to carry out these improvements. What we do not yet know is which parts within these proteins are the best for engineering to achieve the improvements that are desired. For example, we know that altering key behaviours of certain channels will enhance the ability of plants to cope with environmental challenges such as drought; what we need to identify are the molecular parts that are best targeted for change in order to achieve these enhancements.

For this purpose, being able to characterise the plant channels when introduced into Xenopus eggs is vital, because it allows an analysis of the channels free of the background of regulatory factors that are present within the plant cell.

The immediate challenges now are

to identify the relevant molecular parts of each of a small subset of ion channels for engineering, and

to resolve the range of enhancements that can be achieved through such engineering for transfer back to crop plants.

What outputs do you think you will see at the end of this project?

The primary outputs of this work will be in proof-of-principle knowledge and in scientific publications. There is much interest currently in finding ways to enhance crop yields and their efficiencies in water use in the face of global environmental change. Thus, the research is expected to find its way into the highest calibre international journals. As a proof-of-principle, the project is likely also to yield one or more patents and to lead to research that will translate the findings to agricultural crops.

Who or what will benefit from these outputs, and how?

This project is directed to the related challenges of increasing biomass yield and reducing water consumption of crops, and it also addresses the development of tools that make use of biological 'switches'. The concepts behind the proposal are at the core of ideas emerging within the international plant biology communities. These approaches have already proven highly successful using synthetic proteins that have been introduced into many cell types. Using similar strategies that are built on naturally-occurring proteins is one of the most challenging problems in biology. Solving these problems is expected to yield fundamental knowledge as well as informing on ways to improve crop water use and yields.

Benefits

In short-term, the research will benefit fundamental science in its focus on new tools, methods and critical understanding about how plant ion channel proteins function. It will generate a number of molecular tools, based on study of the channels when isolated from the plant, that will enable researchers to probe and understand the physiological mechanics of plant cells and tissues. These tools will allow researchers approach questions that have hitherto been intractable to analysis. For example, it will be possible to

manipulate the mechanics of ion and water flux in real time in order to understand their coordination.

In the medium- to long-term the research it will benefit the applications of scientific knowledge in guiding future work to improve crops. In particular, once we know how to modulate the activity of the ion channels, it should be possible to develop crops with native channels that have been altered in their activity in order to improve both ion and water flux efficiencies, thereby benefitting farmers and society in general by reducing the resource demand of growing crops.

With regard to the applications of this knowledge, it is worth noting that, at present, agriculture consumes 70% of our natural fresh water resources globally. Even in the UK, irrigation of crops has expanded some 1000% over the past 30 years in the face of environmental changes we are experiencing. This trend is set to continue will soon be unsustainable.

How will you look to maximise the outputs of this work?

The project is certain to lead to several platforms for dissemination of the results, including opportunities to share the knowledge with academic and industrial researchers through seminars at scientific meetings, through publication, and through sharing of biological materials, including molecular constructs, with academic colleagues for their own research.

Species and numbers of animals expected to be used

- Xenopus laevis: 40

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Toad (Xenopus) eggs are essential for the data collection element of the studies that use electrical recording methods, so-called electrophysiology, to measure the functional characteristics ion channels. These elements data collection need to be carried out by introducing the ion channels into a non-plant cell in order to characterise the channel behaviour free of interference from regulatory factors that are present in the plant cell. As a further complication, such recordings require data collection over longer periods for full characterisation of plant channels. Such long-term recording periods can only be achieved in Xenopus eggs; they cannot be achieved in other non-plant systems such as mammalian cell (eg. HEK cells) and insect cell lines (eg. Sf9 and Sf21 cells) in which only short recording times are possible. Thus, analysis of channel behaviour initially requires that the channel proteins are situated in a Xenopus egg.

For these reasons, recording from Xenopus eggs has been the benchmark for studies of this kind for over 30 years. These measurements will be important for comparative

purposes and will lead thereafter to further analysis in the plant. For proper introduction of ion channel proteins, it is essential to use eggs at stage VI (late in development), as the eggs become dormant following release and will no longer produce ion channel proteins. Eggs will be harvested by surgery and partial removal of the ovaries of adult female Xenopus toads.

Typically, what will be done to an animal used in your project?

The use of toads (Xenopus) will be restricted to the harvest of unfertilized eggs. An egg harvest will entail one surgery under general anesthesia to removal of part of an ovary with recovery. The total number of animals will be limited to the minimum needed to provide essential insights that can be transferred to analysis of the ion channels in the plant.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible adverse effects include post operative infection and wound breakdown. These are rare events

- the experience of post-operative infection is less than 0.1% over the past two decades - as measures are in place to minimize the risks to the animals and antibiotics may be used to eliminate such infections, usually within 1-2 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the operation is moderate and measures are in place to minimize the risks to the animals. All animals will be subject to this operation severity. Each animal will undergo a single operation under anesthetic with recovery to harvest a collection of eggs. A second egg harvest will be carried out after killing the animal by a Schedule 1 method.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Use of toad (Xenopus) eggs is essential for a subset of data collection. Analysis of function requires that the proteins are introduced into a non-plant cell, since the plant cell will have these channels and related proteins, making defined analysis impossible.

By carrying out these elements of data collection after introducing the channels into the eggs, it will be possible to characterise the channel behaviour free of interference from regulatory factors that are present in the plant cell. Once the characteristics of the channel protein have been determined in this way,

it will then be possible to re-introduce the channels into the plant and to assess the consequences in the native situation.

Which non-animal alternatives did you consider for use in this project?

Mammalian cell lines (eg. HEK293 and CHK cell lines) and insect (eg. Sf9 and Sf21) cells were considered. Recordings from these cells are not possible for two main reasons that are outlined below.

Why were they not suitable?

For analysis of many ion channels, it is necessary to co-introduce 3-5 different ancilliary proteins at the same time; the success of such co-introductions in both mammalian and insect cell lines is vanishingly small, making any comparative analysis impossible

The characteristics of many ion channels demand that electrical recordings are extended over long time periods, often many tens of minutes to hours; such long recording periods are simply not possible with mammalian and insect cell lines. Such stable recordings are essential to analyse many of the properties of the ion channels before they can be transferred to any plant cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals are estimated based on previous projects with similar requirements for testing using toad (Xenopus) eggs.

In general, the major limitation on use of toad eggs is the time over which they survive following an operation and may express proteins. Once isolated, the eggs survive for only 5-8 days and, after a protein has been introduced, there is typically a 2-3 day period over which measurements can be made. The second major limitation is the number or measurements that can be made during this 2- 3-day period. A trained researcher will be able to carry out 6-8 measurements in the course of one day. Finally, the third limitation relates to the quality of the eggs themselves, which will vary from one animal to the next. For this reason, to fully analyse any one protein, it is standard practice to obtain at least 4-5 measurements from each of at least three separate egg harvests.

Because each egg harvest typically yields some 100 usable eggs (ie. in stage VI), significant savings can be achieved by careful planning so that 4-5 different proteins are analysed with the eggs from each harvest.

The need to analyse some 70 different proteins is anticipated over the course of this project. Assuming that roughly 10% of toads do not yield viable stage VI eggs, the above figures indicate the need for 40 animals over the during of the research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental designs take into account opportunities to reduce animal numbers by subdividing each egg harvest into pools and planning experiments to address parallel questions concurrently. This approach is possible as each harvest normally yields more eggs than are needed for a single experimental trial. Following a harvest, the eggs are normally viable for a period of only 5-8 days. Extra eggs from a harvest cannot be stored for longer times, for example by freezing, because the egg membrane breaks down which renders them unusable for recordings. Separate pools will be used therefore to express and test different protein constructs or construct combinations in parallel, thus reducing the total number of animals required.

Undertaking surgery with recovery also reduces the number of animals to be used. The quality of Xenopus eggs varies from one animal to the next and is generally consistent within any one animal. Recovery surgery therefore allows the selection on the next egg harvest of a single animal needed to obtain good eggs after Schedule 1 killing.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Measurements of the activities of the ion channels will build on pre-defined protocols that are the gold standard for channel analysis and will include the parallel experimental designs noted above.

Additionally, these designs will be guided by established computer modelling of the electrical current characteristics and, where possible, by modelling with known physical structures of related ion channels. Electrical currents will be compared with those obtained from wild-type channels (these

include measurements of temporal kinetics, voltage sensitivity, inactivation kinetics, ionic dependencies, etc.) and will be deemed satisfactory for any one construct using normal statistical standards.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Use of toad (Xenopus) eggs, as noted previously, is important for introducing in a non-plant cell and analysing the ion channels, and is the benchmark for studies of this kind. To minimize suffering, a single partial removal of an ovary will be carried out under anesthesia with recovery. A second ovary removal will be carried out only after the animal killed by a Schedule 1 method.

Why can't you use animals that are less sentient?

For proper expression it is essential to use eggs at stage VI (late in development) harvested from toad (Xenopus) ovaries, as the eggs become dormant following release and can no longer be used to introduce proteins for analysis. The eggs are large, easily handled, and enable long-term recordings that are essential for the type of analysis needed to characterize the plant ion channels and their characteristics.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At present, care includes the isolation and close monitoring of each animal after operation until normal behaviours and feeding resume, typically within 12-24 hours. refinements will include the use of local analgesics, subject to guidance from the NVS.

Otherwise, knowledge transfer to work with in relevant native plant systems will be sought as quickly as possible, consistent with groundwork established through analysis of the ion channels when introduced into the eggs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animal husbandry and surgeries will follow best-practice guidance from NC3R and the RSPCA to ensure that egg harvests are as refined as possible.

For experiments using the Xenopus eggs, measurements of the ion channels will use established protocols that are standard for research of this kind (e.g. two-electrode voltage clamp and patch clamp methods). Comparisons with known channel characteristics and internal controls, including quantifying the amounts of ion channel protein present, combined with statistical standards (T-test, ANOVA) will ensure maximum refinement of post-operative experimental procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am updated through the designated office of relevant advances and seek to implement these in consultation with the NVS and NACWO. I expect to take part in 3R events organised within the the establishment I also keep up with the relevant literature and keep informed through regular attendance at conferences.

53. The effects of myocardial infarction.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cardiology, Myocardial infarction, Ischaemia, Ventricular fibrillation

Animal types	Life stages
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims are to investigate the electrical and mechanical alterations that occur during the different stages of recovery following a heart attack in both the surviving and damaged regions of the heart.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue **after the project has finished.**

Why is it important to undertake this work?

In man, heart disease is common, with a poor prognosis. The underlying mechanisms are complex; in some cases, there is a steady deterioration and in others the terminal event is sudden and unexpected. Current treatments are unpredictable in their effectiveness and often disappointing in their ability to reduce mortality. There are examples of studies that

have had to be terminated early due to an increase in mortality in the treatment groups. As these treatments were primarily studied in healthy hearts there is a possibility their effects are different in diseased hearts.

Many patients with diseased hearts have arrhythmias (abnormal heartbeats) and some treatments may have secondary effects at a cellular level that may further compromise the heart's ability to function properly. By far the most common cause of heart failure is myocardial infarction, i.e. ischaemia to myocardium caused by chronic arterial artery disease.

This project will use animal models of myocardial ischaemic damage. In our laboratory, a coronary artery will be permanently or temporarily tied off giving a small area of damaged tissue. The heart will then be studied whole or single cells will be used to examine mechanical and electrical changes. We are also developing a less invasive procedure which will reduce side effects and create an infarct more similar to that seen in humans. Rather than using surgery, a wire will be guided from an artery in a leg or arm into the arteries that supply blood to the heart and an artery will be blocked to simulate a heart attack. This procedure will reduce the risk of post-operative effect.

Studies on human hearts are difficult for several reasons including difficulty in accessing both diseased and normal tissue. Variations in age, medication and other health problems make it difficult to reliably investigate the processes at well-defined time points after a single incidence of damage.

The research proposed using this model is designed to provide new insights into the electrical events that trigger and sustain arrhythmias in cardiac muscle. An improved understanding of what causes these arrhythmias and their relationship with reduced function in a damaged heart is necessary to develop successful treatments that maximise heart performance while minimising the risk of life- threatening arrhythmias. Additionally, the models are used to investigate novel methods designed to improve the strength of contraction after an MI by adding a patch of artificial myocardium.

What outputs do you think you will see at the end of this project?

The project will provide information about the causal mechanisms that link heart tissue damage that results from a block of the coronary artery to (arrhythmic) sudden death. It will provide basic knowledge of the physiological and pathophysiological processes that occur post infarct and will inform future research so we may better understand the hearts healing process and suggest alternative therapeutic approaches. In the clinic, the currently available drugs, although having a rational theoretical basis, have been unpredictable in their clinical effects and have often been particularly disappointing or only marginally effective in their ability to reduce mortality. Indeed, there are numerous examples of trials that have had to be terminated early because of evidence of increases in mortality in the treatment groups.

One possible explanation for these adverse poor effects is the lack of understanding of the underlying primary cause of the electrical disturbances that lead to sudden arrhythmias at the different stages post- infarct. For example, there is increasing evidence that many

antiarrhythmic drugs have different electrophysiological effects in abnormal myocardium that could indeed exacerbate the propensity for arrhythmogenesis. These drugs have primarily been studied in isolated normal tissues whereas arrhythmias electrical disturbances presumably usually arise in damaged a scarred myocardium. It is therefore hoped that the findings of this study will inform subsequent work designed to tailor therapies to the various types of scars that emerge after an area has been damaged by block of the coronary artery. If a new potential therapeutic target or that a currently available drug may have beneficial effects at a given stage post infarct, subsequent studies will incorporate appropriate treatment groups in order to examine that rationale. The results from these studies will provide information concerning the structural and molecular basis for the changing predisposition to arrhythmias and sudden death post- MI, as well as information concerning contractile dysfunction. The work will be published in peer- reviewed journals and allow scientists to develop biomarkers that give an early warning of the arrythmias that lead to sudden death. Furthermore, the knowledge of mechanisms will allow drugs to be designed that will reduce the vulnerability of people with scarred hearts to cardiac arrythmias.

Recent developments in cell biology have resulted in the production of artificial myocardium heart muscle from somatic cells induced into a pluripotent form before differentiation to cultured cardiac cells. These cells can be used to manufacture myocardial patches of artificial heart muscle that can be embedded in the scar and supplement the few surviving myocardium strands of heart muscle post-MI. The new field of regenerative medicine has resulted from this work, but considerable research is required to develop viable patches that supplement myocardial mechanics without enhancing arrhythmias. This topic requires research using larger mammal hearts such as the rabbit with clinically relevant damage associated with the MI procedure to establish conditions that are optimal before testing on large mammals and man. In summary, the research described in this licence will aid in the modification of current treatment strategies to tailor new treatments to the stage of the remodelling process to repair and stabilise a damaged heart

Who or what will benefit from these outputs, and how?

In the short-term, the data gained from these studies will be published in high impact journals, adding to the body of knowledge concerning the mechanisms underlying the adverse effects of heart disease.

This work will also test new therapeutic approaches designed to improve the outcome of patients with ischaemic heart disease. Once these projects have been completed, the approaches that have been established as effective in the animal model, will go onto be tested in human patients by clinical teams.

How will you look to maximise the outputs of this work?

We will continue to collaborate with national and international colleagues and disseminate this work through publication and social media at the earliest opportunity.

Species and numbers of animals expected to be used

- Rabbits: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Rabbit hearts and those of larger mammals use electrical signals that have clear regional electrical variation that closely resembles that seen in the human myocardium. Furthermore, the structure of scars that result from damage to human heart tissue and those seen in the scars that develop in the rabbit heart are largely comparable making this species suitable for studying ways to stabilise and repair the human heart. Smaller mammals have very different electrical signals and the scars resulting from tissue damage are very different from the human heart. The rabbits used are approximately 6-8 months old, this is equivalent to a young adult human and therefore the heart structure is that of an adult animal and allows us to draw conclusions relevant to an adult human heart.

Typically, what will be done to an animal used in your project?

Most animals will only experience transient suffering while being administered an injectable anaesthetic for a terminal procedure (protocol 2).

The animals undergoing thoracotomy procedures will experience moderate pain from the surgery, which will be minimised by an analgesic regimen post-operatively. Further procedures on these animals will typically be limited to non-invasive imaging such as ultrasound and MRI measurements. Where other invasive procedures are required they will, where possible, be carried out under a final general anaesthetic.

Animals undergoing the new non-surgical procedure designed to block the coronary artery would will experience only mild pain associated with the use of cannulas.

All of the above animals would be expected to be killed around 8 weeks after coronary artery occlusion. The rabbits are not expected to show clinical signs of heart failure at this time point. Many humans feel no pain associated with acute coronary artery occlusion, some experience short-term referred pain, but long-term pain associated with a healing or scarred myocardium is not reported and therefore not expected. Any pain associated with the acute MI will be diminished by the post procedure analgesic regimen. Animals will be monitored for signs of pain or discomfort over the subsequent 8 week period and analgesia administered if clinical signs present. Past experience of thoracotomy-based MI procedure is that on recovery from the surgery, the animal does not show any clinical signs of pain or discomfort.

Animals undergoing stem cell implants of artificial heart muscle would experience moderate pain from the surgery. They would require daily injections of drugs necessary to prevent rejection of the implanted material and although the pain is transient, as it is a daily regimen, the procedural burden would be moderate. These animals would typically be killed no more than 2 to 4 weeks after the implantation procedure.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will experience moderate post-operative pain which will be controlled with pain killers this effect typically lasts 5-7 days post-operation (100% of animals after a thoracotomy or a percutaneous procedure).

A small number of post-operative experimental animals (approx. 4% of MI procedures) will experience sudden and fatal arrhythmias. This is an unavoidable consequence of the model used and we cannot predict which animals will be affected.

Due to good surgical and husbandry techniques other adverse effects are very rare.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1 (P1): Surgical induction of MI- moderate severity - 19% of all rabbits. Protocol 2 (P2): Organ removal- mild severity 62.5% of all rabbits.

Protocol 3 (P3): Invivo cardiac phenotyping - mild severity 2.5% of all rabbits. Protocol 4 (P4): Percutaneous induction of MI - moderate severity 9% of all rabbits.

Protocol 5 (P5): Insertion of artificial heart tissue - moderate severity 7.5% of all rabbits.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

These studies require the use of animals rather than humans because the research concerns the behaviour of the whole heart using techniques that include some that can only be used on isolated hearts removed from the body while beating and maintained in specialised equipment for several hours.

Obtaining human hearts under these circumstances is only possible under very rare and special circumstances such as to make this practically impossible. Even access to samples of human myocardium is not practical since samples would be required of diseased and normal muscle. Limited surgical samples of small parts of ventricle (less than 0.1g weight) can be obtained during routine cardiac surgery of diseased but not normal tissue. The small size of the sample, the variation in site of origin, stage of disease,

age of the patient, existing medication and other co-morbidities makes it impossible to get consistent functional data on the parameters required for the study.

Furthermore, the particular projects described in this application are designed to investigate the behaviour of heart muscle in the context of the whole heart e.g. electrical activity of the scar in the context of the whole left ventricle using specialised imaging techniques. These measurements cannot be obtained from the small samples of tissue available from humans. Furthermore, the studies require measurements to be made at well-defined time points after a single incidence of damage. This level of consistency can not be achieved from human studies where the time of the initial coronary occlusion is frequently not known.

Thus, animal models are necessary to study both whole heart and cellular changes of heart muscle in response to damage and after the complex natural recovery processes have been completed. The same arguments applies to research on the effectiveness of artificial myocardium, currently being investigated as a means of repairing hearts. These initial trials would not be ethical or practical on human hearts. Once the new therapeutic strategies have been developed and refined and proven effective in animals, trials will be allowed in humans.

Which non-animal alternatives did you consider for use in this project?

The use of experiments involving cell culture were considered. There are commercially available sources of induced pluripotent stem cell derived cardiac muscle. This artificial heart muscle is considered suitable for attempts to repair the heart, but is insufficient by itself to mimic the complex process that occur during ischaemia and cardiac scar formation. There are no non-animal alternatives that duplicate the damage associated with block of the blood vessels in the heart and the subsequent processes involved in the repair of the heart muscle. Working on isolated hearts from an inbred animal line after a standardised procedure to induce scars will allow us to better understand the events that lead to electrical disturbances and sudden death. These processes cannot be replicated in cultured cells systems.

Why were they not suitable?

There are no cell culture alternative because the process of coronary artery blockade, cell death and then the repair process involving the formation of a scar cannot be duplication outside an animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used this established model of damage to the heart from a blocked coronary artery for a number of years. Based on previous experiments supported by past Project Licences, we know the inter-measurement variation and the size of effects that are functionally relevant. This has allowed us to calculate the sample sizes needed to carry out the experiments and the further proposed studies outlined in this application.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure the minimum number of animals will be used in each section of the project, the experiments have been designed using power calculations to establish the minimum number of animals required to obtain statistical significance between variables. In general, for each measurement, a group sizes of between 8-10 animals will be required. If we design experiments that appear to require greater than 12 animals to achieve the statistical significance, we redesign the experiment/measurement to ensure a group size of 8-10 animals is sufficient

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To optimise the animals used in the study, we continually analyse and test statistical significance as the study progresses; when differences do emerge at the 5% level by n=8, that aspect of the study is stopped, i.e. we do not use more animals for each sub-project than is necessary. If statistical significance is not achieved (or very close to the 5% level) by n=8, the particular measurement is not continued.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocols 1 and 4 have been developed to model a common heart malfunction, described in this project which develops secondary to a block of a blood vessel in the heart and subsequent muscle damage.

Protocol 1 involves a long established method of a single episode of surgery to induce the myocardial injury. We aim to minimise the associated adverse effects by careful anaesthetic and surgical technique, carried out by experienced staff; the use of pre-emptive, intra- and post-operative analgesia, in consultation with the veterinary staff; detailed post-operative monitoring of animals and rapid intervention in cases of post-operative complications.

Previous experience with this model indicates that the expected adverse effects can be controlled and minimised.

In protocol 4, we are developing a non-surgical method of coronary artery block which will reduce or eliminate many of the adverse side effects associated with the surgical model and will provide experimental tissue with damage more similar to that which is seen in humans.

In protocol 5, the use of artificial heart tissue will be tested with a single surgical intervention. Experienced licensees will perform the surgical techniques under aseptic conditions and appropriate pain relief will always be administered. Best practice post-operative care will be employed to ensure any discomfort is minimised. Regular examination by veterinary surgeons and experienced technicians will ensure that any untoward effects that do develop are detected early and steps taken to minimise any distress or discomfort.

Why can't you use animals that are less sentient?

The rabbit heart has clear regional electrical variation that closely resembles that seen in the human myocardium. Furthermore, the structure of mature (healed) human infarcts and those seen in the rabbit are very similar making this species suitable for this study.

Smaller mammals do not develop such a human-like scar. This process of repair takes many weeks after the initial block of the blood vessel and therefore cannot be done as a terminal procedure under anaesthesia. Furthermore, the pattern of electrical disturbances that can be lethal in the human, also occur in the rabbit and involve electrical activity within the scar. This type of interaction is not properly mimicked by smaller mammals because of the size of the heart.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise the harms to animals that accompany our research, we have a long term plan to develop a percutaneous procedure (protocol 4) that will generate an MI and subsequent scar without the need for a thoracotomy. This will reduce the tissue trauma associated with the MI and therefore reduce the harm to the animal. It is hoped that this procedure can replace many of the thoracotomy-based MI procedures required for our research.

To minimise harms in the short term, we use pre and post-operative analgesia and monitor the animals for every 60 mins for the first 3 hours after surgery and twice/day for the first 3 days after surgery and daily thereafter. Robust local standard operating procedures for animal care, monitoring and minimal handling are in place. Lab members will ensure that all animals receive the highest standard of care to ensure animal suffering is kept to a minimum.

For each surgical procedure a Post-Op assessment sheet will be used (see image below) that will record the status of every animal with scoring and well defined limits and actions.

This will ensure that post-operative clinical signs including pain is recorded and appropriate well defined actions taken. This document is referred to at the appropriate places in the Protocols.

Rabbit Post-op monitoring sheet

Scoring of 0 - normal, no action required.
Scoring of 1 in any category - moderate - observe and notify NVS if no improvement in 24 hours
Scoring of 2 in any category - severe - NVS notified and animal killed immediately.

Scoring key	Moderate	Severe
Appetite	Reduced	Not eating
Faeces	Frequency, consistency change	Diarrhoea, constipation
Urine	Reduced output	No output
Wound	Inflamed	Obviously infected, open.
Temperature	39.5°C to 41°C	above 41°C or below 38°C

FGS - NC3Rs scoring system.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all studies we will adhere to published current best practice, and local guidelines. All experiments will be carried out, and any data published, in adherence to the ARRIVE guidelines (NC3Rs, Kilkenny et al 2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere). We hold regular meetings to plan and review our animal work and information on 3Rs advances will be discussed here.

54. Treatment and monitoring of diabetes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Diabetes, Wound healing, Insulin, Blood glucose, Medical devices

Animal types	Life stages
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to provide services to evaluate and develop strategies, therapies and devices to monitor and treat diabetes and related illnesses.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK 3.9 million people have diabetes (2019 figures) and an estimated further 1 million people are thought to have undiagnosed diabetes, suggesting a total closer to 4.8 million. Prevalance in the UK is rising and is expected to reach 5.3 million by 2025.

Age, family history and ethnicity are risk factors of developing diabetes, whilst obesity is the greatest risk factor, accounting for 80-85% of a person's risk of developing diabetes. A diagnosis of Type 2 diabetes is accompanied by an increased risk of premature death from associated conditions and complications, and ultimately premature death, compared to non-diabetic people. Diabetes related conditions include heart failure (currently estimated to lead to 2000 cases per week in the UK), heart attacks (530 per week), stroke (680 per week) and amputation (169 per week). In the UK, diabetes has led to end stage kidney failure for more than 10000 people, and serious effects on eyesight for more than 1700 people.

Worldwide, currently diabetes is the fifth most common cause of mortality.. An estimated 1.6 million deaths were directly caused by diabetes in 2016. Consequently, diabetes has increasingly become one of the major financial burdens on the UK NHS, accounting for approximately £10 billion every year and 10% of the total NHS budget; this has been projected to account for around 17% of the NHS budget by 2035.

The work conducted in this project can answer lots of questions about new strategies and technologies to monitor and treat diabetes and related illnesses, such as impaired wound healing and eye problems, or complications such as renal, vascular or nerve damage.

Sources: WHO, Diabetes UK,

What outputs do you think you will see at the end of this project?

Data will support product development, product registration, patents, and ultimately lead to new products.

Who or what will benefit from these outputs, and how?

For research Sponsor companies, data can demonstrate proof-of-concept as well as assisting elimination of inadequate candidates prior to further costly development, and further animal research.

In the long-term these studies will benefit patients with diabetes and related conditions. Furthermore the impact of this work may be applicable to multiple diseases, such as wound healing in general.

How will you look to maximise the outputs of this work?

Whilst publication of results would not be discouraged, it is expected that in most cases publication or dissemination will not be possible as the research will be conducted as a commercial service to companies.

Internally, the organisation will review processes and procedures after the completion of experiments, and use that experience to inform and develop future studies.

Species and numbers of animals expected to be used

- Pigs: 180

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Larger animals (pigs) are useful to evaluate products in the final stages of pre-clinical development. They are often used for testing medical devices due to their physiological similarities to humans: devices and implants of a similar size to those which would be used in humans can be applied; in comparison to smaller mammals (mice and rats) there is a larger blood volume and the response to treatments can be evaluated over a longer period of time.

Typically, what will be done to an animal used in your project?

Animals may experience the following procedures:

Induction of diabetes and manipulation of blood chemistry

Diabetes may be induced in some animals by injection with streptozotocin. Some animals may receive a modified diet, for example low or high fat, or low or high glucose, to induce certain physiological, biochemical or haematological changes. Animals will be habituated for restraint and handling purposes to minimise distress, and pain relief would be provided for any surgical procedures.

Gastrostomy

Under general anaesthesia, a tube would be surgically placed in the stomach and tunneled through the skin to emerge through the skin of the abdomen or back. This is to enable devices to access the stomach and intestines directly. This would be under recovery or terminal anaesthesia. In both cases, pain relief would be provided.

Multiple laparotomies

For devices in the early stages of development, it may be necessary to deliver treatments and observe tissue multiple times within a relatively short time period, e.g. 3 days. In these cases, it may be necessary to perform multiple surgeries to access the stomach ("laparotomy") within a relatively short time period, rather than place a gastrostomy tube.

Endoscopy and cryoablation

Under general anaesthesia, an endoscopic device would be inserted into the stomach or intestines (via a previously created gastrostomy or via the oesophagus). Cryoablation therapy would be delivered to tissues via the endoscopic device. This would be under recovery or terminal anaesthesia. Pain relief would be provided.

Administration of substances and blood sampling

If a drug or cellular treatment is being investigated, these may need to be administered on numerous occasions during the experiment, for example with food or as injections. Substances may be administered to assist with procedures, such as insulin or glucose. We may also need to take multiple blood samples from the animal during the experiment. The animals will need to be restrained for these procedures, and it may be useful to anaesthetise them. To prepare for this the animals are handled regularly to get them used to the staff and reduce any distress caused by restraining them as much as possible. If repeated blood samples are required frequently over a longer period of time, the animal may undergo surgery to place a cannula in a major vessel, which would then be tunnelled under the skin. Pain relief would be provided for any surgical procedures. A "finger-prick" device may be used for taking very small blood samples multiple times during the day. The sites for this would be rotated, and any discomfort would be very brief as this method is very quick.

Rapid manipulation of blood chemistry, e.g. blood glucose levels

Under non-recovery (ie terminal) anaesthesia, animals will undergo invasive surgery to expose major blood vessels from which we can take repeated blood samples and administer substances such as glucose quickly. Pain relief would be provided for the surgical procedure.

General anaesthesia and surgery

Depending on the length of anaesthesia, the recovery can be around 1-2 hours, during which animals will be uncomfortable and disorientated. Where surgery has been performed, pain and discomfort is expected during the subsequent recovery period (days – weeks), which we will manage with pain relief, and antibiotics will be provided if required. These will be administered with food, as injections, or as dressings. Where the animal needs to be anaesthetised repeatedly, for blood sampling or administration of substances for example, these sessions of anaesthesia will be quicker than the initial surgery, but the animal will still need to take medication and need some time to recover afterwards.

What are the expected impacts and/or adverse effects for the animals during your project?

Induction of diabetes

After induction with streptozotocin, a diabetic state may be temporary or permanent, depending on the dose administered and experimental aims. This would affect the regulation of glucose in the blood and may be accompanied by:

- reduced weight gain, weight loss,
- altered appetite,
- thirst and/or dehydration
- increased urination, which may cause discomfort and urinary scalds, or bladder infection, distended abdomen,

- reduced muscle mass, dry, flaky skin,
- impaired thermoregulation,
- impaired immune responses and wound healing which may lead to prolonged infections, effects on eyesight.
- General anaesthesia and surgery

Depending on the length of anaesthesia, recovery can take around 1-2 hours, during which animals will be uncomfortable and disorientated. Where surgery has been performed, pain and discomfort is expected during the subsequent recovery period (days – weeks), which we will manage with pain relief, and antibiotics will be provided if required. These will be administered with food, as injections, or as dressings. Where the animal needs to be anaesthetised repeatedly, for blood sampling or administration of substances for example, these sessions of anaesthesia will be quicker than the initial surgery, but the animal will still need to take medication and need some time to recover afterwards.

Infection

Infection of surgery sites is possible but unlikely as surgery will be performed under aseptic conditions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals are likely to experience moderate severity effects as a result of the protocols described.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

During later stages of product development, it is necessary to evaluate efficacy and safety in a fully functional physiological system. This is also sometimes needed in earlier stages of product development, where physiological dimensions necessitate evaluation in an animal model earlier than usual (for example, demonstrating a new application of a device which is already used in humans, and thus designed for human-sized tissues, vessels or organs). Adequately testing such devices in vitro would not be possible. Using an animal model means technologies can be evaluated in physiologically and clinically relevant conditions, for instance where blood glucose levels can be monitored and manipulated, in

the presence of other simultaneously active physiological and biochemical processes which are difficult to mimic in vitro or in silico.

Which non-animal alternatives did you consider for use in this project?

We expect project proposals to be based on in silico, in vitro or ex vivo data.

Why were they not suitable?

As a provider of in vivo scientific services we discuss supporting information or studies that can be performed in non-animal alternatives or cadavers with individual Sponsors and provide in vivo models when non-animal options have been exhausted.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated animal numbers are based on examples of likely study designs and timespans, for instance: up to two large animal (pigs) studies a year on Protocols 1 and 2, using 15 animals per study (150 animals per 5 years); and up to 6 animals per year on Protocol 3 (30 animals per 5 years).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures, before commencing larger studies - where possible, pilot study data will be included in the main study.
- Pilot studies will be used to validate the procedures in Protocol 1.
- We frequently recommend cadaver studies to Sponsors, and use cadavers for model development and training opportunities.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures, or to validate models or methods.
- Pilot studies will be used to validate the procedures in Protocol 1.
- We routinely harvest tissues and organs from experimental animals for research and training purposes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocol 1 induces diabetes in pigs. Diabetes will be induced by injecting a chemical, rather than a pancreatectomy: this procedure is a lower risk to the animal. Placing in-dwelling catheters means blood samples can be withdrawn and substances can be administered with minimal restraint and distress to the animal.

Protocol 2 uses pigs for endoscopic cryoablation. For some studies, creating a gastrostomy will require a separate surgical procedure, but will enable the endoscopic device and therapy to be delivered more accurately and easily, rather than having to access the duodenum via the oesophagus and stomach. However, for devices in the early stages of development, it may be necessary to deliver treatments and observe tissue multiple times within a relatively short time period, e.g. 3 days. In these cases, where up to two recovery endoscopic procedures are required within 24 hours of each other, direct access via a laparotomy would be preferable to an extra gastrostomy surgery and longer recovery time. Where more than two recovery endoscopic procedures are required in short spaces of time (e.g. 24hrs between procedures), placement of a gastrostomy would be the preferred choice.

Protocol 3 investigates a non-invasive blood glucose monitor. This protocol takes place under non- recovery general anaesthesia, and pain relief will be provided.

Where surgery is involved in the study, peri- and post-operative care and medication will be provided to reduce pain and minimise the risk of infection.

Why can’t you use animals that are less sentient?

Pigs are often used for these types of experiment because they are a good model for human obesity and diabetes since they have a similar omnivorous diet, a predilection for obesity, a similar cardiovascular anatomy, and a similar metabolism and lipoprotein profile. The ratio of body weight:blood volume is closer to humans than smaller mammals. Their body size, blood volume and growth rates are useful for evaluating techniques and devices over longer treatment/recovery periods (weeks-months) compared to smaller mammals.

The endoscopic device being tested is already used in humans for cryoablation of adenoma in the oesophagus and duodenum. Protocol 2 is investigating a new purpose for the device as a duodenal mucosal resurfacing (DMR) treatment for diabetes. The device is designed for human endoscopy, so would not be suitable to apply to smaller or younger animals. The experiments will be done under recovery anaesthesia to enable evaluation of

haematological and biochemical responses over a longer period of time, during recovery, and histological analysis during longer periods.

For protocol 3, smaller and younger animals (mice, rats, rabbits) would not have a large enough blood volume to produce enough quantitative data, and would be more adversely affected by the magnitude of the changes in blood glucose that would be necessary to adequatley test the device.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely provide post-operative pain relief and antibiotics, and are prepared to extend the provision of these where necessary. All animals are closely monitored immediately after any surgery or intervention, and then observed closely in the days and weeks following, for instance their mood, grooming, movement, weight, eating and drinking, appearance of wounds.

For recovery surgeries, all the animals arrive to the facility at least two weeks before studies start. During this time the animals can get used to the new surroundings and staff, and staff can start to train the animals if this will be needed for the experiment, for instance to stand still for blood sampling. All animals are provided enrichment whilst in the facility: for pigs this would include chains, balls and bars for them to chew.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our facility is GLP-certified and experiments can be performed to GLP-certified standards where required; non-GLP studies are performed to the same standard operating procedures.

The PREPARE guidelines cover many topics that are usually discussed between the research team and Sponsors whilst developing protocols, and an adaptive approach to these will be useful for planning specific studies and continuing the project.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our research staff actively seek opportunities for training and continuing professional development. We circulate the NC3Rs newsletters and take part in IAT and LASA activities. We communicate openly about animal welfare and suggestions and ideas for improvements are welcomed from all staff members.

55. Developing novel tools for kidney disease gene therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Kidney disease, gene therapy, Podocyte, albuminuria, Glomerular filtration barrier

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary aim of the work to be conducted under this licence is to develop new gene therapy vectors to treat common kidney diseases to prevent deaths and other major health care issues associated with these conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic Kidney Disease (CKD) is a major global public health issue and affects approximately 10% of the worldwide population, with an increasing prevalence with age. Risk factors for CKD include diabetes, hypertension, obesity and metabolic syndrome. The risk of cardiovascular events is increased in patients with CKD, which results in an

estimated 40,000 premature deaths in CKD patients each year in England. This risk increases as CKD progresses. Albuminuria is a feature of CKD and has been shown to be an independent risk factor for progression of CKD as well as an independent risk factor for increased mortality (all-cause and cardiovascular). There are no direct cures for CKD and this work aims to develop novel gene therapy tools to reduce albuminuria and prevent the progression of CKD to End Stage Kidney Disease (ESRD).

What outputs do you think you will see at the end of this project?

The outputs from this project will be the development of novel gene therapy tools to lower albuminuria and delay/halt progession of CKD to End stage renal failure.

Who or what will benefit from these outputs, and how?

Most kidney diseases have a chronic, complex course, punctuated by periods of intensive (and expensive) treatment such as dialysis and transplantation. Renal disease is a major healthcare issue for the United Kingdom and is expensive with 2% of NHS budget being spent on treating this condition. Chronic Kidney disease (CKD) affects 1 in 8 adults in the UK and there is a shortage of specific treatments for most forms of kidney disease. Current treatment options for kidney disease are at best only partially effective and some of the agents used have serious side effects. This project, aims to develop novel gene therapy tools to provide new treatment options for patients with kidney disease.

How will you look to maximise the outputs of this work?

This work involves collaboration with several groups, both national and international, who will provide tools and expertise for this project. Work will be published as soon as possible under signed intellectual property agreements and all data made available if products are taken to clinical trials.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

There is an unmet need for medical therapies for all forms of CKD and we want to develop our novel gene therapy tools to treat several of these more common diseases. Currently there are no in vitro models for studying kidney disease which mirror the complexity of the in vivo situation. Therefore, there is no alternative to the use of animals for the studies that need to be undertaken. Where possible we will use in vitro cell models to undertake preliminary studies to validate and ensure the efficacy of our novel tools prior to use in animal models. We will use well established, validated and commercially available mouse models of human disease.

Typically, what will be done to an animal used in your project?

We will use well established, validated and commercially available mouse models of human kidney disease.

The mice develop kidney disease over a period of 4 weeks to 8 months depending on the model. The mice will receive a single tail vein injection of our gene therapy vector and then will be monitored for the development of disease. The well being of the mice will be regularly monitored by measuring the level of protein in their urine and clinical observations using scoring systems targeted to the relevant mouse model.

What are the expected impacts and/or adverse effects for the animals during your project?

All the mouse models used result in renal dysfunction, leading ultimately to kidney failure. Mice will be assessed routinely for general signs of ill health based on a rodent health record score. We will regularly monitor the level of protein in the urine of these animals so that those with renal dysfunction can be identified at a stage before any overt suffering occurs. The monitoring of proteinuria is an important way to minimise harms in all models used.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

With careful monitoring the severity of the kidney disease induced is expected to be moderate in all cases. Monitoring proteinuria is an important way to minimise harms in all models as it will indicate when kidney disease has initiated so that those with renal dysfunction can be identified, regularly monitored using an animal health score and culled before any overt suffering occurs. It is planned that our gene therapy vector will lead to the abrogation of kidney disease in the treated mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The kidney is a dynamic structure responsible for continuously filtering the blood to remove waste productsCurrently, there are no suitable in vitro models for studying kidney development or function and no realistic prospect of developing such a system within the foreseeable future, Consequently, there is no alternative to the use of animals for the studies that need to be undertaken.

Which non-animal alternatives did you consider for use in this project?

In vitro cell modelsare available to carry out all the preliminary work to ensure that our gene therapy tools behave as we expect them to.

However, these do not accurately mirror the complexity of the kidney in vivo and therefore determine the efficacy of these new tools in treating human kidney diseases then animal models are required.

Why were they not suitable?

Where possible we will use in vitro human and mouse cell models to test our novel gene therapy tools, and these do form a major role in the preliminary studies that will be undertaken. However, to fully investigate and establish the efficacy of these novel gene therapy tools, animal models of human disease must be used. Work in cell models will allow us to develop gene therapy tools that are optimal and work efficiently thus allowing us to both replace and indeed reduce the amount of animals we study

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All the mouse models to be used in this project are very well established. The majority of the mouse models are commercially available apart from two, which will be obtained from collaborators. Small numbers of animals of both these models will be obtained and the progression of the phenotype confirmed prior to expanding the respective colonies. Therefore, the time-course of disease development in all models to be used will be well defined and thus mouse numbers required to test the efficacy of the gene therapy vectors can be estimated with reasonable confidence.

Extensive preliminary data will be acquired using in vitro human and mouse cell models prior to any mouse work taking place to fully verify the vector biology.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This work will build on extensive preliminary work showing the efficacy of gene therapy product in mouse models. The project will use well established and recognised models of kidney disease so the time-course of disease development in each model is well known. All proposed work has been designed together with an animal statistician and reviewed extensively by experts in the kidney field.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All gene therapy tools will be extensively tested and validated in well established in vitro human and mouse cellular systems prior to use in animal models. We will then minimise the number of animals used by following the principles of reduction by careful experimental design and the use of pilot studies and power analysis. After the optimal gene therapy tool has been developed and tested in these in vitro models, we will initially perform pilot studies to ascertain the correct dose of virus required to induce an effect and then go on to a formal hypothesis driven experiment using already available and well researched mouse kidney disease models. The specific principles we will use to reduce numbers will include: 1) Unbiased studies (using randomisation and blinding), 2) Adequate Power (control variability), so the experiments can adequately answer our hypothesis driven questions.

3) Wide range of applicability (factorial design). 4) Designing experiments in consultation with an expert statistician to ensure that the data is readily amenable to statistical analysis. We will also implement intelligent breeding strategies wherever possible by selecting breeding pairs in which there is a maximal chance of the off-spring having the required genotype for the required model. Although this takes time in developing, and a number of breeding rounds, ultimately it results in many less mice being killed due to the wrong genotype being born.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen to use rodents, as these are the simplest mammals to have kidneys that resemble that of man. We will use well established and characterized mouse models of human kidney disease. Using these well defined models allows us to design the optimal experiments, reducing the number of animals required and reducing pain, suffering and distress as the timeline of disease development in all cases is already known.

Why can’t you use animals that are less sentient?

Currently the are no in vitro models of kidney disease for testing the efficacy of new therapeutic agents. Although a considerable amount of preliminary work will be done in human and mouse cell culture systems, there is no alternative to the use of animals for the final studies that need to be undertaken. We have chosen to use rodents, as these are the simplest mammals to have kidneys that resemble that of man and we will use very well established, characterized and recognised mice models of human kidney disease already readily available.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For each different genotype to be used the natural history of proteinuria and kidney failure is well defined as these are well established and characterized mouse models of human kidney disease. Monitoring proteinuria is an important way to minimise harms in all models as it will indicate when kidney disease has initiated so that those with renal dysfunction can be identified, regularly monitored using an animal health score and culled before any overt suffering occurs ensuring that no animal exceeds the welfare endpoints defined in this PPL.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult any relevant references listed therein. (Reference: NC3Rs/BBSRC/Defra/MRC/NERC/Royal Society/Wellcome Trust (2019) Responsibility in the use of animals in bioscience research: expectations of the major research councils and charitable funding bodies. London: NC3Rs.)

Animals will be monitored for signs of pain and distress as disease progresses by experienced veterinarians and animal care technicians with significant experience in these species.

Standard Operating Procedures are employed for animal husbandry and procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continuously monitor publications and the NC3Rs website for new and alternative models that could be implemented as part of this project. In addition, articles on advances in the 3Rs and other relevant information is circulated by AWERB as relevant to PPL Holders. Whenever possible we will implement these refinements into our studies.

'Kidney'on a chip models using human and mouse cell lines which have the potential to reduce animal usage are continually being developed and we will keep constantly keep ourselves informed of the latest research in this area. However, although very useful for preliminary experiments these technologies have not reached the stage yet where they can replace the use of animals for the testing of the gene therapy vectors.

56. Molecular mechanisms of haemostasis and thrombosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Haemostasis, Thrombosis, Platelet, Coagulation/anticoagulant pathways, Atherosclerosis

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to furthering our understanding on how blood clots form in blood vessels under normal and diseased conditions (cardiovascular diseases). We want to undertake this work to improve currently available therapies to reduce unwanted blood clot formation and reduce the risk of cardiovascular diseases such as stroke or heart attacks.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The formation of a blood clot is essential to prevent bleeding. However, in some instances it can prevent blood from flowing normally through the circulatory system and arteries or veins can become blocked (thrombosis). In addition, clots can break off and prevent blood circulation in a different location causing a stroke or a heart attack. Currently, there are treatments available to prevent unwanted blood clots such as aspirin or anticoagulants, however they are not 100% efficacious. Indeed, every year 4 million people in Europe still die of cardiovascular diseases (160,000 in the UK alone). Therefore, a better understanding of the vessel wall, cells and molecules that circulate in our blood that are involved in clot formation will enable to identify new ways for treating/preventing thrombosis and fatty build-up in the artery wall, a disease called atherosclerosis.

What outputs do you think you will see at the end of this project?

The ultimate goal of this project is to find new ways to prevent blood clot formation. This will start by gaining new scientific knowledge about how the vessel wall, cells and clotting molecules that circulate in our blood interact in a normal clot to prevent bleeding (a process called haemostasis) and in pathological conditions where excessive clot formation can block arteries and veins (thrombosis). We hope to find new agents to treat thrombosis by increasing anticoagulants naturally present in our blood, by preventing blood cells such

as platelets and white blood cells to interact or by inhibiting important molecules driving clot formation. We have been publishing our findings in academic journals and presenting our work at international conferences and will continue to do so.

Product outputs

- Specific genetically altered mice for gene studies.
- Tissue
- New agents (antibodies) that potentially could be further tested in pre-clinical studies to assess their efficacy in preventing blood clots and ultimately protect against thrombosis and other cardiovascular diseases.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will provide a further understanding of how clot formation occur which should be of interest for research scientist/clinicians in the field but also could have a broader impact as platelets have been involved in various human diseases (e.g. cancer, infections, sepsis). We will also promote and publish any refinements or best practice we identify during this project and make post-mortem tissue available for personal license holders.

In the medium term the pharmaceutical industry will be interested in potential novel therapeutic targets we identify.

The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of thrombosis in humans, benefitting both patients and clinicians by contributing to the development of more effective anti-coagulants or anti-thrombotic agents which will ultimately reduce the economic and health burden caused by cardiovascular diseases.

How will you look to maximise the outputs of this work?

Findings and experimental procedures will be made available to other scientists through publication in open-access journals and presentations at scientific conferences and meetings. We will also seek collaborators with appropriate expertise to ensure the work is progressing smoothly. Data obtained from this project will be disseminated via various means (e.g. websites) through the establishment and various charities.

Species and numbers of animals expected to be used

- Mice: 6730

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

The mouse is the ‘gold-standard’ model for studies on thrombosis and blood clotting. Mice also are a good model of human disease and physiology. A high number of genetically modified mutants are available and there is an extensive amount of work that has already been performed and published. The generation of genetically modified mice is sometime necessary for the study of a particular gene for which the function in unknown or there are no commercial tools available to modify its function.

We will use mostly adult animals as they are of appropriate size for the models described in this project license.

Typically, what will be done to an animal used in your project?

Most animals in our project will be genetically modified but not have any other procedures performed - they will only have samples of their organs and tissues taken for study after they have been humanely killed. Animals may be injected with experimental substances usually once but occasionally more often and small quantities of blood withdrawn. Most animals used in experimental procedures will be under anesthesia with no recovery to study blood clot formation.

Some animals will be subjected to a restriction of blood flow in one of their veins and allowed to recover from the surgery. They are expected to survive the procedure. The clot is allowed to form over few days but most animals in this model will be culled after 48h post-surgery. Some animals may be anesthetised for imaging purposes to be able to follow the formation of a clot in each animal.

To study the formation of plaques in blood vessels, animals will be fed a diet rich in lipids as mice are not prone to atherosclerosis (fatty build-up in the artery wall) unlike humans. Some animals may be anesthetized for imaging purposes to be able to follow the formation of plaques in each animal.

In some instances, animals will be treated with anti-coagulant/antibodies against cells to improve the outcome of clot/plaque formation.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the procedures are expected to cause no more than transient discomfort and no lasting harm.

Animals may be subject to surgical procedures. For all surgical procedures, the animal is under general anaesthesia which is sufficiently deep and stable to ensure the animal is insentient throughout. Animals will be carefully monitored during recovery, and kept warm. If signs of strong discomfort are detected (which may happen rarely) this mouse will be immediately removed from the experiment and humanely killed. For one of the procedure, we will mimic the human scenario where people in bed-ridden position, or long-haul flight develop clot in their lower limbs. For this, flow restriction will be applied in one of the large vein of mice and under careful monitored anaesthesia. Animals usually recover quickly, move and eat normally and don't lose weight. To avoid any suffering mice will received strong pain killers before and after the surgery until the end of the experiment.

A good communication between scientists, vets and animal care technicians will be established to provide highest levels of care. At the end of a procedure mice will be humanely killed in accordance with the approved methods of this project license to avoid any excessive suffering, pain or discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the procedures are expected to cause no more than transient discomfort and no lasting harm. This mild severity is expected to represent around 90% of the mice. The remaining would be expected to experience a moderate level of severity as defined in some protocols of this project license. At all time, humane endpoints will be applied to comply with the level of severity of the corresponding protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although valuable information can be obtained from a test tube, this do not reflect physiologic conditions and the complexity involved in the formation of a clot in a blood vessel or when fatty build-up develop in the artery wall. Therefore animal models are necessary to better understand blood clots and to prevent and treat conditions associated with excessive clot formation. Indeed, the vessel wall has a complex architecture and interactions between endothelial cells that line our blood vessels and blood cells or tissues as well as the immune system cannot be reproduced artificially. In addition, substances need to be delivered in the blood to mimic the human scenario and to be able to treat these diseases.

Which non-animal alternatives did you consider for use in this project?

To answer our scientific questions and study blood clotting, we perform experiments in test tubes, on cells grown in the laboratory, with blood and tissues taken from healthy people or people with a disease, and use computer modelling and analysis. We will continue to use these approaches to avoid unnecessary use of animals.

In particular, our lab has developed over the years many different models to mimic clot formation using microfluidic technology (small plastic channels that ressemble blood vessels). They are invaluable to understand how clot formation take place and how cells interact with each other. These models are part of our informed decision to pursue or not

animal work. We are currently developing a model of venous valves in the laboratory to mimic the human scenario where clots tend to form in the valves of the large veins of the legs. Human endothelial cells (which line our blood vessels) are grown with constant circulation of fluids in silicone microchannels with an artificial valve in the middle of the channel. These channels are made by 3D printing in collaboration with the engineering department. After few days, human whole blood is passed in the microchannels and cell interactions can be studied.

Wherever we can, we will use these alternatives to replace experiments on animals in order to study clot formation.

Why were they not suitable?

Although very useful these models made in the laboratory still do not faithfully reproduce a blood vessel and how a novel drug would be efficacious in a whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated thinking carefully about the number of experiments we will need to do, using our experience of past/present projects, relevant publications in the field for similar procedures, and by performing statistical power calculations using available online tools.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We carefully plan all our experiments to maximise the amount of scientific information possible while using the minimal number of mice. Tools such as the NC3R's Experimental Design Assistant tool as well as published guidelines (ARRIVES) will assist in the experimental design of an experiment, and advice from biostatisticians and other experts in our institute Statistical Services Unit will be taken.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always be mindful to minimise the number of animals that are used in our project. Techniques will always be optimised in view to reduce the number of animals, including the use of non-invasive novel imaging technologies. This will allow to visualise how the disease (e.g. fatty build-up in the artery wall, thrombosis) develop over time without needing to sacrifice the mice and without surgery. Careful experimental plan will ensure that several tests can be performed using blood samples/tissues from the same mice.

Finally, whenever possible sharing data and resources (e.g. animals, tissues, equipment) with researchers and organisations will be applied.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging Refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the ‘gold-standard’ model for studies on normal (haemostasis) and pathological (thrombosis) blood clotting. A high number of genetically-modified mice are available and an extensive amount of work has been performed and published. Mice also are a good model of human disease and physiology.

No adverse effects are expected with most of the models as they are performed under terminal anaesthesia. For all surgical procedures, the animal is under general anaesthesia which is sufficiently deep and stable to ensure the animal is insentient throughout. Suffering is minimised by careful aseptic technique and administration of substances by skilled scientists. For one thrombosis model (DVT model), although these animals are subjected to recovery surgery, they are expected to survive the procedure. To study the build-up of fat in the vessel wall, animals are given a high fat diet.These are very mild models so don't cause any distress or lasting harm and animals will be killed before they experience any adverse effects of the disease.

A good communication between scientists, vets and animal care technicians will be established to provide highest levels of care. Any animals showing sign of distress or pain that cannot be relieved with analgesics will be killed humanely and immediately to keep the animal suffering to a minimum. In all cases, we will use a protocol that causes the least suffering to the animals to achieve our scientific objectives.

Why can’t you use animals that are less sentient?

We will mostly use mice because they are mammals and the least sentient species in which it is possible to manipulate how genes work, to model the diseases we want to study and measure the function of the heart and blood vessels in ways we need to. We can't use less sentient species such as invertebrates (e.g. nematodes/insects) as they have different respiratory, immune and cardiovascular systems than human. We also need to work with adult animals as we need a fully developed cardiovascular system and we need to work with animals that are fully grown from a practical perspective. For 3 out of 5 of the protocols not involved in the generation and maintenance of GA animals described in this project license, animals are terminally anaesthetised. For the other protocols, animals that will require surgery will be given pre- and post analgesics and will be under general

anaesthesia which is sufficiently deep and stable to ensure the animal is insentient throughout.

Recovery surgery and adult animals will be necessary in some cases for the disease process to develop. Increased monitoring by personal licence holders assisted by animal care technicians will be carried out to ensure the best post-operative care for each animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For each model proposed in this project that involves recovery anaesthesia advice will be seek from the vets to use up to date best anaesthesia and analgesic agents. Animals will receive pain relief to treat any apparent discomfort and before any recovery surgery. Surgeons will be trained and assessed appropriately. Increased monitoring of animals post-surgeries as well as rigorous and comprehensive humane endpoints will be applied. Immediate action will be taken to relive suffering if their welfare does not improve after adequate treatment given. Additional refinement measures to enrich the cage environment of animals fed a high fat diet will involve providing additional tunnels and chew sticks to prevent the animals from developing overgrown teeth.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published guidelines issued by LASA & NC3Rs to ensure the experiments proposed in this project license are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

For all procedures, we will continually monitor the literature for methods of refinement and consider whether the use of animals is necessary to address the experimental question under investigation. When necessary in order to best implement the advances in the 3Rs, advice will be seek to the vets and animal care technicians.

57. Combating tapeworm infection by investigating genes and genomes

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Tapeworms, Neglected tropical disease, Genomics, Helminths, Parasitism

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify and validate the genes and genetic systems that control development in tapeworms

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tapeworm infection is responsible for a significant part of the global worm burden, negatively affecting ourselves and our livestock. For example, taeniasis, related to global pork production, is responsible for 1/3 of epilepsy cases in Central America and represents one of the most important neglected tropical diseases caused by these pathogens. Our ability to combat these and other parasitic worms has been significantly advanced in through the characterisation of their genomes. These efforts have relied entirely on laboratory model systems maintained by a small number of labs located in different countries, for which the system described here has been one of the principal systems. At

present, it represents the most fully-characterised genome of any helminth, making it an important laboratory isolate for the wider scientific community. These data can now be employed for empirical work in the laboratory aimed at understanding gene function (e.g. by enabling gene and protein characterisation and expression analyses) which is essential for evaluating potential targets for therapeutic intervention.

What outputs do you think you will see at the end of this project?

In the short term the cultures will provide the biological material required for genetic manipulations in the laboratory, that over the mid-term will principally include gene expression and bioinformatic studies aimed understanding the function and interrelationships of their gene products. Results will be published in leading peer-reviewed journals and presented at national and international conferences. Products will also include the development of new genomic resources, such as genome-wide expression data, that will be released to the public upon production as raw data, as well as in curated form through a dedicated webpages These data will have immediate use by the scientific society and will increase the value of this model system in biology. Over the longer term these data will be synthesised into a model describing key developmental pathways controlling growth in tapeworms that, together with the genomic data and empirical results that support it, will be informative for developing novel chemotherapeutics.

Who or what will benefit from these outputs, and how?

The characterisation and understanding of the genes that control development in tapeworms will advance efforts to control and eradicate the agents of significant neglected tropical diseases, potentially benefiting millions of people in endemic parts of the globe. Genomic resources and information derived from the culturing of these organisms have immediate benefit to basic and applied researchers in both academia and industry by providing access to the complete suite of the pathogen's genes and gene products. Functional studies of the genes underlying their development will advance efforts to identify new targets for therapeutic intervention.

How will you look to maximise the outputs of this work?

One of the principle means of maximising the outputs of our research will be to make all genomic data publicly available, both as raw data and in curated form, as described above. Such data can be put to use freely and immediately by other researchers and will be especially valuable for those requiring a representative species with a fully characterised genome. We will also maximise our outputs through collaboration with leading investigators at UK academic and genomics institutions, allowing us to address fundamental questions in stem cell and chromosome biology in addition to questions specific to the pathogen. Through collaborative research, these cultures will help to ameliorate the need for multiple labs to maintain cultures of the same model organisms. Because the system typically underpins 2-3 graduate student research projects/year, in addition to research conducted by post- doctoral researchers and visiting scientists, the cultures also underpin post-graduate training in molecular and bioinformatic techniques and serve as the principal source of biological material for all of our empirical and

bioinformatic investigations. We will also use the system, as we have previously, to educate and inform the public about neglected tropical diseases and about the biology of these organisms.

Species and numbers of animals expected to be used

- Mice: 500
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Tapeworms are flatworm (i.e. Platyhelminthes) parasites that have complex life cycles involving a minimum of two hosts: an invertebrate host in which they undergo larval metamorphosis, and a vertebrate host in which the larvae develop into strobilated (i.e. segmented), sexually mature forms. Because of these host requirements for the completion of their life cycle, tapeworm parasites of rodents make the most practical model systems in the laboratory, allowing for access to all life stages as well as the generation of new individuals.

Since their initial adoption as laboratory models in the 1960s, species of the genus Hymenolepis have been the most widely employed rodent tapeworms for both teaching and research, with the species H. diminuta and H. microstoma being principal among these. Both species utilise grain beetles (e.g.

Tribolium and Tenebrio spp.) as intermediate hosts; however, Hymenolepis diminuta is a natural parasite of rats, whereas H. microstoma is a natural parasite of mice. The species also differ in other aspects of their biology as well as in their amenability to in vitro culture and other laboratory assays, and hence we will maintain cultures of both species.

Larval stages of both species will be reared in beetles using cultures maintained by the applicant. These will provide access to larval stages for both research and for the infection of rodents in order to produce adult worms (that in turn provide eggs used to infect beetles and thus perpetuate the cycle).

Mice and rats are the natural - and required - hosts of these tapeworm species and tolerate infections exceedingly well, producing no pathological consequences. The species being cultured are a common and normal part of the parasite fauna in wild rodents and beetles around the globe. In addition, no stage in the life cycle of these species poses a threat to human infection, while the requirement for development in an intermediate host precludes contamination of other rodents within the animal facility (i.e. direct transmission from rodent to rodent is not possible as the eggs shed in the rodent faeces are only infective to grain beetles).

Typically, what will be done to an animal used in your project?

Tapeworm larvae will be introduced to the rodent's intestinal tract via oral gavage. They will then be housed and maintained under normal laboratory conditions for up to 6 months, depending on the age and numbers of specimens needed, after which they will be humanely killed using a schedule 1 method and the parasites recovered from the intestine for use in genetic research.

What are the expected impacts and/or adverse effects for the animals during your project?

The rodents are expected to experience mild and temporary discomfort during oral gavage, whereas the establishment of the tapeworm infections is not expected to produce any significant adverse effects (they are a normal part of parasite fauna found in rodents).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild; all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Investigating tapeworm genes and development requires specimens that provide the genomic DNA, mRNA and whole specimens with which to undertake genetic manipulations in the laboratory. The parasites cannot be cultured in the laboratory without the use of their natural animal hosts.

Which non-animal alternatives did you consider for use in this project?

No non-animal alternative is available. In vitro culture can support limited growth of adult worms for a short duration, but does not support sexual development required for the completion of their life cycle, and therefore cannot be employed to perpetuate the life cycle.

Why were they not suitable?

Because in vitro culture does not support the generation of new worms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on average annual need for specimens over the past 10 years, primarily for investigations involving the visualisation of gene expression in whole specimens (i.e. in situ hybridisation) which allows for genes to be associated with different tissues, organs or regions of the body. Individual mice typically host ~10 worms, which is roughly the number of specimens required for each gene assay, while additional specimens are required to provide genomic DNA and messenger RNA (i.e. expressed genes) samples. On average, 100 mice/year generates ~1,000 adult tapeworm specimens, enough to support ongoing studies and two graduate student projects; allowing us to examine the spatial expression of roughly 100 genes of interest per year, as well as providing samples used for genomic investigation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We maintain no more than 10 animals at all times for the purposes of ensuring perpetuation of the parasite's life cycles in the laboratory. Additional rodents will be used to generate specimens only when required, for example during student projects. In this way, we only use animals when they are needed and in numbers relating to the specific number of genes of interest being investigated.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

During periods of inactivity in the laboratory (such as our current lockdown situation due to covid 19) we will maintain no more than 10 animals for the purposes of perpetuating the life cycle.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice and rats as they are the natural and required hosts of the parasites. Oral gavage will be used to introduce tapeworm larvae to the rodent's gut as it is considered to

be most effective and least distressing method to introduce the infection. No additional or other procedures is performed.

Why can't you use animals that are less sentient?

All species of tapeworm require both an invertebrate (intermediate) and vertebrate (final) host to complete their life cycle. The tapeworm species Hymenolepis microstoma and H. diminuta are enteric parasites of mice and rats, respectively, and as adults cannot survive in other animals. Beetles host larval stages of the parasites, but do not support adult development. Our main model will be H. microstoma which is hosted by mice which are considered less sentient than rats (and this is reflected in the lower number of rats cf. mice). However, there are differences in the biology of these two species, including their amenability to in vitro culture in the laboratory. Unlike H. microstoma, limited growth in vitro of H. diminuta has been achieved by other labs and thus we will employ this laboratory model specifically for the development of laboratory assays that require in vitro culture.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will closely monitor the health of the animals and immediately terminate the procedure for any individual in apparent distress or poor health.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will perform oral gavage following the Laboratory Animal Science Association guidelines, employing the use of flexible catheter and a total volume not exceeding 100 microliters.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Primarily through information provided by the Named Animal Care and Welfare Officer (NACWO) and Named Veterinary Surgeon (NVS). The Animals Scientific Procedures Act (ASPA) and the National Centre for the Replacement Refinement & Reduction of Animals in Research (NC3Rs) websites will also be consulted regularly.

58. Efficacy and safety of feed additives / ingredients for farm animal species

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

feed additive, efficacy, safety, farm animals

Animal types	Life stages
Chicken, turkey	adult, juvenile, neonate
Cattle	adult, pregnant, juvenile, aged
Sheep	juvenile, adult, pregnant, aged
Pigs	juvenile, adult, pregnant, aged
Goats	juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to generate data from in vivo efficacy and safety studies in the target animal species to be used:

- to develop and market feed additives, products and substances for use in nutritional supplementation, zootechnical performance and aiding gut health.
- in dossiers submitted for the registration of feed additives, products and substances for use in nutritional supplementation, zootechnical performance and aiding gut health.
- to determine the nutritive value and appropriate diet inclusion rates of novel feedstuffs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to protect human health, animal health and the environment, feed additives have to undergo an efficacy and safety assessment. According to the European Parliament and Council Regulation (EC) No 1831/2003, only additives that have been through an authorisation procedure may be placed on the market. EFSA is responsible for conducting the evaluation of the data submitted requesting authorisations. Authorisations are granted for specific animal species, specific age of animal, specific conditions of use and for ten year periods. The EFSA publications "Guidance on the assessment of the safety of feed additives for the target species" (2017) and "Guidance on the assessment of the efficacy of feed additives" (2018), provide guidance on how to conduct and report studies concerning in vivo efficacy and safety (tolerance) studies. Additives are classed into the following categories:

Technological additives (e.g. preservatives, antioxidants, acidity regulators)

Sensory additives (e.g. flavours, colorants)

Nutritional additives (e.g. vitamins, minerals, amino acids, trace elements)

Zootechnical additives (e.g. digestibility enhancers, gut flora stabilisers)

Coccidiostats and histomonostats

In an application for authorisation, the submitted dossier must include copies of the study reports that demonstrate that the feed additive does not have an adverse effect on animal health or the environment and shall favourably affect animal performance or welfare, satisfy the nutritional needs of the target animal and favourably affect the environmental consequences. Studies undertaken on this project will be reported to the sponsor who may submit them to EFSA for evaluation of additive registration.

Enzymes and probiotics, classed as zootechnical additives have been previously studied at this establishment. In the future, work on additives from other classes may be required.

The process leading to a marketing authorisation for a new product is in five stages. The stages are listed below indicating the stages where work at this establishment will occur.

Initial Assessment, including product discovery, validation and assay development and initial screening.

Optimisation and Development, includingrRefinement and tolerance testing - safety studies and ‘look see’ development studies in target species.

Target Species Trials, including efficacy studies in the target species.

Marketing Authorisation, including efficacy studies to confirm application rate.

Marketing Studies, including commercial support studies.

In addition commercial feed companies are looking at novel feedingstuffs to determine their nutritive value, optimum inclusion rate and impact on animal performance, welfare

and the environment. There has been a recent interest in developing by-products of the newly established bio fuel industry, which would otherwise have no other market and would go to waste e.g. distillers dark grains and solubles (DDGS) and yeasts. These products are classed as animal feedingstuffs (Feedingstuff Regulations, 2010) so authorisation for their use through EFSA does not need to be sought.

On occasion there may be a requirement to establish the safety / tolerance levels of feeding novel feedingstuffs and feed additives. For feed additives, EFSA state the tolerance group of animals would normally be offered a feed additive at 10 times the normal maximum dose for the product. At this dose, haematology and blood chemistry need to be assessed from the animals in the tolerance group. EFSA also state that if a 100 times the normal maximum dose is offered to animals and can be shown to be tolerated without adverse effects, then haematology and blood chemistry is not required.

The majority of the work covered by this licence is commercially driven, although some may be government or grant funded. Developing new feed additives to improve animal performance, health and welfare or have a positive environmental impact is a long complex process. Following the identification of candidate products, in vivo toxicity studies are carried out, followed by similar studies using rat models for example, prior to the product being tested in the target animal species.

Numerous successful studies were conducted under the previous licence, this is a continuation of that licence. Most of the studies were regulatory and conducted according to EFSA guidance. These investigated the efficacy and tolerance of feed additives in target animal species. A range of feed additives were investigated, but enzymes were the most common. Studies were mainly conducted using pigs, chickens and turkeys at various stages of development, but studies were also conducted using cattle. Study results will have been used in regulatory dossier submissions, so that the feed additives could be marketed.

What outputs do you think you will see at the end of this project?

The outputs will be the production of reports of studies completed for sponsors which will be acceptable for regulators. Reports will describe the conduct of studies, according to regulatory and guidance documents, and will come to conclusions on the efficacy / safety of feed additives.

In an application for authorisation, the submitted dossier must include copies of the study reports that demonstrate that the feed additive does not have an adverse effect on animal health or the environment and shall favourably affect animal performance or welfare, satisfy the nutritional needs of the target animal and favourably affect the environmental consequences. Studies undertaken on this project will be reported to the sponsor who may submit them to EFSA for evaluation of additive registration.

The introduction of new products to the market is within the control of the sponsors and there is little communication from the commercial sponsor on their plans for products once studies have been reported.

Who or what will benefit from these outputs, and how?

The primary benefit of this project is the provision of safety and efficacy data to facilitate sound regulatory decisions on the use of feed additives in animal feed.

The benefits of work delivered under this licence are to develop feed additives and ingredients that have the potential to improve animal performance, health and welfare and have a positive impact on the environment.

In order to get approval for feed additives it is necessary to generate data of appropriate quality and accuracy in target animal species in response to inclusion of feed additives. These data will be used in the development of a number of safe and effective feed additive products e.g. enzymes, yeasts and probiotics. There is a mandatory requirement to conduct studies to demonstrate the safety and efficacy of feed additive products before they are marketed in the EU. Therefore the accurate testing of such products to ensure they work and are safe to use, protects animal health, human health and the environment.

The project may also generate accurate data on the nutritive value and optimum feeding levels of novel feeding stuffs. New by-products from the biofuel industry will be available to the feed industry in the UK. Research to determine their nutritional value and develop safe feeding levels to maintain animal performance and health will be required.

As animals are increasingly bred for maximum performance, their requirements for the main nutrients (energy and protein quality) as well as vitamins, minerals, trace elements, amino acids will increase to maintain their health and welfare. Much work was undertaken by the Agricultural Research Council in the 1980s to determine animal requirements by production level in each species e.g. cow milk yield or pig daily liveweight gain. Now that production levels have increased, further research is required to understand animal nutrient requirements. This establishment has the facilities, resources and ability to undertake digestibility, balance and performance studies to help the industry better understand the requirements of high genetic merit animal farmed in the UK today.

How will you look to maximise the outputs of this work?

The outputs of the studies are the production of reports which meet the requirements of regulators. Reports are generally commercial confidential to the sponsor and are rarely published / disseminated, other than with the regulator. This establishment can maximise the output by trying to ensure that studies are conducted / reported so that they are acceptable to regulators. This involves ensuring that regulatory guidelines are followed in the conduct and reporting of studies.

Species and numbers of animals expected to be used

- Domestic fowl: 10,000
- Cattle: 100
- Sheep: 100
- Pigs: 1500
- Goats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of Life stages.

Initial assessments of new feed additives are undertaken in vitro to determine their effect on the target nutrient (e.g. phytase enzymes on cereal phytate). Currently, it is not possible to model the response of the whole animal to a feed additive which therefore necessitates the use of animals in studies. Initially, safety of the additive is typically assessed on the basis of toxicological studies performed in vivo, usually on laboratory animals. EFSA states that efficacy and tolerance studies must be undertaken in the individual target animal species to enable authorisation for the use of feed additive products in a specific species.

Food producing species have different digestive systems e.g. ruminant and mono-gastric, and the nutritive value of an ingredient is different between species. Novel feedstuffs are required to be tested in each target species.

The same applies to assessment of novel ingredients, there are no in vitro tests or prediction models to measure the response of an animal to the ingredient or determine optimum feeding levels.

Typically, what will be done to an animal used in your project?

The administration of the test substance. This will usually be incorporated into the feed or water which will be offered either ad libitum or in restricted amounts. Alternatively, it may be administered by capsule or bolus. The duration of administration may range overone or more production stages over the animal's lifetime. EFSA have published guidance on the minimum duration of tolerance and efficacy studies, for example the minimum duration for an efficacy study in weaner / grower pigs is 42 days, for finishing pigs is 70 days and for sows for reproduction is two cycles (from insemination to the end of the second weaning period).

Variation in the composition, constituents, quality and/or availability of the diet and/or drinking water. This may be required in order to assess the ability of a test substance to compensate for a deficiency

i.e. dietary enzymes are claimed to make previously bound elements available to animals.

Exposure to altered environmental conditions (e.g. increased temperature or spiking the bedding with dirty bedding) to cause a stress to the animals and then monitor the effect of the test substance with this management. This is about trying to test efficacy in an environment more akin to a typical farm and not the sanitised environment typical of this establishment. This is an attempt to replicate typical farm conditions so that the efficacy of the feed additive can be tested in a typical farm situation.

Negative control diets may be required as comparators for diets with the test substance added. These diets may cause low feed intake and/or performance.

The use of electronic capsules to capture or transmit data while in transit through the gut could provide valuable additional information on the digestion process and how specific ingredients and additives affect it. This would be a useful non-invasive method of providing additional data with potentially few adverse effects on the animal. An example of such a capsule is the Heidelberg pH capsule which has been in use in human medicine for over 45 years. It is a high frequency micro-electronic transmitter designed specifically for inter-abdominal pH monitoring. The capsules micro-electronics are encapsulated in medical grade acrylic which is hypoallergenic.

Some feed additives (for example probiotics, prebiotics and acids) have been claimed to benefit gut health or to bind with bacteria in vitro, which might benefit both animal health and food safety. The efficacy of such products in helping to reduce the incidence of harmful bacteria might be tested by dosing birds with field isolates of, for example, Salmonella, E coli, Clostridia, etc, and analysing faecal samples collected directly from the animals, from the floor or post mortem.

The data and products collected to determine the effect of dietary treatments, covered on this licence are:

In vivo

Daily observations of animal health and welfare by the technician and scientific team, of all species.

Observation of animal health and welfare by a veterinary surgeon, as described in the study protocol, for safety studies of all species.

Feed intakes will be determined by the difference between feed offered and feed refused. On occasion individual intakes are required to achieve accurate data, which will require animals to be housed individually.

For scientific / research purposes, weight gain will be determined by weighing animals at the start and end of a feeding period. Data will be used to calculate feed conversion ratio.

Blood samples, one off or serial samples from superficial blood vessels, analysed for metabolic profiles and nutrient analysis.

Faeces and urine samples for the analysis of the main nutrients (e.g. dry matter, energy, protein calcium and phosphorus) to calculate nutrient digestibility and retention of dietary treatments. For total collection over three to five days, pigs are housed in metabolic balance pens for up to five weeks and poultry are housed on slatted floors.

Faeces samples collected by swab, faecal loop or finger may be required in order to determine the effect of dietary constituents on the excretion of nutrients, metabolites or other components (i.e. microflora).

What are the expected impacts and/or adverse effects for the animals during your project?

Procedures undertaken enable the collection of biological material e.g. blood, faeces and urine, to determine the effect of the diet on metabolism or digestibility. Procedures are unlikely to cause adverse effects in excess of mild severity. The protocol allows for moderate severity of up to 15% weight loss in animals (except poultry) to enable assessment of tolerance feeding levels. Control measures and determination of endpoints are clearly defined.

In most cases the adverse effects are likely to be minimal or mild. Where adverse effects are anticipated, animals will be monitored regularly to ensure that the moderate severity limits are not exceeded. Where adverse effects are observed we will intervene to ensure that severity limits are not exceeded.

Where at all possible, animals will be returned to farm or sent for commercial slaughter following veterinary assessment that they are fully recovered from the procedure and pose no risk to human health, animal health or the environment. Where this cannot occur (an unregistered product for example), animals will be klled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Under the current Project Licence (PPL PP7973038) the following severities have been assessed to date:
- Animals in each severity by species (%)

	Sub-threshold	Mild	Moderate	Severe
Pig	0	100	0	0
Poultry	13.2	86.8	0	0
All species	13.2	86.8	0	0

- This covers a total of 2480 animals since the project commenced in March 2021 to the end of December 2021. These severities were assessed according to the combination of the regulated procedures conducted and adverse effects observed. It is anticipated that there will be a similar outcome each year of the project.

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Initial assessments of new feed additives are undertaken in vitro to determine their effect on the target nutrient (e.g. phytase enzymes on cereal phytate). Currently, it is not possible to model the response of the whole animal to a feed additive which therefore necessitates the use of animals in studies. Initially, safety of the additive is typically assessed on the basis of toxicological studies performed in vivo, usually on laboratory animals. EFSA states that efficacy and tolerance studies must be undertaken in the individual target animal species to enable authorisation for the use of feed additive products in a specific species.

Food producing species have different digestive systems e.g. ruminant and mono-gastric, and the nutritive value of an ingredient is different between species. Novel feedstuffs are required to be tested in each target species.

The same applies to assessment of novel ingredients, there are no in vitro tests or prediction models to measure the response of an animal to the ingredient or determine optimum feeding levels.

Which non-animal alternatives did you consider for use in this project?

None, as the regulatory authorities require target animal species to be used in studies designed to determine safety and efficacy.

Why were they not suitable?

The regulatory authorities require target animal species to be used in studies designed to determine safety and efficacy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on experience with the last Project Licence, which expired in March 2021. This licence is a continuation of the work conducted under that licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The sponsor requests a number of treatment groups containing feed additive(s) at different inclusion rates. The best number of treatment replicates and animals per replicate are determined depending on the type of feed additive and the species and age of the target animal. This aims to ensure that where there are differences in performance e.g. daily liveweight gain, feed conversion ratio, etc. between treatment diets that there are sufficient animals to show a statistical difference at $P<0.05$. Conversely, too many animals must not be used, if having less on study would have shown the same result.

Information has been gathered on statistical design of feed additive studies which shows the different responses depending on animal species, age, product and main performance parameter measured. As much information as possible on expected performance response to treatment is obtained from the sponsor and the number of replicates per treatment is discussed and agreed with a statistician. EFSA guidance gives details on the statistical power, suggesting greater or equal to 80% for pigs and poultry and 75% for ruminants. The statistician uses power of detection, predicted differences to be detected, past information on animal response to a product type, to determine level of replication. All study designs are discussed by the AWERB to ensure the right number of animals is used.

Individual penning, using one animal per replicate is used when appropriate, with all species except growing poultry. When the variability between individuals in the parameter measured is low this gives more robust data and reduces the number of animals used. For example this study design is used for grower pigs at Drayton. Weaner pigs are more variable and vulnerable, so three pigs per replicate are used to get the most robust data and ensure replicate numbers are maintained. Individual poultry have variable performance and are therefore group penned at commercial stocking densities. Group housing is representative of farm practice, which is important as the feed additive / ingredient being tested will be used in commercial production. On study completion, the statistician determines the best type of statistical analysis for each dataset, this is normally analysis of variance with determination of least significant differences.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Screening of animals while on source farms can sometimes help to select the most suitable animals for enrolment onto studies. This can help to reduce the numbers of animals unnecessarily used. This might involve taking samples (blood or faeces for example) or physical examination of candidate animals.

Pilot studies with a small number of animals can help verify / confirm procedures selected before conducting a larger studies involving many more animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The methods employed on studies are usually dictated / implied by the guidelines. This project licence has a wide scope so that it encompasses a wide range of models and methods.

Animals are inspected regularly by animal care staff, and twice each day as a minimum. As a minimum, the Named Animal Care and Welfare Officer inspects all livestock weekly and the Named Veterinary Surgeon inspects all animals monthly. There are methods in place to evaluate adverse reactions, e.g. scoring systems, and these help to ensure that interventions are carried out in order to prevent severity limits being exceeded.

Methods of killing other than those in Schedule 1 are proposed as they are, in our experience, more humane. The methods and limits proposed are confluent with council regulation 1099/2009 on the protection of animals at the time of killing.

Where possible animals will be penned in groups of similar animals. Where individual penning is required, animals will be within sight and sound of compatriots.

Animal husbandry is to a very high standard, by experienced staff following up to date guidelines and regulations. Prompt veterinary attention is provided to ill animals, which are observed closely until resolved.

Why can’t you use animals that are less sentient?

It is a requirement in the guidelines that the test animals used should be representative of the age, sex and class for which the claim is made. Use of species other than the target animal species may be made in exceptional cases, e.g. in the case of minor species, but their use would need to be justified.

How will you refine the procedures you’re using to minimise the welfare costs (harms) for the animals?

When adverse reactions are anticipated and/or observed, the frequency of observation is increased and continuous monitoring will be conducted to help ensure that severity limits are not breached. If unexpected adverse reactions are observed, or the frequency is higher than expected, procedures are in place to ensure that staff with responsibilities under A(SP)A are informed.

Environmental enrichments will be provided where possible and these are tailored to the requirements of the species. Dust baths, perches, nest boxes, toys and auditory stimuli (radio) will be provided for poultry. Toys will be provided for pigs and nesting material or farrowing pigs. Feed for adult pigs may be offered on the bedding, to stimulate natural foraging / rooting behaviour or intact bales of straw may be added to the pens.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Regulation (EC) No 1831/2003 of the European Parliament and of the Council on Additives for Use in Animal Nutrition. www.irmm.jrc.ec.europa.eu

Guidance on the assessment of the safety of feed additives for the target species. EFSA Journal 2017; 15(10): 5021. www.efsa.europa.eu

Guidance on the assessment of the efficacy of feed additives. EFSA Journal 2018:16(5): 5274. www.efsa.europa.eu

The Animal Feed (England) Regulations 2010. No 2503. www.legislation.gov.uk

Defra. Codes of Recommendations for the Welfare: Laying Hens, Meat Chickens and Breeding Chickens, Pigs, Cattle, Sheep, Goats and Turkeys. www.defra.gov.uk/food-farm/animals/welfare

Agricultural Research Council (1980) The Nutrient Requirements of Ruminant Livestock. Agricultural Research Council (1981) The Nutrient Requirements of Pigs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The methods employed on studies are usually dictated / implied by the guidelines. We will monitor for updates to guidance documents and husbandry methods, and will implement any changes with immediate effect.

59. Characterisation of a mouse model of Barth Syndrome

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

heart, tafazzin, genetics, lipid, metabolism

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this study is to characterise and analyse a mouse model of Barth Syndrome, an inherited genetic metabolic disorder caused by a mutation in the gene Tafazzin (Taz).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Barth Syndrome is an inherited genetic condition, which is sometimes fatal. The symptoms of this condition include heart problems, muscle weakness, feeding problems and susceptibility to infection. Analysis of a mouse model of this disease will allow us to understand how a single genetic alteration causes such a wide variety of symptoms. This will allow the development of treatments to reverse the effects of this disorder.

What outputs do you think you will see at the end of this project?

New Information: These studies offer the potential to better understand the processes that go wrong in metabolic disorders and how these cause the clinical problems identified in affected individuals.

Publications: Work arising from these studies will be published in scientific journals and presented at national and international meetings to disseminate knowledge (to scientists and clinicians). We will also publicise our results to the public at open evenings, social media, and on our website.

Products: This work may lead to the identification of drug targets which might be used as a therapeutic for metabolic disease such as Barth Syndrome. We have generated the first model of Barth Syndrome by mimicking the genetic changes observed in patients, and this model has been distributed to many laboratories throughout the world.

Who or what will benefit from these outputs, and how?

This work is aimed directly at benefitting individuals with Barth Syndrome, who will benefit firstly from a better understanding of how this disorder affects them. This should allow a better management of the clinical consequences of condition in affected individuals. The knowledge gained will also be of interest to the scientific community (short term) by expanding knowledge of mitochondrial diseases. By the end of this project this work may allow us to develop new therapeutic approaches (long term) benefiting patients who suffer from metabolic disorders such as Barth Syndrome.

How will you look to maximise the outputs of this work?

We will collaborate with a number of different labs,each with different areas of expertise, to be able to better understand the consequences of the genetic alteration. Our mouse model will be given freely to other researchers in the field to study and develop treatments for the condition. In addition, our work will be published in scientific journals and we will attend relevant scientific meetings to discuss and disseminate our findings with other researchers as well as the affected individuals and their families.

Species and numbers of animals expected to be used

- Mice: Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Using genetically altered (GA) mice allows us to assess the relevance of these genetic changes in the normal physiological and disease settings using the complete animal. This is particularly relevant when studying metabolic disorders. We are using GA mice to model how a particular gene alteration associated with a genetic disorder called Barth Syndrome manifests the clinical symptoms in these patients.

Typically, what will be done to an animal used in your project?

Genetically altered animals will be bred together to achieve specific cohorts of interest which will be aged and tissue harvested to determine the effects of these genetic changes in the whole animal. Some of the animals (<20%) may be put on a high fat diet to modify their metabolism and test how these specific genetic changes adapt to these metabolic conditions. A small number of animals (<10%) will undergo ultrasound imaging to help with this analysis. To better understand these changes we may administer labelling reagents prior to humanely culling animals, which aids our analysis of the tissue.

Animals will be maximally aged to 12 months of age.

What are the expected impacts and/or adverse effects for the animals during your project?

Normal animals placed on high fat diet may gain weight but are healthy otherwise. Males with a Taz gene mutation have a slightly reduced body weight but this does not cause welfare concerns and the mice are otherwise healthy.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals on this project will have a subthreshold severity meaning they will show no harm. A small proportion (<20%) will be placed on a high fat diet and/or undergo non-invasive imaging which maximally will be a moderate severity due to repeated anaesthesia.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studying metabolism in the lab has obvious limitations and the true effect on energy metabolism as a result of dietary changes can best be achieved in a living organism. Long-term consequence of altered metabolism (i.e. diabetes) is also best modelled in the living animal. Furthermore, tissues are made up of different cell types which can all contribute to cues influencing the reaction to metabolic stresses which is often difficult to model in non-animal alternatives.

Which non-animal alternatives did you consider for use in this project?

Our mouse experiments are an extension of robust laboratory investigations from work on cultured cells and only progress using mice when sufficient rationale is obtained based on cell culture, including embryonic stem cells and where possible colonies of cells

resembling mouse tissues.

Why were they not suitable?

Metabolic disorders are difficult to model in a dish and for the long term effects these are best carried out in the mouse. In particular mutation of Taz gene has different consequences in, for example, heart cells and liver cells. Of these heart cells are the most relevant to the human disorder, but adult heart cells do not survive well in culture. Aspects of the Taz phenotype also rely on communication between different cell types.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have considerable experience the design of such experiments and the statistical approaches required to analyse metabolic alterations. We often use inbred strains of mice which reduces experimental variability. Most of the animals will be used in a breeding programme to attain the relevant genetic alterations. Many experimental animals require to carry multiple genetically altered alleles simultaneously, so this involves breeding of multiple strains carrying these different alleles. Where possible excess animals from breeding are shared with projects ongoing in our facility. The estimates also take into account that for example, non-invasive imaging techniques will be carried out to facilitate as much data from a smaller number of animals as possible. Sperm/embryos will be frozen from lines not immediately required for scientific studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Numbers are calculated based on our own experience, using pilot studies in the first instance, to inform on how many mice we require with advice from our in-house statisticians. We try to scale up experiments and stop recruiting into cohorts when we achieve a statistically significant result.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use inbred strains of mice which are nearly identical to other in genotype resulting in less variability between animals and allow us to use fewer animals to achieve a statistically significant result. We routinely perform pilot experiments using only a few animals, before scaling up to the appropriate numbers for a full study. We maximise the breeding programme to generate the most effective breeders to create the genetics of interest.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative

care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using a mouse model with a knockout of the Taz gene. This is identical to the genetic alteration in affected individuals with Barth Syndrome. We will use widely applied techniques to study metabolism, primarily using changes to diet (e.g. high fat diet) which requires less handling of animals. When animals are on a high fat diet, regular monitoring of weight/welfare will allow us to complete studies at the earliest endpoint in which we observe a significant result to prevent unnecessary suffering by extending the study period. Some animals will be imaged to look directly at the metabolic consequences of the genetic alteration of the Taz gene. The imaging is non-invasive and performed using anaesthesia. We are using state-of-the-art imaging equipment which undergoes rigorous testing, quality control procedures, regular maintenance and calibration. Imaging agents are formulated to clinical standards.

Why can’t you use animals that are less sentient?

The mouse is a mammal and warm-blooded which shares many features of human metabolism not found in other cold-blooded species such as flies and worms. Drosophila and zebrafish with a Taz mutation have been studied and provide some information about the role of Taz function, but these do not display the physiological abnormalities observed in cardiac and skeletal muscle. Additionally these models cannot be adequately used and manipulated to study the long range effects of gene alteration in the whole organism and do not allow development and testing of potential therapies. With the ease of manipulating the genetics of the mouse, this makes the mouse the best model organism to understand the genetic changes observed in metabolic diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals are health checked daily in addition to the routine monitoring by the researcher. Where any animal shows abnormal behaviour this animal is placed on enhanced inspection.

Animals on a high fat diet are weighed at regular intervals to detect early clinical signs.

For imaging experiments animals need to be anaesthetised. Body temperature will be maintained during anaesthesia with the use of heated imaging beds. Normal mouse food may be supplemented with gel diet or other treats to encourage eating and drinking after anaesthesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The researchers and animal facility staff at the Institute regularly review the NC3Rs website. In addition, we adhere to both the PREPARE guidelines: Planning Research and

Experimental Procedures on Animals: Recommendations for Excellence as well as the 'Animal Research: Reporting In Vivo Experiments (ARRIVE) Guidelines'. These are complementary checklists for researchers designed to improve the planning and reporting of animal research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continually review our processes and take advice from the Named Veterinary Surgeons, Home Office Inspectors and the NC3Rs website. Our technical staff are very proactive in adopting 3Rs advancements such as non-aversion handling and single-use needles.

60. Genetic alteration and distribution of Xenopus frogs for scientific use

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Xenopus, resources, cell and developmental biology, transgenic lines, gene editing

Animal types	Life stages
Xenopus laevis	adult, embryo, juvenile, neonate
Xenopus tropicalis	adult, embryo, juvenile, neonate
Xenopus borealis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Xenopus frogs are used to discover new knowledge about how cells and organisms work, to understand how chemical released into the environment may affect animals and to study human diseases. The aim of this programme is to ensure that many users of the Xenopus models for biomedical and environmental research have straightforward and efficient access to all of the high quality resources that they need.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The African clawed frogs Xenopus laevis and Xenopus tropicalis have a long history of successful use in research; they are used for discovery science in cell and developmental biology, ecotoxicology and regulatory testing. The recent growth in the number of researchers using them is very likely to continue for two main reasons; first, their large cell size and the fact that we know which each cell in the embryo becomes, make Xenopus the organism of choice for analysing all of the molecules that regulate early development at the same time and in the same embryonic cell. Second, the ability to make specific changes to the accurately-sequenced genome very easily and efficiently, particularly in X. tropicalis, means that gene function can be studied successfully in embryos and tadpoles, often without having to breed them. This has opened a new area in Xenopus-based research for the rapid and cost-effective analysis of human genetic diseases. To support this research, resource centres have been established to make, curate and supply the many genetically altered lines the community needs.

What outputs do you think you will see at the end of this project?

At the end of the project we will have current and newly-made genetically altered lines of frogs fully characterised and easily available to researchers across the world. This will result in a more effective research community using Xenopus frogs. As part of the wider programme improvements to frog welfare will be sought continuously and this has been successful in the past, with measures taken and widely adopted to decrease the stress experienced by male frogs due to travel for example.

Who or what will benefit from these outputs, and how?

The outputs from this programme will benefit users of the Xenopus model by making their materials more consistent, providing access to the full range of Xenopus methods (including to users of other experimental models) and allowing groups that use Xenopus beyond stages where the head to tail axis is formed no longer to keep frogs. Together these benefit the frogs themselves by reducing the numbers used and ensuring that good practice is shared in terms of refinement.

The identification and characterisation of gene function will be of benefit to developmental and cell biologists studying basic biology. They will be able to integrate the data about the function of these genes into the genetic regulatory networks that drive development. This will lead to a better understanding of developmental and cellular processes. Now that Xenopus can be manipulated genetically, researchers and clinicians studying human genetic diseases will also benefit from the lines made to support their phenotype analysis or as part of testing whether a specific change to the genome causes a disease.

How will you look to maximise the outputs of this work?

We already work with more than 200 labs across the world, providing resources that underpin their collaborations and publications. We also present our work at all meetings that focus on this model organism and publish methods and original research papers. We also publish collaboratively, for example with labs that do not normally use Xenopus as their main experimental model and with labs that do not keep frogs themselves.

The reach and ease of access by the frog community to existing and new Xenopus lines is greatly enhanced by placing the animals on the community's NIH-funded bioinformatics resource, Xenbase. The lines are not only available as a searchable database but also

linked to the relevant genepage(s), making it almost certain that someone studying a particular gene will become aware of the availability of any relevant transgenic or mutant line.

We also work closely with the US Xenopus resource, exchanging newly-made lines annually to ensure that there is a duplicate of each and to minimise the transatlantic travel of animals, with concomitant increased ease of obtaining the lines for users locally.

Species and numbers of animals expected to be used

- Xenopus laevis: 6350
- Xenopus tropicalis: 11250
- Other amphibians: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Xenopus are used since the entire aim of this programme is to supply Xenopus and related resources to the research community. Adult animals are needed to produce oocytes, sperm, eggs and embryos/tadpoles. Oocytes are used for studies on ion channels and receptor function, sperm are used to propagate dominant, genetically altered lines, eggs are used for biochemical analysis of DNA repair and the control of cell division, embryos/tadpoles are used for studies of cell and developmental biology and to test whether chemicals that might escape to the environment are dangerous. X. laevis remain the most commonly-used species, since they have particularly robust embryos that can be manipulated both physically and by some genetic methods. X. tropicalis have slightly less robust embryos but are diploid and have very few gene duplications compared with other model vertebrates, this makes them particularly suited to genetic studies, including those on human diseases. X. borealis are very seldom used and we keep few of them, however they are used to understand cross-species interactions since they are similar to X. laevis and transplants between them work well.

Typically, what will be done to an animal used in your project?

For adult animals which are used to produce embryos for these experiments the females have an injection of hormone and the next day are gently massaged to stimulate them to lay eggs, since this procedure causes very little discomfort to the animal it can be repeated 15 times at 90 day intervals. The eggs are fertilised using sperm from male frogs that have been killed humanely. One type of genetic manipulation needed to alter genes in frogs requires oocytes, these are removed from the ovary of a frog under anaesthetic. High quality oocytes for these experiments are not found in all frogs, so frogs that produce high quality oocytes will be re-used up to 4 times.

The genetically-altered tadpoles produced from these embryos and oocytes often carry a reporter gene to allow specific cells, sub-cellular organelles or proteins to be seen; these are not expected to be harmful. However some will be loss of function animals that are defective in a specific developmental or cellular regulatory mechanism. In addition to the adverse effect of this, they may be anaesthetised (up to 4 times) to allow them to be

observed.

What are the expected impacts and/or adverse effects for the animals during your project?

For the adult animals that produce eggs for embryos, long experience shows that the adverse impact is very limited. Fewer than 1 in 500 animals shows any sign of egg retention or infection at the injection site. If they have not recovered after 48 hours of treatment these animals are killed humanely, limiting the period of suffering. Occasionally (0 - 5%, depending on unidentified factors) we see deaths due to coelomitis post-ovulation. We are taking steps to reduce these occurrences with some success. For oocyte removal from X. tropicalis the situation is much less clear since it is only being performed in two establishments in the US, direct contact with them reports that this is much the same as when the same operation was done routinely on X. laevis and that infection or failure to heal has not yet occurred in the limited number of animals used. Were either of these to occur then after 48 hours of treatment these animals would be killed humanely, limiting the period of suffering.

For the affected tadpoles there will be diverse adverse effects including: heart or circulation defects, failure of the brain to develop normally producing seizures or altered behaviour, gut defects limiting the ability to feed properly and there may even be alterations in overall body structure. These tadpoles are normally killed humanely after less than three weeks but earlier if there are any clear health problems, endpoints revealed by poor swimming, a lack of feeding or responses to stimulation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Xenopus for gamete production: Mild (30%) Xenopus for oocyte production: Moderate (1%) Genetically altered tadpoles: Mild (69%)

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project is to produce Xenopus and related resources. Intact animals are needed for the studies in user laboratories since they investigate developmental processes that involve interactions between multiple cell types in the context of an intact organism.

Which non-animal alternatives did you consider for use in this project?

None

Why were they not suitable?

Genetically altered or normal Xenopus adults, eggs, oocytes and embryos cannot be produced without the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is largely based on the use of animals on the preceding licence. For example we are making around 600 sets of X. laevis embryos to send directly to users each year, added to this are the animals used to curate and test the lines held in the centre and to make and assess new lines for users. Large numbers of GA embryos are inevitably made when testing whether mutations/transgenes are in the germ line and often these have to be grown (normally as sets of 50 - 100) beyond the feeding stage for phenotypes to be analysed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The reduction of animals is built into the programme: keeping genetically altered lines at resource centres reduces the number of animals held; using frozen sperm reduces the number of males required to produce a set number of embryos; making and curating lines with dedicated, experienced scientists reduces the number of animals required; sharing oocytes and embryos between multiple laboratories also reduces overall use of Xenopus.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have a dedicated co-ordinator who ensures that the shipping of resources is optimised to share animal products effectively. Secondly we share eggs and oocytes across the four Xenopus-using research groups based here. A large whiteboard is used to plan each week's experiments to minimise the number of adult animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why

these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Of the experimental models used in biomedical research, Xenopus frogs provide a good balance between similarity to humans and limited suffering. The accessibility and large numbers of Xenopus offspring lead to limited suffering since few adults are used to produce them and there is no need for surgery to access embryos as in models closer to humans such as mammals. Xenopus are tetrapods and share their genome organisation closely with humans, they have lungs, legs and are generally more closely related in every sense to humans than zebrafish, which is the other vertebrate model animal with similar advantages to frogs in terms of minimisation of suffering.

Why can’t you use animals that are less sentient?

The users of the centre already use oocytes, eggs, embryos or tadpoles for their work thus taking advantage of immature life stages where possible. These are produced by hormonal stimulation of adults. The next least sentient model organism is the zebrafish, which lacks a number of anatomical similarities with tetrapods and has a distinct genomic organisation, thus making it significantly less similar to humans than the frog model. Amphibia have an almost complete suite of mammalian pain receptors and many of the neural circuits needed to transmit and process pain (reviewed below). Even as adults however they lack a part of the brain, the cerebral or limbic cortex, that from brain imaging and lesion experiments in humans produces the negative emotional aspects of pain (reviewed below). This evidence supports the more limited ability of amphibia to respond to pain than mammals; this is even more true of the larval form in which the vast majority of this programme is based.

Analgesia in Amphibians: preclinical studies and clinical applications. C Stevens. Vet Clin North Am Exot Anim Pract. 2011; 14, 33-44.

Cognitive and emotional control of pain and its disruption in chronic pain. M Bushnell et al. Nat Rev Neurosci. 2013; 14, 502-11

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We refine the procedures by: close monitoring of animals after procedures, moving genetically altered animals as sperm/testes rather than as animals and eliminating surgery with recovery from procedures whenever possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The new "frog book" is about to be published by CSH press including chapters on care and best practice methodologies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are at the centre of the worldwide network for the use of Xenopus and meet monthly over video to receive and disseminate improvements in methodologies and welfare, as well as to ensure that unnecessary duplication of experiments is avoided.

Home Office

61. Defining the role of the senescent cells upon the cancer and pre-malignant microenvironment.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Liver, Cancer, Senescence, Immunity, Endothelium

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Senescent cells are the earliest stage of cancer. We seek to understand the interaction between senescent cells, the cells that line blood vessels and cells of the immune system within the liver.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Background
The development of cancer occurs when cells of the body accumulate damage to the genetic code that is present in every cell in our bodies. This generally occurs slowly, but can occur more quickly in parts of the body affected by long-term inflammation, such as

liver cirrhosis or inflammatory bowel disease. Having these illnesses leads to damage to the genetic code and activation of cancer-causing genes. At the earliest stages, prior to our current ability to detect cancer, the body has defence mechanisms to suppress these cancer-causing genes and prevent cancer progressing. One such mechanism is called cellular senescence, where cells of the body sense this damage and respond by irreversibly preventing that cell from dividing any further. Senescent cells also signal to other cells around themselves preventing them from reproducing as well. Senescent cells also attract circulating immune cells that kill the senescent cell and the cancer-causing genes that it contains. Therefore, understanding how senescent cells are detected and killed by the immune system is important and could be a way of treating patients to prevent them getting cancer in the first place.

Immune cells, which circulate in our blood protect us from infection and cancer. They enter different parts of our body by sticking to the walls of the blood vessels when they detect a problem, such as inflammation. Within the liver the blood vessels are lined by sinusoidal endothelial cells, which can attract immune cells into the liver to kill bacteria and viruses. We know that immune cells enter the liver when cancer develops, but we do not know how this happens when cells of the liver become senescent. Nor do we understand whether the endothelial cell is important in this process. If we could understand the processes that cause immune cells to enter the liver to kill senescent cells, then we might be able to prevent cancer developing in the first place, through boosting the body's natural defences. Boosting the immune system to fight cancer has already been shown to be effective in other cancers, such as melanoma.

If we can find out whether it is possible to improve the functioning of the immune system and improve the ability to clear the earliest forms of cancer within the liver, we might be able to design treatments that prevent patients in the future from developing cancer.

What outputs do you think you will see at the end of this project?

If successful, this project has a number of significant outputs:

Scientific advancement and publication

The aim of this project is to increase knowledge of the role of the endothelium (cells which line the blood vessels) and immune system (cells which attack infections and cancer) in combating the earliest forms of cancer. By the end of this project we hope to understand how pre-cancerous, senescent cells, signal to the endothelium and the immune system to prevent cancer from developing and how this system fails.

We will aim to promptly publish and disseminate the results in open access, peer-reviewed, high- impact scientific journals and regular presentations of data at high-profile meetings. Some data that is important for working with industry to develop new medicines may not be released straight-away, until intellectual property restrictions are sorted out.

Drug-development and potential collaborations with industry

Through this work, we may identify drug targets to boost the immune system in the clearance of pre- cancerous cells with the ultimate goal of developing new drugs to work in patients. Any potential drugs or drug targets that we discover would be tested in subsequent projects.

Public engagement

We will use well-established routes at our institution to engage with the wider public, explaining why we believe this research is important.

Who or what will benefit from these outputs, and how?

The following groups will likely be beneficiaries of this project:

Other scientific researchers

This project will be directly of benefit to scientific researchers working in the fields of senescence, liver biology and liver cancer. Scientists will be able to access our newly developed knowledge through:

Publication of results in open access, peer-reviewed, high-impact scientific journals and regular presentation of data at national and international meetings. This will promote new scientific work from other groups around the world.

Sharing of our study data through online open access databases. Generation of publicly available data will drive discovery by other groups, but also prevent the need for repetition of expensive scientific studies.

Future patients

Through development of knowledge about how senescent cells are cleared from the liver, we will be able to design novel immunotherapy treatments to prevent the development or progression of cancer.

Society and the economy

If we are successful and find new treatments, these will be developed in partnership with pharmaceutical companies. In addition, if we can develop new treatments for cancer, this will improve people's health-span: their length of healthy life. Of course, if people live into dependent old age this may increase societal costs later.

How will you look to maximise the outputs of this work?

We wholly support making our published findings available through Open Access. We intend to make data generated during this project open to the wider scientific community and the public, via multiple routes:

Communication

New ideas from this research will be shared with scientists through talks at local, national and international scientific conferences; and educational talks for students. We hope that some of our findings will be of general interest and we will work with the public engagement teams at our institution to make the information interesting and digestible for lay readers.

Dissemination

All the results arising from this project will be submitted to peer-reviewed journals and presented at national and international conferences.

Our published data will be deposited in publicly available databases, allowing access to our findings. Useful reagents derived from this study, will be distributed upon request or deposited in publicly accessible repositories, such as Addgene (https://www.addgene.org).

Engagement

We have previously been active in explaining our work to the general public, both at fundraising events such as public tours of our institution, at science fairs, such as our institution's regular Science Festival and talks at local schools.

Development and exploitation

It is possible that potential new treatments will be generated in this project. We will get advice and support from the Technology Transfer Team at our institution to help develop these further.

Species and numbers of animals expected to be used

- Mice: 14080

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our project intends to study how senescent liver cells communicate with the cells lining the blood vessels and white blood cells of the immune system. The use of mice allows us to study several types of cell at the same time, in the development of cancer.

Mice have very similar biology to humans, particularly in their immune system. They have short development and generation times that will allow us to perform our experiments in a timely and efficient manner. Due to the widespread use of mice in cancer research there are a wealth of scientific tools, like antibodies available and drug doses already worked-out for experimental use in mice. To alter genes or pathways in the liver requires targeted genetic manipulation. There are many well known techniques to genetically-modify different cell types at different times in mice. In some cases this can be achieved through injected DNA molecules or viruses, but in the case of modification of the vascular endothelium will require the use of genetically altered mice. We have used all of these approaches before.

Therefore, the use of mice represents the best animal model for our experiments.

Senescence. We will make senescent liver cells through genetic modifications or using viruses. This is an established technique that we have used in mice that are 6-9 weeks old. It has not been demonstrated to work in other animals or in mice at other life stages.

Chronic liver disease. We are interested in understanding human liver disease; mice can

get a similar form of liver disease. We will give the mice a modified high-fat diet or treat the mice with a drug (carbon tetrachloride), leading to the development of chronic liver disease in 6-9 months. Experiments studying liver disease in mice are in widespread use around the world. There are models of chronic liver disease that work faster or earlier in life, but they do not look like human liver disease

Transplantation. To look at the way different cell types communicate with each other, we can perform transplants of different types of cells together into mice that lack an immune system and then study their growth and interaction. The lack on an immune system is crucial to prevent rejection of the transplanted cells. This is a very straightforward process in mice, where animals lacking immune systems are commercially available.

Typically, what will be done to an animal used in your project?

To manipulate the biology of senescence and chronic liver disease requires targeted genetic manipulation. In some cases this can be achieved through injected DNA molecules or viruses, but in the case of modification of the endothelium will require the use of genetically altered animals. We will also use several other techniques:

Liver-specific genetic alterations: For these mice we will alter gene function within different cell types in the liver using combinations of inducing agents, viruses or drugs. These mice will be monitored by clinical signs or intermittent imaging / blood tests over the course of weeks or in a small minority of mice, months. We will not let the mice develop into old age.

Hydrodynamic tail vein injection: This involves the injection of genes in a large volume of saline into the mouse and results in delivery of the genes straight to the liver cells. We will use this technique to induce senescence within the liver cells before following these mice over the course of a month, or in a small minority of mice, months. We will not let the mice develop into old age.

Induction of chronic liver disease: We will induce chronic liver disease by giving these mice a high-fat diet and / or treating them with carbon tetrachloride (a chemical that damages the liver), whilst altering liver gene function using viruses or drugs. We will follow these mice for several months and monitor them by clinical signs, imaging or blood tests. We will not let the mice develop into old age.

Transplantation: These mice will be injected with complex mixtures of cells, either into the skin, spleen or liver. This allows us to study these cells for prolonged periods of time and see how they interact. These mice will be monitored by clinical signs, periodic imaging or blood tests. In mice with skin tumours, we can measure the tumour size directly with calipers. For mice with liver or spleen tumours, we will monitor the tumour using imaging, such as ultrasound. We will not let the mice develop into old age.

What are the expected impacts and/or adverse effects for the animals during your project?

We are proposing a diverse plan of work that includes several procedures that the mice may find stressful. These can be divided into short-term and long-term impacts:

Short-term impacts

Anaesthesia for procedures: Animals may find single or repeated general anaesthesia stressful. We will ensure that the mice are handled sensitively and keep repeated sessions to a minimum. Anaesthesia will last for less than 2 hours; it may be repeated, but not more than twice in a 24 hour period.

Blood taking / injections: This requires handling and injection which may be painful. This will last only a few minutes.

Treatment with drug or inducing agents: This requires handling which may be stressful. Some substances can be given in modified feed. Some substances need to be given by oral gavage which might be stressful. Some substances need to be given by injection which may be painful. Some agents need repeated dosing. We will ensure that we use the fewest number of doses to achieve our intended effect.

Some inducing agents, like tamoxifen, can be painful when given by injection into the abdomen. We will ensure we use the fewest number of doses required. Tamoxifen can cause weight loss in some mice. We will closely monitor this in the mice receiving this treatment.

Hydrodynamic tail-vein injection: Animals have to be placed in a restrainer, before intravenous injection of a large volume of saline. We inject mice whilst they are awake when they may suffer from pain or distress, as lots of scientific data around the world has been gained in this way before. It might be better to perform this in mice under anaesthetic, but we do not know whether this will give the same results or lead to more mice dying. We intend to compare the two methods during this project. After the injection the mice remain lethargic for around 30 minutes, but then recover without problems in most cases. Mice will only undergo this procedure once.

Transplantation:

Under the skin: We will transplant mixtures of cells under the skin of some mice, to understand the effect of pre-cancerous cells upon endothelial cells. This is a quick procedure that involves one or two injections.

Into the liver or spleen: We will transplant mixtures of cells transplanted in the liver or spleen of some mice. We will do this under general anaesthetic to ensure accurate placement and to minimise stress to the mice. Mice will only undergo this once.

Longer-term impacts

Induction of chronic liver disease: To induce chronic liver disease, we will either:

Give the mice a **modified high-fat diet**. The mice will get fat and so may move around less;

with or without repeated **injections of carbon tetrachloride**. This can take up to a year to develop depending on the dietary modification that we use. This involves repeated injections in the abdomen that could be stressful or painful;

We will not let mice reach the point where the mice start developing problems from liver failure.

Repeated investigations: In some mice we will perform drug treatment or imaging

several times over the course of an experiment. There is a tension here between performing more investigations on a small number of mice or fewer investigations on a larger number of mice. In our application we have set limits to the number of treatments or procedures that a single mouse can undergo, to prevent undue suffering.

Liver tumour or transplanted tumour development: Some mice will develop liver tumours in the longer term after tail-vein injection or dietary modification. Mice undergoing transplantation will develop tumours in the skin, liver or spleen. We will closely monitor animals who might develop tumours and ensure that they do not develop signs of distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice	% of total
Mild	54.5%
Moderate	45.5%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

When the liver is damaged, cancer of the liver can develop. Our goal is to understand how different cells within the liver interact when the liver is damaged and what goes wrong to allow cancer to develop. Crucially, we need to understand the activation of the immune system in long-term liver damage and whether the endothelium is involved in this process.

To understand the complex relationships between different cells in the liver, we need to study these cells in a living animal, as we cannot study these relationships using cells cultured in a laboratory. Importantly many of these processes are very slow and occur over a period of days or weeks. Animal experiments allow us to perform these experiments over longer time periods.

We can study some of these processes in liver samples obtained from patients, but these only allow us a snapshot. To manipulate or change the behavior of specific cell types in the liver means we need to use genetically-modified animals.

Which non-animal alternatives did you consider for use in this project?

For some experiments we will use cells cultured in the laboratory, that allow us to study how two liver cell types communicate with each other. We have already utilised cultures of endothelial cells with either pre-cancerous senescent cells or cancer cells to determine the

effect upon the endothelial cells.

In addition, we will make use of cutting-edge techniques, such as three dimensional (3D) cultures or liver-derived organoids that more closely resemble the normal liver, where possible. These will allow us to use human liver tissue in the laboratory, something that was not previously possible to do. We can also genetically modify these organoids, replacing some of the mouse experiments.

For experiments where we do not need to manipulate anything, we will study cell behavior in human liver samples removed as part of patients routine clinical care.

Why were they not suitable?

Study of cells grown in the laboratory allow us to develop ideas about which signalling pathways we will then study in living animals. However, these cell experiments do not allow the study of complex interactions, such as the immune system. This can only be studied in living animals:

Cell culture systems can work for two different cell types, but to study more than this is impossible, due to different growth rates and need for different culture conditions.

Cell culture systems cannot keep cells alive for long enough to study the effects of injury over prolonged time scales required to be representative of human chronic liver disease.

Introduction of the complete immune system into cell culture systems is nearly impossible due to the short lived nature of some cells of the immune system and the very slow growth of other white blood cells that protects us from infectious diseases and cancer. To study the effect of induced endothelial behaviours upon the immune system requires a living animal.

Studying human tissues is important to understand human health problems, but we are unable to manipulate specific cell types to see what effect these changes have. Experiments in mice allow us to do this.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animal used in experiments will be carefully predicted based upon data from our previous work and previous published work by other groups. In all cases we will use the minimum number of animals required, for the experiment to give us useful data. We will work with statisticians to make sure that a minimum number of mice are used to generate significant results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whenever we design experiments we are mindful of the 3Rs and the need to continually optimise our plans. We will reduce the number of mice required in our experiments by:

Reducing breeding. We are going to use cutting-edge techniques including specific viruses and genetic-editing technology to improve the efficiency of our breeding programme. These will reduce the number of mice that are bred with the wrong genotype.

Improving experimental design. We will follow the PREPARE guidelines and use experimental planning tools, such as the **NC3R's Experimental Design Assistant** to improve the design of our experiments. We will perform pilot experiments, where we are unsure as to the effect size. This will ensure that we use the minimum number of mice in our experiments. For complex experiments we will seek help from local statisticians to ensure that our experimental designs and mouse numbers are appropriate.

Making sure we get the maximum information from each animal. For each experiment we will try to get the maximum amount of information from each mouse. This will be through repeated scanning, where possible, and analysis of several organs after death. We will also share both samples and data with other scientists, so that experiments do not have to be repeated.

Reporting our findings properly. To report our scientific findings we will follow the ARRIVE guidelines, so that our findings are clearly set-out. This means that the experiments will not need to be repeated by other scientists.

Use of previously generated tissues. Through literature review, we will ensure that similar experiments have not been conducted before. If similar experiments have been conducted we will approach the study authors to ask for access to the banked tissue samples, potentially reducing the number of animals needed to be used in our study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use a number of cutting-edge techniques that will allow a reduction in the numbers of mice that are required to be bred. Complex breeding programmes always generate large numbers of mice of the wrong genotype. Our techniques allow specific genetic modification of liver cells and include:

Hydrodynamic tail-vein (HDTV) injection. We currently use this technique on a regular basis, which allows delivery of small sections of DNA to liver cells, where it is cut and pasted into these cells DNA, altering their behaviour. Using this method we can take any mouse and express any gene that we have designed in the laboratory, within the liver, without the need for complex and wasteful breeding strategies.

Adeno-associated viral (AAV) **injection.** These viruses home to the liver, again allowing gene delivery to liver cells without the need for complex breeding strategies. This strategy is complementary to the HDTV above, but only allows certain genes to be expressed.

In vivo **CrispR-based DNA editing**. This novel technique allows us to use either HDTV or AAV to deliver molecular machines (Cas9 enzymes) allowing us to edit the DNA in liver cells. Therefore, this technique allows us to create specific mutations in the liver cells in a live mouse, without the requirement for complex breeding strategies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice to study the interaction between senescent cells and blood vessel cells in liver disease. To do this we will induce liver cell senescence or chronic liver disease via:

Modifying the DNA of liver cells. Using either hydrodynamic tail-vein (HDTV) injection or injection of adeno-associated viruses (AAVs) will allow us to directly modify the DNA of liver cells, to induce senescence or modify specific genes or pathways. Both are standard techniques that we currently use in our laboratory. The main drawback of the HDTV injection technique is the success rate of delivery; currently about 70% in our hands. Although successfully-injected mice develop shortness of breath and lethargy shortly after the procedure, the mice return to normal within 30 minutes.

The HDTV injection has previously been delivered whilst the mice are awake to allow comparison with previous experiments. A refinement to the technique might be to perform HDTV injection under general anaesthetic, where the mice would experience less pain or distress. We intend to compare the two techniques to ensure that injection under anaesthetic works in the same way.

Induction of chronic liver disease. We will use well established techniques to induce chronic liver disease (CLD) in mice by:

Modifying the diet of the mice to include lots of sugar and fat. These modified diets will lead to chronic liver disease, that looks like human fatty liver disease within 6-9 months;

Treating the mice with a drug called carbon tetrachloride. This leads to liver damage and over time the mice will develop chronic liver disease, that looks like human liver cirrhosis

These techniques are well established and used in many laboratories around the world.

We have significant experience with these models of liver disease, including the problems which may develop. The mice will be closely monitored to ensure they remain in good clinical condition. These interventions will occur in normal or genetically modified mice. To target particular tissues at particularly timepoints we will use conventional transgenic modification:

Genetically modified mice will allow us to study particular genes or pathways, particularly at specific times. Where possible we will use inducible DNA modification (e.g. Cre-LoxP) to specifically target particular tissues and limit the effects on the mouse. This will be particularly important to limit our modifications to the cells that line the blood vessels.

Why can’t you use animals that are less sentient?

Mice develop liver disease, that looks very similar to liver disease in humans, but it occurs much more quickly. Lower species such as flies or worms do not develop chronic liver disease and do not have immune systems like humans. Indeed, their body organs are so different to humans that they are not suitable to study. Mice permit us to study senescence, chronic liver disease and the role of all components of the immune system. Many suitable genetically modified mice already exist and if they don't the tools are available to create them. Therefore, mice represent the most appropriate animal model for our experiments.

We are unable to study earlier stages of development as:

We are interested in senescence or pre-cancer. This has not been demonstrated or produced in embryos or juvenile animals in previous scientific studies.

Induction of senescence or chronic liver disease takes time, which would result in the animals being adults by the time that chronic liver disease had developed.

We are unable to perform experiments under terminal anaesthesia as senescence takes days and chronic liver disease weeks to develop. Performing this under anaesthesia is clearly unfeasible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will seek to constantly improve the experiments that we perform.

Staff development. This work will be performed by experienced doctors, scientists and technicians who will closely monitor the mice. A key refinement is ensuring that staff performing techniques are fully trained. This has been the key in our current facility to improve the success rate of delivery of hydro- dynamic tail-vein injection.

Housing and husbandry. We will ensure that we use environmental enrichment in order to promote normal animal behaviour in our mouse colony. We will plan to house the mice together where possible to avoid loneliness. We will ensure that mice have access to environmental enrichment, such as wooden chew sticks, nest-building materials and fun tunnels, in order to reduce stress. In our current mouse facility we identified that our mouse colony was on a diet too rich in fat and were developing fatty liver disease. On changing the diet to one lower in fat content, the weight of our mice does not increase as much over time and they do not develop fatty liver disease.

Improved experimental design. Pilot experiments will be performed when we try new techniques or models, allowing us to identify any unexpected problems and improve the full experiment. This approach will also mean that we will only use animals that are absolutely necessary.

Improved techniques. We set strict limits to minimise the harm or suffering to the animals used. We will only use a limited number of surgical procedures and ensure that pain is treated after these procedures. We will use general anaesthesia for non-invasive imaging procedures, allowing us improved pictures of the liver. We will monitor the mice throughout the procedure and during the recovery period after anaesthetic. Close monitoring during longer-term experiments will ensure that animal suffering is kept to a

minimum and clinical signs are picked up promptly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have extensive experience in studying senescence and chronic liver disease in mice. We will use this experience during this new project, but will make use of published guidelines to improve our experiments.

We will improve experimental design following the **PREPARE guidelines** and using tools, such as the **NC3Rs experimental design assistant**.

Our animal experimentation programme will be run according to the guidelines and position statements from the **Laboratory animal science association (LASA).** We will care for our mice according to the guidelines laid out in the **Workman et al** (British Journal of Cancer (2010) 102, 1555 – 1577)**,** on animal welfare in cancer research.

During our experiments we will collect data on mouse phenotype and clinical signs according to the
FELASA guidelines.

When reporting our experimental results we will adhere to the **ARRIVE guidelines**, aiming to provide a comprehensive description of experiments and findings.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

During this project I will ensure that I keep abreast of the latest developments in the 3Rs through several sources:

Continuous professional development. I will attend relevant training courses to keep my license current, that will include developments in the 3Rs.

Institutional 3Rs search tool. A web-based search tool that allows scientists to keep up to date with the 3Rs.

Online tools. There are a number of websites for organisations that promote best practice in animal welfare that provide up-to-date information, such as the National Centre for the 3Rs (https://www.nc3rs.org.uk/) or the Norwegian National Consensus platform (https://norecopa.no/).

Peers and colleagues. In biomedical research I have extensive connections with other researchers throughout the UK and the world. I attend numerous conferences, where new findings are presented, allowing improvements in our techniques and experiments. An example of this is the use of AAVs to genetically alter liver cells; I learned this technique from scientific colleagues and have now brought this to our establishment, significantly reducing unwanted breedings.

62. Modelling ciliopathies.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Joubert syndrome, Disease mechanisms, Therapeutic development, Rare disease

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to better understand the genetic disorders known as ciliopathies (typified by Joubert syndrome) to improve genetic diagnosis by clarifying how the genetic changes affect disease presentation and ultimately to use this knowledge to develop treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The diseases known as ciliopathies affect a range of organs including the brain, eyes and kidneys of children - causing learning difficulties, blindness and life-threatening kidney disease. There are currently no life-sparing treatments beyond dialysis and kidney transplant and the underlying disease mechanisms remain poorly understood.

What outputs do you think you will see at the end of this project?

Outputs will primarily be in the form of publications that will increase understanding of the diseases known as ciliopathies. We have already made significant, high impact,

contributions to the field, eg, demonstrating for the first time the critical importance of previously unrecognised mechanisms affecting the onset and progression of kidney disease.

Who or what will benefit from these outputs, and how?

In the short term, this project will inform the scientific and clinical communities and help to refine and direct research efforts in this area. In the longer term, our studies will benefit patients suffering from these disorders by improving the accuracy of clinical diagnoses and prognoses and it is hoped that the project will progress towards early stage clinical research into novel treatments during the course of this licence.

Furthermore, our work will benefit the wider scientific and clinical communities by serving as a paradigm for how to improve understanding of rare genetic disease using GA mice in parallel with patient cells and other model systems.

How will you look to maximise the outputs of this work?

We publish in high-visibility, internationally-recognised, multidisciplinary research journals that have extensive readership.

We collaborate widely across Europe and USA sharing expertise and technical advice.

We engage extensively with patients, patient groups and charities - locally, nationally and internationally - and regularly publicise our work and our patients in the mainstream media to raise public awareness of rare disease.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use juvenile and adult mice carrying genetic alterations analogous to the mutations found in ciliopathy patients in this project. These have been chosen because we will be using the animals to model both the onset and development of the disease and thus need to analyse animals over a range of life stages. In this way we can discover mechanisms that drive both the initiation of disease and influence its progression, and can subsequently investigate therapeutic intervention targeting both early and later stages of the disease.

Typically, what will be done to an animal used in your project?

Typically mice will be bred to produce animals carrying mutations analogous to those found in patients. These mice will either be killed humanely to provide cells and tissues for analysis in laboratory to help identify the underlying mechanisms causing the disease, or will be injected with potential therapeutic agents and their disease monitored, for example

by MRI scanning and urine analysis to assess any therapeutic benefit.

What are the expected impacts and/or adverse effects for the animals during your project?

Typically, genetically altered animals will develop kidney and eye defects that reflect the kidney disease and retinal degeneration typical of the ciliopathies but will show no overt adverse effects. Both conditions progress very slowly in the mouse and, in this regard, mutant mice are indistinguishable from their wild type littermates. However, some animals will present with brain abnormalities that result in a misshapen head caused by fluid on the brain. This is also a progressive condition but can often be ameliorated by delaying weaning of juveniles and providing a soaked dietary supplement - mice that do not respond to interventions will be evident by 5 weeks of age and humanely killed.

Urine analysis (overnight urine collection to assess kidney function) and MRI scanning (up to several hours scanning with anaesthesia to measure kidney structure) may be used to monitor changes in the kidney in live adult mice and these may cause transient stress to the animals whilst they are away from their home cage.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity limit is moderate although the majority (greater than 75%) of mice bred and used on this licence will be mild or sub threshold.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project models developmental disorders that affect multiple organs and the complex interactions that lead to the disease, in particular the genetic components we are interested in, cannot currently be modelled without the use of animals.

Which non-animal alternatives did you consider for use in this project?

Our programme of work is based upon comparing mouse models in parallel with DNA profiles from patients and with cells that we directly isolate from patient urine. In this way the mouse models are directly relevant to the human condition and "standard" (commercially available) cell systems are not useful as their DNA profiles are unknown.

Why were they not suitable?

Standard cell systems used in basic research are not representative of patients - they do not accurately model the DNA changes within the patient, nor do they reflect accurately the organs that are affected in the disease and the complex cellular interactions that underlie these conditions. Furthermore the overwhelming majority of cells used in research laboratories must contain cancerous changes in order to be grown in the laboratory and thus are clearly not suitable for modelling a disease that is not cancer.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have a statistician within our team, who is an expert in population genetics, to help us design our genetic studies and estimate animal numbers needed to generate robust data whilst using the smallest number of animals. Our previous studies within the field indicate that our approach accurately reflects the situation in the patient groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We refer to NC3Rs guidance and the Efficient Breeding of Genetically Altered Animals Assessment Framework when designing experiments and routinely conduct power calculations, receiving advice from statisticians to ensure that the minimum number of animals are used in each study to accurately model patient populations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding colonies will be monitored carefully to avoid over-production of animals, and animals of specific genotypes that are produced (and tissues) will be shared and used by more than one research group whenever possible. Breeding colonies that are not required in the short/medium term will be stored as frozen embryos or frozen sperm, to minimise continued production of GA animals. Where specific genotypes are readily available from academic or commercial sources, mice will be acquired for each study, to avoid maintaining a breeding colony. We actively engage with a number of national and international initiatives for archiving and sharing of mouse lines and phenotyping information as well as maintaining informal arrangements for sharing lines with collaborators and institutional colleagues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use genetically altered mice that model developmental syndromes of man and have designed our research to focus on the early stages of these conditions in order to understand the underlying disease mechanisms and identify and test potential treatments whilst minimising the harm to the animals, for example, patients typically present with brain abnormalities, retinal degeneration and can progress to life-limiting complete kidney failure whilst in their teens/early twenties but we have optimised our experimental strategies such that we can identify and test treatments before our mice progress to end stage renal failure, whilst minimising the adverse effects arising from brain and eye abnormalities.

Why can’t you use animals that are less sentient?

We complement our work on mutant mice with zebrafish. Zebrafish can provide important clues as to the fundamental biological processes occurring within cells, however the zebrafish possesses a very primitive kidney (consisting of two nephrons) and has evolved to live in an aquatic environment. In contrast mouse and human kidneys are remarkably similar in terms of structure and function (consisting of thousands of nephrons). Furthermore, the mouse allows treatments to be tested in an animal that has similar circulation/metabolism to that of a human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The majority of genetically altered animals bred under the authority of this project will have no clinically deleterious phenotype, as the lines are maintained as heterozygous animals. Homozygous animals with a deleterious phenotype are produced only when specifically required for the project, or, if produced during a breeding programme, are humanely killed as soon as possible after a welfare problem is identified.

Deleterious effects in some lines develop only after several weeks, and in these instances, breeding programmes are devised to make use of younger animals, that are then humanely killed before the deleterious phenotype is expressed.

During breeding, litter size, number successfully weaned, and any specific adverse effects will be documented by regular (daily) observation of the animals. Husbandry modifications (eg use of soft diet, later weaning dates for smaller juveniles, additional bedding etc) will be adopted as required, as outlined in Wells et al, 2006.

Genotyping will normally be undertaken using tissue removed when ear-notching for identification purposes. When this is not suitable, and tail-biopsy is required, then a specific justification will be submitted to the AWERB before this method is used. If tail biopsy is required, it will be undertaken under brief general anaesthesia (eg with isoflurane) and analgesia (eg meloxicam) administered.

Furthermore, we have refined our use of metabolic cages by introducing "housing" that is

non- absorbent so does not adversely affect the experiment but provides the mouse with an enriched environment within the metabolic cage. We have refined the MRI scanning process such that animals are not transported to and from the MRI facility for each scan but housed adjacent to the MRI scanner to minimise their stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to guidance and training opportunities accessed via AWERB, best practice guidance is regularly sought from websites such as the NC3Rs, Home Office and EU (https://ec.europa.eu/environment/chemicals/lab_animals/index_en.htm). For example, we have recently implemented "non-aversive handling" across our mouse colonies (https://www.nc3rs.org.uk/implementation-non-aversive-mouse-handling-welfare-refinement-and- reduction-mouse-numbers#:~:text=However%2C%20there%20is%20now%20compelling,obtaining%20more%20precise%20research%20results).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of the AWERB mailing list and hold an account with the NC3Rs, receiving the monthly newsletter via email directly from the NC3Rs website. I receive internal institutional updates and alerts highlighting local discussion forums and events on animal welfare that I attend. I also regularly browse the EU guidance for updates on aspects of the 3Rs.

63. Investigating the genetics of cardiovascular disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

hypertension, cardiac hypertophy, genetics, therapy, gene targeting

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to understand the genetic causes of high blood pressure and its associated impact on the cardiovascular system. Better understanding of these processes and how the genes interact with environmental modifiers such as salt intake or obesity will allow new treatment strategies to be developed for cardiovascular disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

High blood pressure (hypertension) is the leading risk factor for heart disease, kidney disease and stroke, accounting for approximately 12.8% of all annual deaths world-wide. It is estimated that 31.1% of adults (1.39 billion) worldwide had hypertension in 2010, and the prevalence of the disease continues to increase. Hypertension is a complex disease and there are multiple causative factors responsible for its development. Risk factors include age, high sodium intake, obesity, alcohol consumption, physical activity, and

heritability (genetic factors). A range of blood pressure drugs are currently available to treat hypertension. However only one-third of treated patients achieve target levels of blood pressure possibly due to the complexity of the blood pressure control mechanisms. Therefore, there is a need to discover novel pathways and drug targets that will lead to new treatment strategies or enable more effective targeting of current therapies.

What outputs do you think you will see at the end of this project?

Outputs from this project will include increased knowledge in the field of hypertension and its associated cardiovascular diseases as well as the identification of new targets and development of novel treatments.

The results of the project will be presented at scientific conferences and will be written up and published in peer-reviewed scientific journals. The data generated will be used to support future grant applications.

Who or what will benefit from these outputs, and how?

The expected benefits arising from this project are multifold, and will be in relation to both the advancement of scientific knowledge (short-medium term) and further to potential clinical translation of novel therapies (longer term).

Investigations of the candidate genes and proteins identified in our studies will lead to better understanding of the mechanisms responsible for development of hypertension and cardiovascular disease. This novel information will allow us to develop new therapeutic strategies to prevent or reverse the disease processes, which are suitable for clinical application. Improved therapies for hypertension would reduce the number of people suffering and dying from cardiovascular disease and would thereby ease the burden on the healthcare system and the economy.

How will you look to maximise the outputs of this work?

The results from this project will be disseminated to the cardiovascular research scientific community through presentation at national and international scientific conferences, publication in peer reviewed scientific journals and through our local and international collaborative network.

We have already established strong links with medical professionals and pharmaceutical companies, which will assist in the longer term translation of our outputs to the clinic.

Dissemination of data from studies with negative or neutral outcomes will still be possible since publication of neutral and negative studies is now being actively encouraged by some journals.

Species and numbers of animals expected to be used

- Mice: 7000
- Rats: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will use mice or rats across a range of developmental stages i.e. fetal, neonatal, juvenile, adult and during pregnancy. This is necessary to allow us to understand the underlying mechanisms contributing to cardiovascular disease development at different life stages. Gene expression within a cell is dynamic and can differ depending on the developmental stage of an organism. Different levels of expression can modify the role the gene plays in physiological or pathophysiological processes. Therefore, there is a requirement to assess gene function at different developmental stages.

The rat and mouse models we use are carefully selected based on their unique genetic profiles. Some of the models we use will have established hypertension, which occurs spontaneously (naturally) in adulthood. These models will not only allow us to determine the direct contribution of specific genes on the disease process but will also allow investigation of novel therapeutic strategies which may be applicable for future translation to the clinic. Some of our models (mice and rats) have been genetically modified to inhibit (knock out) the function of specific genes, which allows us to understand the role these genes play in the development of cardiovascular disease.

Typically, what will be done to an animal used in your project?

During this project we will maintain colonies of rat and mouse models of cardiovascular disease, and we will utilise these models to examine the underlying disease mechanisms. We will conduct our investigations in control animals and in animals which have been genetically modified to alter specific genes or proteins that may play a role in the disease process.

We will carry out a range of methods for assessing the characteristics of the cardiovascular system in our rodent models. These methods typically include repeated blood pressure monitoring and repeated echocardiography to examine changes in heart function and structure. Echocardiography is a non- invasive method requiring brief general anaesthesia for imaging purposes. Blood pressure monitoring is typically carried out on a weekly basis by non-invasive means. However, when scientifically relevant, blood pressure can also be monitored continuously and in greater detail using a probe that is surgically implanted under general anaesthesia into the animal. These studies may also involve collection of blood and urine samples at regular intervals. Typically, animals will remain on procedure for 8 weeks.

Some of our studies will also involve modifying the function of the cardiovascular system in our rodent models by altering the diet, or administering drugs or hormones, or altering the function of specific genes in order to modify the disease processes. The majority of these substances are administered to conscious animals, however certain substances requiring continuous delivery, will be administered by minipump, which are surgically implanted subcutaneously under general anaesthesia. These intervention studies will also involve monitoring of blood pressure and non-invasive imaging repeated at regular intervals, as well as the collection of blood and urine samples. Non-invasive monitoring will require brief general anaesthesia. Typically, animals will remain on procedure for up to 12 weeks (with a maximum limit of 16 weeks).

What are the expected impacts and/or adverse effects for the animals during your

project?

Some of the rat models used in this project contain harmful mutations in their genes which result in cardiovascular disease characteristics of moderate severity (i.e. hypertension and stroke). We observe approximately 6% incidence of stroke in male rats. The majority of these strokes are sustained after the age of 4 months, which is the time of established hypertension. Spontaneous strokes are almost never encountered in female hypertensive rats (<1%).

Pain as a result of surgical procedures: all animals undergoing surgery may experience some pain Analgesics will be given in consultation with the NVS and for as long as necessary.

Anaesthetic death (1%)

Weight loss from repeated anaesthesia (1%)

Decreased palatability (1%) and weight loss (1%) as a result of dietary manipulation. Although special diets are not expected to produce any major short-term weight loss or adverse clinical effects in rats or mice (other than the desired cardiovascular modification), palatability issues may result in gradual weight loss over longer intervention periods (e.g. 2 weeks or longer). Body weight will be monitored at regular intervals (typically twice weekly). Body condition scoring will be implemented if palatability issues are anticipated for specific diets.

Acute toxicity (5%) to the maximum viral vector dose in our in-house colony of rats. Sensitivity may be increased in rats from external sources. Acute toxicity is not anticipated in mice. Any animal displaying signs of acute toxicity (e.g., pallor, collapse, tachypnoea) will be immediately culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

50% of the rats and mice in this project will experience adverse effects that are mild, causing no more than transient discomfort and no lasting harm. Justification:
Although some of the rats contain mutations in genes that can result in cardiovascular disease of moderate severity, the majority of these genetically modified rats (>90%) will be studied before overt clinical signs develop.

The genetically modified mice used in this project show no overt clinical signs.

The adverse effects for the breeding protocol and the majority of the phenotypic characterisation methods are considered mild and transient.

For potentially stressful methods in conscious animals such as tail cuff plethysmography and use of metabolic cages, animals are acclimatised to the equipment prior to measurement and tolerate the procedures well.

44% of the animals in this project will experience adverse effects that are classed as

moderate severity. Justification:

Most of the animals undergoing phenotype assessment and intervention studies will experience multiple monitoring procedures (of mild or moderate severity). In our previous experience of similar studies involving multiple assessment/intervention steps in combination with genetic modifications, we have identified no lasting harm as a result of cumulative adverse effects. Animals on these studies maintain weight, show normal behaviour and do not exceed scoring sheet limits of moderate severity.

A small number of animals may show sensitivity to dietary or pharmacological intervention resulting in body weight loss. These animals are carefully monitored using welfare scoring sheets and are removed from study or killed before exceeding moderate severity limits.

Some animals will experience surgical procedures that are classed as moderate. All animals undergoing these procedures are given analgesia and are allowed time to fully recover from the effects of surgery before undergoing further procedures.

6% of the animals in this project may experience adverse effects that are classed as severe

Some hypertensive rats will experience sudden stroke.

Some mice administered angiotensin II may experience sudden death due to aortic aneurism.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The nature and complexity of the cardiovascular disease process makes finding alternatives to live animal models extremely difficult. Although cell-based models are available to examine normal and disease mechanisms in cells from blood vessels, the heart and kidneys there are limitations associated with interpretation of results from these models. These cells are mainly derived from juvenile or neonatal animals and therefore results may not be predictive of the cellular response in the intact adult animal. Usually, a single cell type will be grown in isolation (e.g. vascular smooth muscle cells or endothelial cells), whereas in the intact animal, different cell types develop together and function as units. Also, our cell-based models have no blood supply, whereas in the live animal the blood circulation can contribute to disease development by providing a pathway for inflammatory and immune molecules between the target organ and the rest of the body. Therefore, it is important to understand the disease mechanisms in intact organisms, which show similar cardiovascular characteristics to humans.

Which non-animal alternatives did you consider for use in this project?

Where possible we use non-sentient alternatives to live animals. For example, cell culture has replaced the use of animals in some of our functional analysis studies of candidate genes and gene networks and protein/protein interaction studies (e.g. H9C2 cells to determine the role of specific genes in cardiac hypertrophy, and primary cultured mTAL cells to examine the role of specific genes in ion transport mechanisms). Furthermore, we use cell culture to develop and optimise the viral vector gene delivery system in our gene transfer procedures before in-vivo testing is carried out.

To simulate some of the greater complexity of the whole heart, blood vessels or kidney, another consideration is the use of an organ-on-a-chip (OOC), which is a multi-channel 3-D microfluidic cell culture chip that can mimic the functions of human organs. This technology can provide a more detailed and more physiological approach than cell culture studies based on a single cell type. Whilst organ-on- a-chip systems are routinely used for drug efficacy screening, appropriate in-vitro model systems of cardiovascular disease that fully recapitulate the essential changes and mechanisms seen in the disease, are still in the developmental stage.

Why were they not suitable?

Human heart cells are difficult to obtain and can only be maintained in culture for a short period of time and are therefore not suitable as a robust testing model.

Whilst organ-on-a-chip systems are routinely used for drug efficacy screening, appropriate in-vitro model systems of cardiovascular disease that fully recapitulate the essential changes and mechanisms seen in the disease, are still in the developmental stage, and are therefore not currently suitable for use.

Although cell-based models can provide important detailed information on mechanisms occurring within the cell, and will be used alongside our rat and mouse studies, they cannot fully replace the use of live animals for investigation of cardiovascular disease progression where an intact cardiovascular system is necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The total number of rats and mice estimated is based on my experience of performing similar studies over the past 20 years. The numbers will ensure that we would have sufficient animals for breeding purposes and to carry out each protocol enough times to generate data for approximately 20 publications over the duration of the licence. The numbers indicated are the maximum we would use, but the actual numbers are likely to be lower and would depend on the success of current/future grant applications to support the work. The maximum numbers are quoted to ensure it is possible to carry out the studies without the need to repeatedly revise the project licence in future.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Expert statistical advice has been obtained from in-house statisticians and online tools (e.g. NC3R's Experimental Design Assistant) have been utilised during the experimental design phase of this project. For all our studies we follow ARRIVE guidelines to ensure good laboratory practice and transparent scientific reporting.

Use of methods that permit repeated measurements in the same animal allows for optimisation of the number of animals we plan to use. For example, echocardiography permits a range of cardiac parameters to be determined at a number of different time-points, non-invasively in a single animal. The ability to carry out repeated imaging allows the investigation of the evolution of cardiac disease and the potential influence of dietary, or pharmacological or gene transfer interventions to be carried out in a single group of animals removing the need for multiple groups of animals to be humanely killed at each time point. This also increases the statistical power of the studies whereby the effect of an intervention can be assessed in the same animal over time. Also, since data for each time point come from the same group of animals, there is reduced variability in the data sets and consequently smaller group sizes are required when power calculations are carried out for study design.

Where possible, animal numbers will be reduced by using a single positive and/or negative control group when several different treatment groups are being run concurrently. For longitudinal studies, animals may be used as their own controls by carrying out baseline measurements and assessing subsequent change in phenotype in response to treatment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Apart from good experimental design, we will optimise the numbers of animals we use through efficient breeding i.e. striking a balance between the numbers of animals required to assure continued genetic integrity and reduction, replacing breeders before reproductive performance declines, replacing non- productive breeders as soon as possible, using experienced males.

Any tissues harvested when the animals are killed at the end of the study, that are not used for the purposes of this specific project, will be processed and stored for use in future studies by ourselves or will be made available to our collaborators. This bank of stored tissues will reduce the requirement for repeating batches of experimental animals at later date for follow up molecular or histopathological analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The hypertensive rat model used in our studies is an excellent model of human essential hypertension and one of the best existing models of human stroke displaying many characteristics in common with the human disease. Use of this model demonstrates consideration of published guidelines to improve experimental design, in an effort to improve translation from pre-clinical to clinical studies by using a model with many existing co-morbidities. This model has advantages over other hypertensive rat models for use in our studies because it displays salt-sensitivity and end-organ damage (e.g. in kidneys and blood vessels) that other non-stroke prone hypertensive rat strains fail to show.

Genetically modified rat and mouse models (e.g. knock-out, knock-in, conditional) are widely available for detailed functional investigation of specific candidate genes. The most appropriate models will be chosen to assess the candidate genes identified in our human and rodent studies.

Our protocols have been chosen to provide the maximum detailed information necessary for dissecting the complexity of the multiple genetic factors contributing to cardiovascular disease, whilst at the same time ensuring that the animals under investigation experience the least pain, suffering, distress or lasting harm. For example, the radiotelemetry procedure (for direct arterial blood pressure measurement), although requiring an initial surgical procedure will, after complete recovery, allow the continuous monitoring of blood pressure without the stress of repeated handling. Radiotelemetry also provides superior data output allowing assessment of day time and night time variation in blood pressure which not possible with other methods of blood pressure measurement.

Administration of substances will be carried out by the least severe/painful method available. For example, substances may be administered in the diet or in the drinking water rather than by injection. The substances we propose to use for our gene transfer studies are well characterised, and the maximal dose for our rat and mouse colonies has already been established. We will ensure that this maximum dose is never exceeded, and all batches of adenoviruses will be titered using our established in-house techniques.

Animals will always be housed in pairs or groups unless individual housing is required due to welfare reasons or for scientific purposes.

For all studies involving animals we follow ARRIVE guidelines to ensure good laboratory practice and transparent scientific reporting (e.g. we randomise our animals when including them in our experimental studies and our researchers remain ‘blinded’ to the treatment groups until after the study is completed. This reduces unconscious bias in experiments).

Why can’t you use animals that are less sentient?

Mice are the least sentient vertebrate group in which the process of hypertension development and its associated target organ damage in the intact animal can be interrogated. However, the rat is the more tractable model of the human cardiovascular system, displaying greater similarity with humans in terms of disease pathophysiology. The project cannot be entirely conducted in terminally anaesthetised animals because the disease processes develop over a period of weeks.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All of our animals are monitored on a daily basis. Those animals undergoing surgery or other interventions to modify the cardiovascular system will be scored according to a numerical scoring sheet for pain/discomfort/distress in mice & rats, and if necessary will be humanely culled.

Regular non-invasive monitoring by blood pressure measurement or echocardiography will typically identify harmful changes in the cardiovascular system prior to the development of overt clinical signs.

To reduce stress, animals are regularly handled, and will be acclimatised for short periods in metabolic cages and familiarised with the blood pressure recording procedure prior to the actual measurement phase of the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice local guidelines as well as guidance published by the NC3Rs and the Laboratory Animal Science Association (LASA). In addition, we will adhere to ARRIVE guidelines for appropriate transparent reporting of our research outputs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Project Licence holder and members of the research team will ensure continued professional development in the 3Rs area through regular attendance at meetings/workshops such the Animals in Science Regulation Unit (ASRU) annual meeting, 3Rs workshops/ symposiums held at local or national Research Institutes, and also attendance at local training workshops organised by the NTCO.

Home Office

64. Sensory function in zebrafish

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Auditory, Deafness, Brain, Sensory systems, Hair cells

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this programme of work is to define the critical physiological steps required for the maturation and function of the auditory (hearing) and vestibular (balance) systems, and how they integrate to other sensory inputs (e.g. visual information) to inform animal behaviour. How biological systems orchestrate these mechanisms are major challenges in the quest to understand human biology and diseases.

Like mammals, zebrafish have auditory and vestibular organs that contain the sensory receptor hair cells. Moreover, the basic biological aspects covered in this proposal are common to all vertebrates. The advantage of using the zebrafish is that we can provide an understanding on how these sensory organs work in vivo, which is currently an unachievable task in mammals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

The sensory systems are key to our daily life. One of such system is the auditory system, which allows us to perceive sound in all of its different forms, from noises to speech and music. The sensitivity of these sense is remarkable, allowing us for example, to detect sounds as low as the drop of a pin or as loud as an explosion or an airplane taking off. It is also key for survival in many animal species, as its speed in processing information is unparalleled among sensory systems. This is the reason why time- critical sports such as sprint races start with a gunshot and not, for example, with a flash of light.

Despite the importance of this sensory system, we still have a poor understanding on how it achieves these unparalleled performances. How does the brain develop its ability to extract information from sounds? How does it combine this information with other sensory modalities to make decisions to drive behaviour? These are critical questions in our quest to understand how the brain works, as well as to understand the physiological basis of sensory disorders.

The research listed in the proposed work is aimed at elucidating how the auditory and vestibular systems are refined in their complexity during development. More importantly, the project aims to determine how auditory and vestibular inputs are processed and integrated with other sensory modalities in the brain, and why genetic and environmental effects lead to deafness.

What outputs do you think you will see at the end of this project?

The main outputs of the proposed project are publications in peer-reviewed journals and the identification of potential therapeutic targets to slow down or even prevent hearing loss and balance disorders. In addition, we use our research to deliver outreach activities in public events and school visits.

Who or what will benefit from these outputs, and how?

Hearing loss is the most common sensory deficit and one of the most prevalent chronic disease in the elderly. About 12 million people in the UK and ~500 million worldwide have disabling hearing loss (>900 million people expected by 2050) [WHO 2021; RNID]. Hearing loss excludes people from basic day-to-day communication, which is associated with significant psychological and medical morbidity, including social isolation and depression. Hearing loss in mid-life is the largest modifiable risk factor for dementia. The exact prevalence of vestibular dysfunction among people is less clear, but it can be as high as 35% in adults aged 40 years or older. The number is largely increasing in the elderly, affecting their quality of life.

Currently, our ability to develop new effective treatments for auditory and vestibular disorders is that very little is known about the underlying molecular and cellular mechanisms leading to their dysfunction.

Since the basic biological aspects involving these sensory systems are common to all vertebrates, we have selected the zebrafish for the proposed program of work because it will allow us to study the molecular and cellular mechanisms in in vivo, which is currently not possible in mammals.

This will offer a great social benefit since it would contribute, in the long term, developing therapeutic intervention to ameliorate or prevent different forms of hearing loss and

deafness, and possibly vestibular dysfunctions.

How will you look to maximise the outputs of this work?

The work will deliver several scientific publications of the mechanisms used by the auditory and vestibular system to develop and function. Dissemination of the data will also be maximised via invited seminars and scientific conferences around the world. The findings will also be disseminated to the general public via the several outreach activities performed by the hearing research group.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of animals is essential for this project since at present it is the only means of obtaining any fundamental information about the physiological properties of cells in the intact neuronal circuits responsible for sensory perception.

The zebrafish is currently the least sentient animal model to study sensory integration and the mechanisms leading to hearing and vestibular function and dysfunction in vivo. This is not only dictated by the several similarities of these sensory systems among vertebrates, at both molecular and cellular level, but also due to the relatively small size of the zebrafish and the ability to generate zebrafish with similar sensory defects as those present in humans. As such, the finding obtained from using the zebrafish will be used to further our understanding of sensory function and dysfunction in humans.

Because we are interested in studying how sensory systems become specialized and function, we will use zebrafish at all stages of development spanning from egg fertilization up to adult stages. Zebrafish during early stages of development are transparent, allowing us to image deeper into the fish under in vivo conditions, which is not possible with other vertebrates showing comparable sensory systems to that of mammals. From this work we will be able to learn more about how organs, tissues and cells develop. We will look at older stages of fish to be able to understand how these sensory systems function when reaching a mature stage. This allows us to investigate the mechanisms used by the hair cells to become such highly specialized sensory receptors.

This knowledge will then be implemented in future studies in mammals to test for possible common mechanisms, which will help understanding and addressing sensory-related dysfunctions.

Typically, what will be done to an animal used in your project?

The large majority of zebrafish will be immersed into an anaesthetic (non-recovery anaesthesia). Anaesthetized zebrafish will be placed on a chamber in order to perform imaging or electrophysiological measurements from the sensory systems or brain. Adult

zebrafish, which normally require gill movement for breathing will be intubated under anaesthesia (procedure: terminal anaesthesia). Experiments normally last no more than 4 hours.

In a subset of zebrafish, when we have evidence that the anaesthetic is going to alter the normal physiological responses, the fish will be restrained in agarose prior performing any measurements. Restrained zebrafish will be placed on a chamber and cells and neurons from the sensory systems or brain imaged. Experiments normally last no more than 4 hours.

Sometimes, when we need to test the effect of a compound (e.g. the ototoxic aminoglycoside antibiotics), zebrafish will be anaesthetised prior the administration of any compound, these experiments usually last for no more than 4 hours. Zebrafish are recovered and analysed for the effect of the compound at a later timepoint by 1) fixation of the tissue (under non- recovery anaesthesia); 2) anaesthetized or embedded in agarose as described above. The overall procedure can last several days (free swimming fish when not anaesthetized or restrained in agarose).

The use of neuromuscular blocker will be required for a very small number of experiments in larval zebrafish (up to 10 days post-fertilization), when we have evidence that the anaesthetic is compromising our measurements, and the method of restraining is not suitable for the type of procedure (e.g. activating the lateral line of the zebrafish with water motion to simulate swimming behaviour).
Zebrafish will be placed on a recording changer and cells and neurons from the sensory systems imaged. Experiments normally last no more than 2 hours and at the end the animals are killed.

What are the expected impacts and/or adverse effects for the animals during your project?

For all experiments, including those involving the use of the neuromuscular blockers, the adverse effects might include some discomfort and a potential increased stress level. Very rarely, larval and juvenile zebrafish may become unable to swim, although at this age they breathe through the skin. Nevertheless, these potential adverse effects will be monitored during procedures (e.g. ability to swim and heartbeat) and minimized using the best practise. Zebrafish in distress such as inability to swim upright if not linked to vestibular mutations or conditions that differs from siblings (e.g. lethargy or hyperactivity) will be immediately killed by a schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of fish should experience no more than mild severity or non-recovery (typically 90%) with a subset of animals experiencing no more than moderate severity (10%).

What will happen to animals at the end of this project?

- Killed

Replacement
State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding the basic biology and diseases in living organisms is a major challenge for scientists. However, complex biological systems that span from the periphery to the central nervous system cannot be replicated in non-living animals (at least at the moment). This is additionally complicated by the fact that the sensory system, such as the auditory and vestibular, are deciphering and integrating several environmental signals. As such, scientists are dealing with a twofold experimental design: how to represent with high fidelity such intricate sensory systems and how to combine this with the large variability and dynamic range of environmental information. Currently, we do not have the answers for all these problems, which is why we need to use living organisms to gain the required information to develop more bench-based and theoretical approaches.

Which non-animal alternatives did you consider for use in this project?

Theoretical models represent an additional approach that can be used to address aspects of our research questions. Currently, we are developing projects that will use this modelling approach to predict animal behaviour. However, models are only as accurate as the information used to inform these models. As such, a meaningful model can only be delivered if we use real measurable data from the biological process under investigation. Currently, this can only be obtained from in vivo animal
experiments. Therefore, theoretical models and in vivo animal experiments must be used in conjunction, at least for now.

Organotypic cultures have been used for some experimental work on mammals, including testing the susceptibility of the hair cells to several ototoxic compounds. However, we still rely on in vivo animal experiments to fully understand organ development and function. These types of cultures have not been developed yet for the zebrafish because of the difficulty associated in explanting the required tissue from the animal.

Why were they not suitable?

Organotypic cultures are not suitable because they lack the complex architecture of the nervous system, which prevents signal processing and sensory integration. Theoretical methods are not suitable because they can only be used to provide ideas on how a system may work, but they cannot address the problem directly. Although animal models are still the only means to understand the intricate mechanisms implicated in the development and synaptic transmission in the nervous system, we are currently working with colleagues to build a computational model of sensory function using the data collected by our experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot

studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used is estimated based on previous work done in our lab for more than 10 years under two previous licenses. Moreover, we use the expertise present in the zebrafish facility at Sheffield, which has helped us to keep the use of zebrafish to a minimum. For complex electrophysiological and imaging functional studies, we will require at least 6 zebrafish per experiments to reach a meaningful statistical analysis. The total number vary a lot depending on how many experiments. In the last two studies, which we have just concluded, we used a few hundred zebrafish.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Several of the approaches used in this proposal (e.g. zebrafish intubation; agarose), and selection of the most appropriate anaesthetic for the different procedures, were developed in my group over the last several years. This has allowed us to drastically reduce the number of zebrafish used under this project.

To reduce animal surplus, we follow the very strict breeding guidelines from our zebrafish facility

In order to decide the sample size needed for the experiments, we use the statistical inference technique suggested in the NC3Rs website.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We follow the Zebrafish Embryo Genotyper (ZEG), which helps to reduce the numbers fish raised by only raising those that are of the correct genotype and required for experiments. We will also use pilot studies where applicable to determine baseline parameters.

All personnel involved in the project undergo a compulsory training in all procedures used prior working with animals, which is designed to keep the number of animals required to a minimum.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The use of the zebrafish as a model demonstrates the use of a species of a lower neurological sensitivity compared with mammals. The large majority of the procedures are designed to test physiological aspects of the sensory systems using imaging and

electrophysiology methods, which are non-invasive techniques and does not require any surgical operation.

Why can’t you use animals that are less sentient?

We need to use animals in which the sensory systems have some strong resemblance to those present in mammals since we want to be able to translate our finding in the future to human; the long-term aim is to devise therapeutic intervention to ameliorate or prevent sensory disorders. There are not alternative animals that can be used for this project that have less sentient, while retaining the same genetic tractability and similarities with the mammalian system. Although most of the procedures will be performed under terminal anaesthesia, some are not possible because of its well- known side effects on the nervous system, including the sensory pathways.

We will use zebrafish from early stages of development up to adult stages because the project is aimed at understanding not only how the sensory systems are put together during development, but also how they function in the fully mature animal. This requires us to investigate zebrafish over a wide range of ages.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During our procedures we will carefully monitor the condition of the animals and will apply early endpoints should any notable pain, suffering or distress become apparent. In addition, we are constantly monitoring our experimental endpoints to determine if the questions posed can be answered through reducing experimental time.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To the best of our knowledge there are no published best practice guidelines for the zebrafish work listed in this project license. However, we use philosophies of experimental design advocated by the likes of Festing and Wurbel in order to refine our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will consult our NC3Rs regional programme manager to discuss advances in the field of 3Rs and keep abreast of new 3Rs initiatives through the NC3Rs website and/or attend future 3Rs workshops related to the use of non-mammalian species.

65. Safety, efficacy and immunogenicity of regenerative cellular therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Regenerative medicine, Stem cells, Cellular therapy, Immune response, Tissue engineering

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to study the biological behaviour of regenerative cellular therapies when transplanted into rodent models. The purpose is to confirm that the cellular therapies survive after transplantation, are safe, function, and to understand how they are recognised and affected by the immune system. Our priority is to work on development of cellular therapies for liver disease, diabetes, brain disorders (such as Parkinson's Disease), bowel disorders and blood disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Many patients with end-stage organ failure die of their disease or need organ transplantation to survive. In cases where treatment is available, such as insulin therapy

for diabetes or dialysis for renal failure, current treatments do not cure the disease and the quality and duration of the patients' lives are severely affected. Cellular therapies, such as those derived from stem cells, represent a promising opportunity to develop methods to repair or replace diseased organs and tissues. The proposed work is essential to ensure that cellular therapies under development for human patients are safe and effective.

What outputs do you think you will see at the end of this project?

The proposed project is expected to lead to new discoveries about the function of regenerative cellular therapies, and how they are recognised and rejected by the immune system. More specifically, we expect to generate at least one cellular therapy and advance it to a stage that it can be investigated further in large animal models. In the long-term (5-7 years), we expect that the findings of this study will result in the design of at least 1 human clinical trial to test the safety and efficacy of a cellular therapy developed in this project. The findings of the studies will be disseminated widely through publications and presentations.

Who or what will benefit from these outputs, and how?

In the short-term (1-3 years), the primary beneficiaries of the proposed project will be other researchers who are also developing cellular therapies for treatment of medical conditions. We anticipate that the findings of this study will be of broad relevance to the research community in this field. In the medium term (3-5 years), we anticipate that industrial companies involved in the manufacture of cellular therapies will also benefit from the findings of this study. These companies and manufacturers are essential for the production of cellular therapies that are eventually used for treatment of patients. In the long-term (5-7 years), this project will benefit patients with conditions such as diabetes, liver disease, bowl disease, blood disorders or Parkinson's disease. The benefit will initially be limited to those patients enrolled in clinical trials investigating the cellular therapies developed in this project. We hope that ultimately (7-10 years) large numbers of patients will benefit from the findings of this study, after the cellular therapies have been shown to be safe and effective in clinical trials and can be manufactured at large scale.

How will you look to maximise the outputs of this work?

We will disseminate all findings of our studies, including unsuccessful approaches, through publication in peer-reviewed journals, presentation at scientific conferences, and through meetings with other researchers. All publications will be open access, including through platforms such as F1000Research. This project includes collaborations with a large number of researchers with expertise in complementary areas. This network will be utilised to maximise the dissemination of the new knowledge gained through this project.

Species and numbers of animals expected to be used

- Mice: 4675
- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mainly mice will be used in the proposed project. A small number of rats which may be used if the technical aspects of the surgery mean that it cannot be performed safely and effectively on mice due to their small size. It is anticipated that less than 5% of the animals used will be rats and that more than 90% of the mice used will be adults. Mice are the lowest species with a comparable physiology that enables useful information to be gained relating to the safety and effectiveness of human cellular therapies. Importantly, genetic strains of mice are available that allow studies to be designed that can generate valuable information about specific cellular therapies. In a small number of experiments (estimated at less than 5% of total animals used), new-born mice must be used in order to allow for studies investigating how the immune system rejects human cellular therapies. The new-born mice will be approximately 4 days old. Due to their young age, these mice will develop a more functional immune system, which will enable more informative data to be generated in a limited number of specific experiments.

Typically, what will be done to an animal used in your project?

In a typical experiment, the animal will undergo one surgical procedure during which it will be transplanted with a cellular therapy (for example, into the abdomen). The typical animal will then be kept alive for 4-12 weeks before being culled, so that the tissues can be harvested and examined. The animal may undergo blood sampling typically 2-4 times per month during this period. Approximately 50% of the animals will also receive an injection to give them human immune cells (such as white blood cells) to study rejection of cellular therapies. Approximately 25% of the animals may also undergo a procedure such an injection of toxin or oral dosing of a drug into the stomach via a tube. The purpose here will be to induce a disease, such as liver failure or diabetes, to test the effectiveness of the cellular therapies. Approximately 10% of animals may undergo injection of a toxin or drug into the brain, followed by behavioural testing. The typical animal will undergo one surgical procedures and be kept for approximately 12 weeks. The typical animal will then be culled electively while still well and without clinical signs. In some cases, the animals will be culled by removal of organs while under deep general anaesthetic. Newborn mice will only receive one injection of cells to administer immune cells. All all procedures on these mice will be performed later when they are adults.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that most (more than 90%) of animals will recover rapidly and well from stem cell transplantation.

Injections with immune cells (such as white blood cells) is also generally well tolerated. Most (more than 90%) animals will not experience adverse effects from this procedure.

Animals that undergo a procedure to induce a disease, such as diabetes or liver disease, would be expected to display the effects of that disease (such as abnormal glucose levels in diabetes or abnormal liver function in liver disease). In most cases, this would only manifest in the form of abnormal blood results (for example, high glucose levels or abnormal liver tests) and the animals will not display any clinical signs. Injection of toxins into the brain followed by drug testing may results in transient abnormal behaviour such as circling. Circling behaviour is when the animal walks in a circle after administration of the drug. This behaviour is expected to last no more than a few minutes. The circling

behaviour ends when the effects of the drug wear off and is not lead to lasting harm.

In some cases, the animals may experience weight loss, reduced food intake, reduce movement or an abnormal coat. In such cases, the animals will be culled if these clinical signs do not respond to treatment (such as high energy and easily digestible diet) and persist for up to 24 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals that undergo a surgical procedure will be expected to experience moderate severity. This is expected to be the case for the majority (65%) of experimental animals. A small proportion of animals (25%) will only undergo injections and will experience mild severity. The remainder (10%) may be culled for tissue and will experience subthreshold severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the project is to study the safety and function of cellular therapies and how they are recognised by the immune system. Robust and reliable investigation of these characteristics of the cellular therapies requires the use of animal models that can mimic the biology and diseases encountered in humans. We routinely use extensive laboratory experiments to characterise the cellular therapies without the use of animals. However, complex responses such as their ability to reverse clinical signs of a disease, or rejection by the immune system, cannot be studied comprehensively without animal models. Importantly, data generated from animal models are essential for gaining regulatory permission for the ultimate use of these cellular therapies in human clinical trials.

Which non-animal alternatives did you consider for use in this project?

The majority (more than 90%) of the cellular therapies used in this project will be derived from humans. Mouse cellular therapies may be used as controls in less than 10% of experiments. Importantly, this is itself an significant part of our Replacement strategy. Very few animals will be used to generate cellular therapies: human tissue will be used instead. Moreover, we have and will continue to make extensive use of specialised human cell culture systems, where human cells can be examined for their function in the laboratory. By growing cells in the presence of human immune cells, we are also generating important data about the therapeutic potential of, and the immune response to, our human cellular therapies. Similarly, we utilise human organs, supplied with human blood on specialised

machines, as a site for transplantation of some cellular therapies. This approach further reduces the need for animal experimentation.

Why were they not suitable?

As outlined above, we make extensive use of human tissue and human cells, as well as sophisticated human cell culture systems and human organs examined on machines, to replace the use of animals in many studies. However, these alternatives cannot entirely replace the use of animals as they do not fully replicate the complete repertoire of the biology of the cellular therapies when administered to patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals have been estimated based on the range of studies that are planned, as well as based on the previous similar studies we performed during the last five years. Based on our previous experience, we are able to predict, for each study, the number of animals that are required to generate reliable and reproducible data. Using our previous experience, we are also able to predict how many studies we can perform in a given time period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have generated a wealth of data from previous experiments that enable us to estimate the anticipated effect size and variation in the experimental data. This data will be used to ensure appropriate experimental group sizes. We routinely randomise animals to experimental and treatment groups. All experiments are conducted and/or data analysed in a blinded manner to reduce bias. When a new cellular therapy is under investigation, we will first perform pilot experiments with small animal groups (typically 2-3 animal per group). The pilot experiments will be used to confirm the appropriateness of the experimental design and to generate pilot data to enable group sizes to be formally calculated. We will also use tools such as the NC3Rs Experimental Design Assistant to ensure experiments are appropriately planned to generate reliable and reproducible data. We will also take into consideration any regulatory requirements relating to the reproducibility of the data, in order to ensure data generated from this study is suitable for informing design of future clinical trials.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to reduce the number of animals we use through a number of simultaneous strategies:

We will share excess breeding animals with other researchers and use any animals culled

as tissue donors for use by our group or by other researchers.

Where possible, we will use each animal as its own control. For example, we will transplant two cellular therapies in two separate sites (for example, into each kidney) in the same animal in the same operation. This will reduce inter-animal variation and reduce the number of animals used.

By generating large quantities of human cells, where appropriate, we can continue to perform new studies using the same human cells. This reduces the variation associated with different human donors and reduce the number of animals used.

By monitoring animals for prolonged durations, and through the use of non-invasive monitoring techniques (such as imaging), we can generate longitudinal data about cellular therapies without the need to cull animals at numerous timepoints.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experimental models and techniques used in this project can be broadly divided into three groups:
Transplantation of cellular therapies into animals to assess the survival and safety of the cellular therapies

Reconstitution of the animals with a human immune system to assess immune response to the cellular therapies

Generation of a disease state in animals to assess ability (function) of cellular therapies in reversing disease

All experimental models have been refined to ensure they cause the least pain and suffering. The disease models have been designed so that biochemical abnormalities (e.g., high blood glucose levels or abnormal liver function tests) can be used as experimental endpoints in the vast majority (more than 95%) of experiments, without animals displaying harmful clinical signs. Importantly, none of the procedures are expected to result in severe clinical signs (such as persistent abnormal behaviour or persistent weight loss). Animals will be culled if they display clinical signs that do not respond to treatment (such as easily digestible food or pain relief medication). Animals therefore will not be permitted to experience lasting harm.

Why can’t you use animals that are less sentient?

Mice are the least sentient animals that can be used to generate valuable data to investigate the therapeutic potential of human cellular therapies. As the response to, and

the function of, cellular therapies takes hours to days to manifest, experiments cannot be performed exclusively under terminal anaesthesia. Rats will be used in a very small number of experiments (approximately 5%), because their larger size will enable some surgical procedures to be performed more successfully and without adverse effects.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In close collaboration with the staff at our animal facility, we have a robust mechanism for the post- operative monitoring of our experimental animals. Animals are also given routine post-operative pain relief medication, which has been proven to be effective in previous similar studies. When adverse effects may be expected, we readily increase the frequency of monitoring to identify animals that may be experiencing adverse effects. We also have our own dedicated animal technicians who ensure that our animals receive close attention if there are any concerns. We have achieved a number of significant refinements during the previous series of studies, including: enhanced environmental enrichment (such as extra card-board housing); use of high-energy or tasty diets to prevent weight loss; improved techniques for transplantation of cells in the kidney or abdomen (such as using special needles to shorten the duration of the procedure) and administration of toxins into a specific organ to prevent spread of the toxin in the whole body. Where adverse effects may be expected, we will perform particularly close and frequent monitoring of animals. These will include the use of observation sheets and body weight records. We will continue to strive to develop new refinements.

A important aim of many of the proposed experiments is to determine how long cellular therapies survive after transplantation. Where possible, we will use imaging methods to monitor the survival of the transplanted cells. Such imaging can be performed using a short anasethetic (lasting less than 5 minutes) and without any harm or surgical procedure on the animal. Importantly, this means that we can obtain important data from the same animals over several weeks, without having to cull animals at multiple time points.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will be conducted and reported in adherence to best practice guidelines including those published by the Laboratory Animal Science Association (LASA). We will follow guidelines on record keeping, performing surgery, education and training, and reporting of experimental results. We will also follow the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines on experimental conduct including study design, randomisation, avoiding bias and statistical analysis of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a current project license holder, I am closely involved with the activities of the 3Rs committee at my institution, including the development of recommendations and dissemination of information relating to advances in 3Rs. I intend to continue with my activities, including through review of relevant publications, guidelines and best-practice information.

66. Non-Clinical Safety

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Toxicity, Rodent, Safety, Assessment

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

- To characterise the toxicity of test substances and/or monitor concentrations of test substances in the body to enable selection of the best candidates for future development as potential new medicines, help improve drug discovery and/or assist with choosing the correct doses for subsequent studies.
- To develop or improve methods used in our studies to understand toxicity of test substances

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
It is important to undertake this work to assist in the selection and development of new medicines that can be used to treat medical conditions in humans and therefore improve

the quality of life for patients. Effective treatments for many diseases are not available because the underlying causes are unknown, and whilst some medicines do relieve symptoms they do not change the underlying causes.

The Company is a science-led healthcare company and our medicines and vaccines are improving the quality of life for patients around the world. However there are still millions of people who would benefit from future advances in medicine development and new or better treatments.

Achievement of the objectives of this project will provide high quality data to help to ensure that only the most favourable substances (medicines) are selected for further development and ultimately reduce the impact of human diseases.

What outputs do you think you will see at the end of this project?

High quality information generated from animal studies conducted under this project is expected to enable decisions to be made on whether a potential new medicine (substance) should continue into the next phase of development or be stopped from development because of unfavourable characteristics.

The information may also be used to improve the way in which potential new medicines are discovered and synthesised by the Company.

The benefit of stopping development of unsuitable substances early in their development is that it will avoid toxicity evaluation in larger studies using more animals, and allow resource to be focussed on other substances, improving the potential of bringing medicines more quickly to patients. In addition, data generated from studies conducted under this project may be used to help choose doses for subsequent studies, help to identify measurements which should be monitored during subsequent toxicology studies or may be used to modify the substance to increase the chance of it successfully becoming a new medicine. The data generated may also provide information that shows how a potential new medicine may cause toxicity which will support assessing the risk for patients who may ultimately take the medicine.

Without these studies progression of potential new medicines to early human studies and to patients cannot occur.

The design of studies conducted under this project will be kept under review and it is possible that further development, validation or refinement may be required (for example due to advances in technology) to improve the information that they provide.

Who or what will benefit from these outputs, and how?

The purpose of this project is to provide data to contribute to the overall process of medicine development with the ultimate goal of developing safe and effective medicines for the benefit of patients. The data generated from small early studies in rodents will be provided to the Company’s Project Development Teams.

The data may be used for:

- Making decisions on which potential medicine candidates show promising characteristics for future development and which medicine candidates show

unfavourable characteristics for which development will be stopped.
- Provision of information to help choose doses that may be used in future studies.
- Helping drug discovery teams choose better candidates for potential medicines.
- Understand how toxicity may have occurred and how findings in animals may also be seen in humans.
- The preliminary toxicity of test substances will be assessed as follows: Assessment of general toxicity
- The purpose of general toxicity studies is to generate data to understand the general effects that a test substance will have in the body usually by assessing effects on various tissues and blood constituents. The goal of these studies is to investigate the relationship between the various doses of the test substance administered and any adverse effects observed.
- Assessment of genetic toxicity

The purpose of genetic toxicity studies is to investigate the test substance's ability to damage genes (i.e. DNA). If the damage is not repaired effectively then this can change the DNA sequence to cause mutations, which result in changes to or loss of gene function. The most serious mutations in cells of the body can lead to cancer or inherited birth defects. Therefore, it is important to identify this potential hazard early in drug development to avoid exposure to humans.

Information may also be generated that can be used within the Company to develop or improve the methods used in our studies to understand toxicity and improve animal welfare. Examples of these may include new ways to measure toxicity (e.g. to detect damage to components of cells), use of new equipment to collect measurements and samples (e.g. use of a specialised camera to measure body temperature or specialised bedding to collect urine), use of new methods (e.g. to enable blood samples with test substance-induced mutations to be stored for longer periods without deterioration).

How will you look to maximise the outputs of this work?

Work conducted under this licence will not be included in scientific publications when it is confidential and is subject to intellectual property constraints. Where these restrictions do not apply, information may be shared (for example work that may involve scientific collaboration with academic or industrial laboratories and be included in scientific publications). Information will also be shared with the wider scientific community if there are potential 3Rs benefits (e.g. refining methods that reduce the impact on animal welfare).

Information generated using this licence is stored in searchable company databases, so that it can be used by all company researchers. The information generated will remain available, even after likely project and personnel changes, and will be a valuable future resource for understanding previous toxicity findings to support company programs for new medicines.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For Regulatory Authorities to give permission to conduct trials of potential new medicines in humans they require their safety to be assessed in regulatory studies in animals, generally in two species of mammals according to published guidance. Studies conducted under this project are small preliminary (non- regulatory) studies conducted early in the development process for decision making purposes.
Since they are designed to provide early characterisation of toxicity and may support subsequent regulatory studies it is necessary to conduct them in the same rodent species (rats and mice) intended for use during the subsequent regulatory development programme. The same animal models and methods are used in the preliminary toxicity studies to correlate the findings with the bigger regulatory studies.

Rats and mice will be used for this project because they are acceptable to Regulatory Authorities for the assessment of toxicity. Adult animals will be used since they have developed physiology and organ systems representative of human patients, and align with the ages of animals used in regulatory studies.

Typically, what will be done to an animal used in your project?

During preliminary toxicity studies animals will normally be given a dose of test or control substance once or twice a day via the mouth, nose or injection into a vein, under the skin, into muscle or the abdominal cavity. Usually only one route will be used but rarely, a combination of two of these routes of administration may be used on each dosing occasion (for example where the intended route of administration in humans will not result in high enough blood and/or tissue levels to explore toxicity in animals). Where possible, the same route as that intended for humans will be used. Dosing will typically be carried out for 3 to 14 days but may range from a single dose to 28 days dosing. Typically, three groups of animals will be given different doses of the test substance.

Animals will be restrained to facilitate some dosing routes (e.g. by placing them in clear plastic restraint tubes) typically for under 5 minutes (e,g. when dosing rapidly into a vein) but for up to 4 hours (e.g. for doses breathed in via the nose or when it is necessary to introduce the dose into the vein slowly over a period of time). Prior to dosing by the intravenous route animals may be placed in a warm environment (sometimes with less freedom to move around) at up to 40ºC for up to 15 minutes to assist with locating the appropriate vein.

Animals may be trained for some procedure so that they become used to them before they are used on a study (e.g. prior to dosing, animals may be placed in restraint tubes to get them used to the procedure that will be used during the study).

Typically, animals are expected to experience mild, transient pain and no lasting harm from the procedures used to administer substances.

Blood samples will typically be collected following the first and last dose (and rarely on other occasions) from conscious animals over 24 hour periods during which up to 8 samples will be taken (called a profile) to measure levels of the test substance in the blood

and sometimes to assess any effects that the test substance may have on the components of the blood (e.g blood cells and other elements that normally make up the blood) over the profile. Additional blood samples may be collected on further occasions if a substance is designed to remain in the body for a long time or it is necessary to assess components of the blood in conscious animals on different occasions from when profiles are measured.

Blood may be collected from veins in the tail, legs or neck following introduction of a needle into the vein or by making a small puncture wound over the vein.

Animals will be restrained to assist with blood sampling using clear plastic restraint tubes for typically less than 5 minutes and prior to this they may be placed in a warm environment sometimes with less freedom to move around at up to 40ºC for up to 15 minutes to assist with locating the appropriate vein and dilate the vein to increase blood flow. Conscious animals are expected to experience no more than mild and transient discomfort from blood sampling.

The amount of blood that can be collected from the animals will be kept within carefully controlled limits to prevent adverse effects and only the minimum amount necessary to conduct the measurements will be taken.

In order to assess any effects that the test substance may have caused on the components of the blood, blood samples will also typically be collected at the end of studies with the animals under general anaesthesia. The animals will be killed whilst still anaesthetised. The animals will be aware of the anaesthetic being administered and may experience mild distress but are anticipated to not experience pain.

Other measurements may be necessary to understand the characteristics of the test substance such as:

Collection and analysis of urine that may require animals to be housed singly without food for a period of up to approximately 16 hours to ensure the best quality urine sample. Assessment of effects on the eyes which may require applying drops to the eyes to dilate the pupils, shining a light into the eye to assess pupil constriction or to measure the pressure within the eye by direct contact of test equipment with the eye surface.

An assessment of effects on body temperature either from a microchip injected under the skin or from a temperature probe inserted into the rectum.

These additional procedures are expected to cause no more than mild and transient discomfort.

At the end of the study, the animals will be humanely killed. Tissues may be collected after death and may be weighed and examined to find out if the test substance has caused any changes. Various tissues and /or blood may be used for other purposes (e.g. to determine levels of test substance in them).

Some studies may be performed to develop or improve methods used in our studies to understand toxicity. Dosing and measurements on these studies will be determined by the specific study objectives, but they are expected to not cause more distress or pain than those included on toxicity studies.

What are the expected impacts and/or adverse effects for the animals during your

project?

The most common adverse effects will be loss of body weight or reduced weight gain, and reduction in the amount of food the animals are eating. Other common adverse effects include altered coat condition, reduced activity, postural changes, partially closed eyes, abnormal breathing and fur staining and are likely to be transient in nature, with clear signs of improvement within 2 hours of the onset of signs, and throughout the day following dosing. Generally adverse effects will be absent prior to the next dose or on the next day although some animals may still show slight effects

The majority of animals will experience mild adverse effects with effects of moderate severity estimated to occur in approximately 10% of animals.

In rare cases the severity of adverse effects may worsen rapidly as doses are increased and in these circumstances the animals may experience severe effects or be found dead after dosing despite careful dose selection and close and frequent monitoring.

Animals will be monitored and undergo regular observation and action will be taken to minimise adverse effects. This may result in animals being killed to prevent further suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 90% of animals are expected to experience mild adverse effects, approximately 10% will experience moderate adverse effects and less than 1% will experience severe adverse effects.

Approximately 10% of the total number of studies conducted under this project are anticipated to be preliminary genetic toxicity studies.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Regulatory Authorities require the safety of potential new medicines to be evaluated in mammalian species before they will give permission to conduct trials in humans. There are currently no reliable and robust animal alternatives acceptable to Regulatory Authorities for this purpose. Information generated under this project which is used to make decisions to support the development of new medicines therefore needs to be obtained from studies in the same animal species that are intended to be used in subsequent regulatory safety studies.

Which non-animal alternatives did you consider for use in this project?

Whilst there has been much progress with the development of non-animal alternatives such as organoid cultures (three dimensional cellular structures held within a matrix gel), they are not yet at a stage where the relevance of the data generated from them for humans is fully understood and accepted as suitable alternatives by Regulatory Authorities. Similarly, experiments using many small pieces of isolated various tissues or cells do not yet reproduce the level of complexity and integration of body systems within a living animal such as the ability of cells and organs to continuously communicate. Non animal alternatives are also not yet adequately able to simulate absorption, distribution, metabolism and elimination of medicines throughout the body.

Consequently, non-animal alternatives are not yet fully characterised and/or validated to provide confidence to replace data from studies in animals.

Why were they not suitable?

In order to generate relevant decision making information from studies conducted under this project they need to use the same experimental animal models to correlate with those studies required by Regulatory Authorities before a potential new medicine can be given to humans. There are currently no non-animal models that are considered acceptable to drug regulatory authorities for this purpose and it is therefore not possible to consider the use of non animal alternatives for this project at this time.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals required to support the Company’s plans to develop new medicines has been estimated based on experience of similar work and projects previously supported in the Company.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of groups and number of animals in each group are based on core study designs that have been used extensively in studies conducted by the Company. Using the information generated in preliminary studies, the Company has a track record of successfully designing follow on studies and stopping development of unsuitable substances. The numbers of animals used in studies are typical of those used throughout industry.

Where possible blood samples will be collected using microsampling technology. This allows measurements to be made using reduced volumes of blood and for some studies will support a reduction in animal numbers.

A large pool of scientists are available to provide expertise to assist with the design, conduct and interpretation of the studies and all studies undergo internal scientific and ethical review to ensure the best possible designs.

The use of robust study design principles will be used to maximise the likelihood of generating non- biased experimental results and limit the number of animals needed to generate good quality decision making data.

Where appropriate, samples of tissues or body fluids will be collected for use in future investigations. The results from preliminary cell based assays in mammalian cells to assess genetic toxicity are used to decide what measurements are required in subsequent studies evaluating genetic toxicity in animals. Where possible these cell based assays will be planned so that subsequent measurements in animals can be combined into the same study in order to minimise the number of studies and reduce animal use.

For test substances causing damage to genetic material in cell based assays, methods have recently been developed to evaluate them in rodents used in repeat dose toxicity studies. Previously it was necessary to use specially bred animals for this purpose but where possible this assessment can now be conducted in the same animals used for the preliminary toxicity studies and therefore potentially reduce animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The animal models used in this project are well established with large historical control databases, and have a proven track record for provision of data aiding assessment of toxicity. Where appropriate, these animal models will be modified and refined, to maximise the toxicity information generated during the study (for example using tissue or blood samples for measurements that would normally be conducted in separate studies).

To help minimise experimental variation, studies are conducted in facilities providing an optimal environment suitable for the species, with a limited number of dedicated staff performing the technical procedures, animal care and husbandry. This will help to ensure that animal group sizes are the smallest possible to achieve the scientific objectives of the study.

Where possible microsampling technology will be used to reduce the volume of blood required to assess levels of the test substance in the blood and if feasible the same animals will be used to provide samples to measure levels of test substance in the blood or tissues as those used to assess toxicity.
This allows direct comparison of treatment effects and test substance levels and reduces the number of animals required overall. Where appropriate, samples of tissues or body fluids will be taken for use in future investigations and in some cases, this may avoid the need for separate investigative studies.

Studies may involve ‘staggered starts’ to limit the overall number of adverse effects by reviewing data from previously treated groups of animals before choosing doses for later groups.

Animals will be randomly assigned to experimental groups using a computer-generated random number generation system which will reduce bias in animal allocation that could

influence the data generated.

Although experimental work authorised by this project is not performed using Good Laboratory Practice (GLP) guidelines it is performed to the general standards of GLP in order to ensure quality and data integrity.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Studies conducted under this project are small preliminary (non regulatory) rodent studies conducted early in the development process typically to characterise the toxicity of test substances with the potential to become human medicines.

Information from preliminary studies is used to make decisions which include selection of potential new medicines with favourable characteristics for progression into the next phase of development, selection of doses for subsequent studies, helping drug discovery teams choose better candidates and potentially may also help understand the causes of toxicity and whether findings in animals are also seen in humans. They are not designed to provide data to allow Regulatory Authorities to authorise testing of potential new medicines in humans because they do not comply with the study design guidelines required by Regulatory Authorities for this purpose. Such regulatory studies are conducted outside of the Company at Contract Research Organisations. However, the same animal models and methods are used in the preliminary toxicity studies to inform and influence the designs of the bigger regulatory studies.

Preliminary toxicity studies (both general toxicity and genetic toxicity) are generally short studies (typically 3-14 days) using small numbers of animals (with controls as appropriate) to understand how effects relate to the dose of test substance administered. The first phase of genetic toxicity studies is used to determine a maximum tolerated dose that can be used in the second phase to assess damage to the genetic material.

During these studies the animals will be observed regularly to monitor changes in appearance and behaviour and an assessment of their body weights and amount of food they consume will usually be made to assess any potential effects that the test substance may have on the animals' general wellbeing. Blood samples will typically be collected to assess concentrations of the test substance in the body (in either the animals used to assess toxicity or in separate satellite animals (dedicated to providing blood samples), depending on the volume of samples required), and to assess any changes in blood components. Tissue samples will typically be examined to evaluate any changes in their weight, structure and function (and may occasionally be used to assess concentrations of test substances in them). For genetic toxicity investigations blood or tissues will be analysed for evidence of genetic damage.

Occasionally, based on knowledge of the test substance being studied, other measurements may be required such as analysis of urine, measurement of body temperature and an examination of the animal's eyes. Occasionally, information will be generated to develop or improve methods in our studies leading to 3Rs benefits. The measurements collected during preliminary studies are similar to those widely accepted by regulatory authorities to assess the toxicity of potential new medicines in regulatory studies. Prior to conducting preliminary general toxicity studies information will typically have been generated to ensure that a substance has the desired qualities to be considered suitable for development. This may include information from the use of predictive computer software packages, the literature and early assays in cells to predict safety concerns that may be associated with the substance or its mechanism of action. A limited assessment of how the substance persists in the body over time is also typically available and in some cases data from other studies conducted using the same substance or with similar substances may be available to support dose selection.

A tiered approach will be used for evaluation of genetic toxicity. A literature-based assessment is initially performed to identify potential issues that might occur, and expert computer systems will be used to determine if there are any concerns that the chemical structure of the test substance could cause toxicity. This information can also be used by drug discovery teams to improve the quality of future test substances. There is a strong correlation between a test substances ability to cause genetic toxicity in bacterial cells and cancer in rodents so if a test substance does cause genetic toxicity in bacterial cells it would typically be stopped from development prior to the use of animals. Test substances that show potential genetic toxicity in tests using mammalian cells or when there is concern about how they work in the body, may be assessed in preliminary genetic toxicity studies in rodents to understand if genetic toxicity might be produced in humans.

Regulatory Authorities generally require characterisation of toxicity in regulatory studies at maximum tolerated doses or doses that are large multiples of the levels of test substances anticipated to be used in humans. Since studies conducted under this project may be needed to support subsequent regulatory studies it is therefore generally necessary to perform them at high doses that may produce clear signs of toxicity. This may cause the animals to show clinical signs, reduced body weight gain or body weight loss and/or reduction or cessation of food consumption.

The scientific endpoints are those considered to be the minimum required to achieve the study objectives. The core study designs are based on internal guidance in order to provide quality decision- making data balancing the need to achieve study objectives while minimising animal use. The core study designs have been used extensively under previous project licences, and in other facilities, and have proved successful in characterising the toxicity of test substances and/or assessing the concentrations of test substances in the body. They are generally in line with those used throughout the pharmaceutical industry.

The combination of activities outlined in this section will ensue that the study objectives are achieved whilst causing the least pain, suffering, distress, or lasting harm to the animals.

Why can't you use animals that are less sentient?

There is a mandatory regulatory requirement to characterise the toxicity of potential new medicines in mammalian species (rodents and non rodents) during the programme of regulatory studies. Preliminary toxicity rodent studies need to use the same rodent species

intended for the regulatory programme and accepted by Regulatory Authorities, to ensure the outcome of the preliminary studies are likely to be predictive of the outcome of the studies conducted during the regulatory programme. Since findings in animal studies are used to understand the potential risks of giving a potential new medicine to humans experiments will normally be conducted in conscious young adult animals with complex, integrated and well-developed physiological mechanisms and organ systems representing those of patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experiments described within this project will undergo continual review to ensure that the number and frequency of procedures and necessary harms caused will be kept to the minimum required to achieve the study objective.

All animals will be monitored closely after dosing with the frequency of observations related to the nature and intensity of any adverse effects observed. Where the condition of an animal gives cause for concern, observations will be continued until clear signs of recovery are evident or further action will be taken to ameliorate them.

Additional refinements to the cage environment (e.g. provision of enrichment) and good practice in animal handling will be considered and implemented where practicable throughout the duration of this licence. During the course of the previous licence, various refinements were implemented including:

- Use of nesting material to provide environmental enrichment for rats without compromising regulatory requirements.
- Use of additional nesting material as well as paper based nesting material to provide environmental enrichment to mice without compromising regulatory requirements.
- Changing the way that mice are restrained for procedures by using a soft (e.g. sponge) rather than a rigid surface.
- Handling of mice using tube/tunnel/cupping method.
- Regular attendance at our scientific and ethical review forum by representatives from research statistics as part of the scientific and ethical review of studies.
- Introduction of enhanced caging for a study with an extended duration. This will be considered for future studies where applicable.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following published documents will advise on experimental design, animal welfare and husbandry during the life cycle of this licence:

- Guidance on the operation of the Animals (Scientific Procedures) Act 1986. (Home Office 2014).
- NC3Rs - Responsibility in the use of animals in bioscience research: expectations of the major research council and charitable funding bodies (2019).
- LASA - Guiding principles on good practice for animal welfare and ethical review bodies. (2015)
- Prescott MJ, Lidster K. Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46:152-156, (2017).

- Review of harm-benefit analysis in the use of animals in research. Report of the Animals in Science Committee Harm-Benefit Analysis Sub-Group chaired by Professor Gail Davies (2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Company’s Named Information Officer (NIO) will help distribute information associated with animal welfare, best practice and 3Rs. The project licence holder and other key personnel who operate under this licence, also regularly attend the Company’s internal Animal Welfare and Ethical Review Body (AWERB) meetings, where animal welfare, best practice and 3Rs related information is shared.
Furthermore, regular referral to the NC3Rs website, published literature (including new or revised guidance issued by Regulatory Authorities), and feedback from external conferences, symposia and workshops will ensure that advances in 3Rs are identified. 3Rs matters are highlighted, discussed and action taken to implement within the Company via these forums.

67. Connectivity and plasticity of developing and mature central nervous system circuits

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neurobiology, Synapse formation, Synaptic plasticity, Development

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how neuronal circuits in the brain form and are modified by experience.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work carried out here will not only enhance our understanding of how the brain is built during development but also provide insights into how organisms can adapt to their environment. This work may also shed light on key events that are compromised in neurodevelopmental disorders, such as autism and epilepsy, and may identify targets for future treatment.

What outputs do you think you will see at the end of this project?

The main outputs form this work will be in novel findings regarding the how brain forms, matures and adapts to its environment. The general understanding of the developmental processes that lead to the correct formation of our functional circuitry in the brain is essential to comprehend the complex brain functions such as memory, learning and behavior and makes it one of the fundamental issues in developmental neuroscience. But it is also important for processes involving axon regeneration after injury or disease and for understanding the mechanisms of neurodegenerative diseases. Notably, studying the mechanisms of neural circuit assembly will also help to gain insights into the basis of a range of mental disorders, such as Schizophrenia, bipolar disorder or autism, where links to neurodevelopmental causes, such as the establishment of axonal pathways or synapse formation have been established. In addition, this research has important links to epilepsy research, where circuits become hyperactive and loose stability.

Who or what will benefit from these outputs, and how?

The general understanding of the developmental processes that lead to the correct formation of our functional circuitry in the brain is essential to comprehend the complex brain functions such as memory, learning and behavior and makes it one of the fundamental issues in developmental neuroscience. We expect this work to lead to a greater understanding of the normal developmental processes that occur during synaptic and circuit formation in the developing brain, and how these processes are modified by the environment or perturbed in models of neurodevelopmental disorders such as autism spectrum disorder, epilepsy and schizophrenia. It will also establish *in vitro* and *in vivo* systems that we will use to test novel pharmacological agents.

In the short-term our findings will be useful to better understand the basic mechanisms behind the brain development and plasticity. This will mainly benefit scientists in the field. In the longer-term, we anticipate that our findings will also have an impact on clinical applications. The close links of this research to neurodevelopmental disorders could lead to the identification of potential cellular/molecular processes that can act as targets for drug treatments. We therefore anticipate that our findings may have an impact on clinical applications.

How will you look to maximise the outputs of this work?

We will make our data available first as preprints in BioRxiv and then through peer-reviewed scientific journals that can be accessed through PubMed, allowing our main findings to be monitored for accuracy and content. In line with current policy we will also ensure that data are published in journals with an open-access policy of not more than six months. Any reagents produced will be made freely available to the scientific community immediately on publication. We plan to publish and/or present our data at meetings.

Species and numbers of animals expected to be used

- Rats: 490
- Mice: 11600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will do these experiments in rats and mice. It is critical to achieve a balance between relevance to humans and sentience, and we feel that rodents offer the best compromise. The regions of the brain that are known to be important for neurodevelopmental disorders are reflected in rats and mice, and choice of model can be validated with relevant behavioural phenotyping (which, although caveats apply, are more relevant than, for example, in invertebrate species, and impossible in purely in vitro approaches). Further, mice are ideal due to the number of transgenic mice available including disease- relevant mutations and reporter lines, and increasingly transgenic rats will be available as well. Although currently there is limited availability of transgenic rats, rats have a wider repertoire of behavioural tests available and show better pharmacological alignment with humans so will increasingly will be the model of choice. The availability of inducible and conditional mouse lines allows specific targeting of developmental stages and cell types/circuits, which also minimises adverse effects. Additionally, in collaboration with molecular biologists, we can reduce or overexpress candidate molecules and examine their effect on the development of connectivity. Working with rats and mice also builds on the wealth of knowledge and research already available and minimises unnecessary repetition.

Typically, what will be done to an animal used in your project?

Animals in this project will mostly be transgenic animals (Protocol 1) where the expression of specific genes, some of which can be induced (Protocols 2 and 4), will allow us to either visualize or modify the activity of neurons but will have no harmful side-effects. In some instances, animals may undergo surgeries to either introduce genes or cells into the brains of mice at the embryonic (Protocol 3) or post- natal (Protocol 5) stage. In addition, to establish the role of neuronal activity on the development of the brain, we will also alter neuronal activity in animals during development to assess the role this plays in the formation of neuronal circuits in the brain (Protocols 1 and 5 to 7). Using tools that allow the visualisation and modification of neuronal circuits we will then measure the properties of neurons and the networks that they form (Protocols 6 and 7). This will initially be done in either in vitro or ex vivo systems for which mice will be sacrificed and the neurons from the brain removed to assess their properties (Protocol 6). Alternatively, neurons and their circuits will be imaged in vivo (Protocol 7).

What are the expected impacts and/or adverse effects for the animals during your project?

There is a low risk of complications that may arise from the anaesthetics and surgeries performed in this project and an equally low risk of post-surgical infections. Both will be monitored and minimised. The delivery of genetic and cellular material into embryos and post-natal animals are not expected to exhibit any harmful adverse effects, other than complications that may arise from the anaesthetics and surgeries described above. Finally, the in vivo imaging of neurons in the brain will require the implantaiton of a small cranial window that is not expected to exhibit any harmful adverse effects other than those that may arise from the anaesthetics and surgeries.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The procedures described here will be mild (Protocols 1) or non-recovery (Protocol 6) and will never exceed a moderate severity (Protocols 2, 3, 4, 5 and 7).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand the fundamental processes underlying the development of synaptic and circuit development of the brain, and how they are modified by experience, we need to be able to manipulate the expression of genes and environment, as well as conduct invasive experiments that are not possible to do in humans. Mice provide an excellent mammalian system for the type of experiments proposed here. Mice share 95% of their genes with humans and genes linked to diseases in humans have also been shown to cause similar deficits in mice. They are relatively easy to maintain, reproduce rapidly and there are many transgenic animals that help scientific research. As a result, mice have provided an advantageous model system due to their close genetic and physiological similarities to humans, as well as the ease with which their genome can be manipulated and analysed.

Which non-animal alternatives did you consider for use in this project?

We have considered a number of non-animal alternatives. In fact, we will conduct a significant amount of the proposed work in vitro and ex vivo, predominantly in acute or cultured brain slices and cultured dissociated neurons, which will complement our study. In addition, we will also include using human iPSC-derived neurons and grown in vitro. Finally, we also considered the possibility of using zebrafish, a model system that we have used in previous collaborations.

Why were they not suitable?

Although in vitro and ex vivo rodent neurons will be useful in some mechanistic studies, to fully understand mechanisms that underlie normal development and how these are changed by experience, we will need to conduct work in vivo as well. We are also experimenting with the use of human iPSC- derived neurons grown in vitro but we find that this technology is not reliable yet and shows a large variability when assessing the formation of neuronal networks. Although promising, it is still an emerging technology with many caveats that need solving. Finally, although we have also considered using zebrafish as a possible system, we find that in many cases they have very different neuronal morphologies to rodent neurons (eg: most axons in the visual tectum originate from distal dendrites) that make it harder to interpret our findings.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were calculated based on the known or anticipated success of surgical procedures, biological variability and measurement variability. For example, experiments relying on repeated imaging of neuronal structures during development require a number of experimental steps with relatively low chances of success. Implantation of chronic imaging chamber is successful on 80% occasions (due to bleeding, damage to dura, or animals failing to recover fully from surgery). Before the animals enter a chronic imaging protocol, they are allowed to recover from surgery. During this time, bone growth, thickening of dura, and/or the incidence of infection can obscure the transparency of the imaging window which is essential for obtaining high-resolution images with a two-photon microscope. Only about 35% of successfully implanted animals pass this stage. As chronic imaging continues, the
windows of more and more animals grow over due to bone growth), such that on average only about 15% of the successfully implanted animals outlast the imaging protocol. Moreover, because imaging is carried out in animals expressing fluorescent proteins in a subset on neurons in the brain, the likelihood of finding labelled cells in the correct brain regions is about 50%. Thus the total success rate is 80% x 15% x 50% = 6%. It follows that for a control experimental group, data from at least 10 successfully imaged animals is necessary to carry out statistical comparisons (i.e. in this example, 10 / 6% = 167 animals requiring surgical implantation). In addition, the delivery of genes/cells/labelling agents to the brain has a limited success rate (about 75%), which further reduces of carrying out a experiment to its full completion. All these parameters were taken into account when assessing overall animals numbers needed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The proposed experiments will generally use factorial experimental design, which will maximize the data collected from each animal. We will use the appropriate statistical methods for analyzing the data (largely MannWhitney or ANOVA), and seek statistical advice as necessary. All experimental groups will be randomised and blinded where possible, and analysis of data will be done blind and/or automated. As soon as preliminary data is available to calculate effect size (Cohen’s d) appropriate power calculations will be undertaken to optimise sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

By doing much of our work in vitro or ex vivo experiments in tissue, either following schedule 1 or terminal anaesthesia, we will be able to obtain data from multiple cells and/or tissue slices to maximise data obtained from each animal. Further, we will use

tissue from transgenic animals of both sexes and all genotypes post-schedule 1, meaning we will generate far more information without any additional numbers of animals or suffering. Where specific brain regions are used we will store any remaining tissue for future use, to prevent unnecessary animal use. Where possible we will use internal controls (eg unaffected brain hemisphere) or paired 'before and after' design (eg for drug studies) to maximise power and minimise numbers.

We will minimise variability by using inbred strains of mice, housed in standard conditions, ensuring careful matching of age and standardisation of experimental protocols, including good breeding colony management. The use of live imaging will also allow a reduction in the number of animals used as data from sequential times is obtained, rather than using different animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of species/model:

We will do these experiments in rats and mice. It is critical to achieve a balance between relevance to humans and sentience, and we feel that rodents offer the best compromise. The regions of the brain that are known to be important for neurodevelopmental disorders are reflected in rats and mice, and choice of model can be validated with relevant behavioural phenotyping (which, although caveats apply, are more relevant than, for example, in invertebrate species, and impossible in purely in vitro approaches). Further, mice are ideal due to the number of transgenic mice available including disease- relevant mutations and reporter lines, and increasingly transgenic rats will be available as well. Although currently there is limited availability of transgenic rats, rats have a wider repertoire of behavioural tests available and show better pharmacological alignment with humans so will increasingly will be the model of choice. The availability of inducible and conditional mouse lines allows specific targeting of developmental stages and cell types/circuits, which also minimises adverse effects. Additionally, in collaboration with molecular biologists, we can reduce or overexpress candidate molecules and examine their effect on the development of connectivity. Working with rats and mice also builds on the wealth of knowledge and research already available and minimises unnecessary repetition.

Choice of method/minimize suffering:

The methods outlined in the protocols in this application have been carefully chosen to allow us to achieve our objectives while minimising animal suffering. The vast majority of animals will only undergo a single procedure, and much of the work will be done in fixed tissue or in vitro / ex vivo using tissue obtained after Schedule 1 or terminal anaesthesia. All animals undergoing surgery will be given analgesics to minimise suffering and the

electroporation system we will use has been shown to result in optimum survival and minimal tissue damage. Further, many of our preliminary experiments will be conducted either in cell culture or in live tissue taken from wild type rodents which will enable us to plan experiments and minimise animal usage and suffering. Finally we aim to implement a variant on the standard methods of in vivo imaging that is much less invasive and therefore represents a refinement of technique.

We do not plan to use any protocols categorised as severe.

Why can't you use animals that are less sentient?

This work centres around the development and plasticity of neurons in the brain. In particular, these studies focus on understanding how sensory inputs can modulate brain development and are also linked to developmental disorders, such autism, schizophrenia and epilepsy. As a result, we need to work on animals that are closely related to humans but where we can also perform invasive experiments. Mice provide an excellent mammalian system for the type of experiments proposed here. Mice share 95% of their genes with humans and genes linked to diseases in humans have also been shown to cause similar deficits in mice. They are relatively easy to maintain, reproduce rapidly and there are many transgenic animals that help scientific research. As a result, mice have provided an advantageous model system due to their close genetic and physiological similarities to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will make sure that animals undergoing a procedure undergo the best care possible. This includes a constant re-evaluation of post-operative monitoring and care to minimise welfare costs following a procedure. In parallel to this, we include in each protocol, stringent pain management procedures to further decrease discomfort that we have developed over the past 5 years. These procedures will be regularly re-evaluated an updated to reduce harm as much as possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will keep up to date with the current literature to ensure our experiments are designed optimally. Individual experiments will generally involve factorial designs, to maximise the information gathered using the minimum number of animals. For the design of complex experiments, advice of a statistician will be sought.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow, as we regularly do, the 3Rs section of the NC3R website. This site provides all the latest information and advances in this area.

68. Breeding and Maintenance of GA poultry lines

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Breeding, Maintenance, Poultry

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to breed and maintain genetically altered poultry lines. This licence will act as a service licence to facilitate the provision of genetically altered eggs, embryos and birds to other research projects. By providing these valuable tools, a wide range of scientific research will be facilitated.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chickens, eggs and embryos can provide a valuable model for a wide variety of scientific research programs. Globally the chicken is the most numerous agricultural animal. Gaining greater knowledge of the species has important implications for poultry and human health and can contribute to global food security. Better understanding of the species can be utilised to improve welfare standards of farmed chickens. By breeding birds on this licence, a wide range of research will be possible.

What outputs do you think you will see at the end of this project?
This purpose of this project is to support the research goals of institute and greater scientific community. The measurable outcome of work carried out will be the provision of

GA eggs, embryos and chickens.

New information and publications subsequently arising from use of this material are likely be high given the diversity of projects which will be supported. Lines held under this licence have provided the basis for greater understanding and publications in developmental biology such as eye and limb formation.

Development and structure of cells and organs have also be strongly aided by these lines.

Who or what will benefit from these outputs, and how?

Material generated under this licence will be supporting a wide range of projects including chicken physiology, immune function, vaccine development and productivity. The potential benefits will be relevant to be human and chickens. Poultry disease can have severely detrimental effects upon commercial and subsistence farmers. Through greater understanding of the chicken and its' immune system, there is potential to reduce disease incidence and increase food security.

Agricultural companies will potentially benefit as their production costs though greater understanding of the birds and how to increase their production capabilities.

How will you look to maximise the outputs of this work?

By its nature, this project is supportive to and reliant upon a collaborative approach. Detailed records of material supplied internally and externally to the institute will be kept. Details of successful publications for institute staff and students are collated and displayed on an external facing website. Other initiatives such as the recently held Avian Research Symposium (Feb. 2021) encourage information sharing and collaboration. Strong links with external researchers utilising material generated from this project will help to share positive and unsuccessful lines of enquiry.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The main driver for production of GA chickens specifically is the downstream requirement for material for use in related projects. Utilising the chicken is a valuable model. Study of GA eggs and embryos can allow research, such as developmental biology, to take place at a very early developmental stage. The benefit, when compared with mammalian models, is the ease and non-invasive way in which the egg/embryos are collected. Juvenile and adult birds are required for projects such those studying the immune system and vaccination effects.

Typically, what will be done to an animal used in your project?

The main remit of this licence is the provision of GA embryos, eggs and chickens. Given the scope, the licence will be minimally invasive. Blood samples may be taken to confirm the presence and the nature of the genetic alteration. Birds will generally be group housed with natural mating allowed to take place. Natural mating may be supplemented with artificial insemination should it be required.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the birds bred under this licence will not display any detrimental effects as a result of the genetic alterations. A smaller proportion of birds may display behavioural and physiological changes due to carrying the alteration. For the most part, any changes are limited to lethargy, reduced weight gain.

Within strains affected by the carrying a genetic alteration, raised mortality against the background strain has been noted. Birds or bird lines which are negatively affected by GA will have a clearly defined care plan.

Birds, though not all, will be blood sampled which may result in localised bruising. Bruising which occurs generally clears over the course of a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority will be subject to a mild severity limit with many individuals falling into the subthreshold category with a smaller number falling into the moderate category. Proportionally, the ratio of birds falling into the two categories is expected 80% and <20% respectively for mild and moderate.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?
The chicken is a globally significant food source with commercial farmed chickens outnumbering humans. Many complex body systems cannot be studied without directly looking at the birds themselves. For birds which are supplied to vaccination and infection studies, observations and data gathered directly from chickens is necessary. When considering developmental biology, visualising developing cell populations and organ development can give unique insights. Use of early age embryos generated under this project will allow other projects replace protected animals are therefore reduce overall numbers.

Which non-animal alternatives did you consider for use in this project?

Given the remit of the licence, there is difficulty in considering suitable alternatives to using an animal model. Dialog with end users will be ongoing and any alternative models which become available for their specific project communicated. Though, it is expected that anyone using chickens bred on this licence will first robustly then continuously seek non-animal models.

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous utilisation of eggs, embryos and birds has been used to inform the estimated numbers within this project. Within each breeding line, numbers will be calculated by taking into consideration the output required and the minimum number of individuals required to maintain a healthy population.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Care and consideration will be used to create bespoke breeding plans for all individual lines. Generally, GA birds bred on this licence have been created on a commercial hen background. Commercial hens will be raised in the unit and periodically interbred with GA lines. By crossing our GA lines with a commercial line, the number of individuals required to maintain a healthy population is greatly reduced.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

By ensuring efficiency in all steps of incubation, hatching and rearing, the number of individuals required for egg production is reduced. Where birds are generated to provide tissue samples, sharing of resources will be strongly encouraged to reduce the overall number of birds required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime

of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Birds will be naturally mated and eggs collected daily. In some cases artificial insemination may be required. In the majority of the chickens, there will be no apparent effect from the genetic alteration. Genotype may need to be confirmed prior to assigning new breeding groups. By using hatching shell waste to determine genotype, this can reduce the need blood sample live birds. All chickens will be held to home office guidelines in floor pens with bedding material to encourage display of natural behaviour.

Why can't you use animals that are less sentient?

Chickens supplied for use within additional projects will only be supplied if the lack of suitable alternative has been robustly demonstrated.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Prior to arranging new breeding programs, where possible, genotype will be determined using egg shell waste negating or reducing the need to blood sample. As procedures other than blood sampling will be undertaken on this licence, the main refinement will be though the promotion of good husbandry practices. Most birds bred will not display any negative effects due to the genetic alteration. Lines which do display an effect will have bespoke care and welfare plans which will be well documented.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All animals will be kept in accordance with the Home Office Code of Practice, though the majority of chickens will be afforded greater space than the minimal requirements. Close communication with the NVS and the Poultry Welfare Taskforce will allow communication of technique development.

Procedures carried out under this project will be undertaken by the dedicated poultry teams, competencies in techniques will be regularly considered to ensure best practice. The NC3Rs website will be accessed with regard to efficient breeding strategies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Care of animals created within this project will be undertaken by our dedicated poultry husbandry and technical staff. There is very strong communication between the poultry team and both Named Veterinary Surgeon and the Animal Welfare Ethical Review Body. The NC3R website will be regularly visited to ensure effective communication of new information. To further promote welfare and best practice, a recently set up Poultry Welfare Taskforce will spearhead raising standards and promoting the 3Rs within our poultry facilities. Methods for creating new lines with reduced incidence of negative effects are being developed within the institute, close collaboration with researchers will allow communication of new developments.

69. Xenopus as a model for vertebrate development

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Xenopus, develomental biology, Stem cell biology, cancer

Animal types	Life stages
Xenopus laevis	adult, embryo
Xenopus tropicalis	adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how animals develop. It is difficult to study development in humans as the embryo develops inside the mother and gestation can take up to 9 months. Scientists therefore use animal model systems such as Xenopus (the African claw toed frog), which are easier to study to look at developmental events.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Knowledge gained from research in model organisms can be applied to human development especially as over the last 100 years it has been clearly shown that many developmental processes are conserved between humans and the rest of the animal kingdom.

In order to assess a genes function, a rapid way of testing whether mutation of the gene

causes a specific phenotype which could be linked to specific disease is required. While primary cell cultures, organoids and biochemical studies are informative in some cases, these cannot reflect the complex interactions that occur within tissues, organs and whole organisms. Although mammalian models can be used, the ethical and financial cost is high so alternatives are sought. Of these, Xenopus is most highly related to mammals and alone shares its genome architecture with humans. Data from labs around the world has shown that Xenopus is an effective model in which to make and test mutations of specific genes in orer to better understand their function in higher orgnaisms.

What outputs do you think you will see at the end of this project?

At the end of this project we would hope to have a better understanding of many aspects of developmental biology. This will be evidenced by the publications of papers in relevant journals and the generation offunding for proposed projects.

Who or what will benefit from these outputs, and how?

In the short term the beneficiaries of our work will be students and other researchers trained in the lab to be the scientists of the future.

The identification and characterisation of developmentally important genes will be of benefit to developmental and cell biologists studying basic embryology. They will be able to integrate the data about the function of these genes into the genetic regulatory networks that drive development. This will lead to a better understanding of developmental processes.

In the medium to longterm our research will be of relevance to understanding the causes of and treating human conditions such as developmental abnormalities, genetic abnormalities, cancer development and metastasis. Our work will have the potential to help others to develop novel treatments or preventatives for such conditions?

How will you look to maximise the outputs of this work?

I will endeavour to publish the groups work wherever possible in appropriate journals. Myself and others in my lab will attend relevant conferences and present our work in the form of invited talks or posters.

Species and numbers of animals expected to be used

- Xenopus laevis: 7500 tadpoles - before protected age (st.45), 125-200 adults
- Xenopus tropicalis: 1800 tadpoles - before protected age (st.45), 50-100 adults

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

We are using the tadpoles of Xenopus laevis (the African clawed frog) and Xenopus tropicalis as model organisms. We use Xenopus because the females can be induced by a simple injection to lay eggs all year around when kept in an ideal environment and this

provides us with a source of embryos (frog spawn). During the course of a year a colony of approximately 150-200 frogs will be induced to lay eggs 1-3 times. The better the quality of care of the frogs the better the quality of the eggs/embryos they produce. To therefore minimize having to repeat experiments it is essential to have healthy animals.

The Xenopus embryos develop outside the mother and they are large which makes observation and manipulation relatively easy. Tadpoles have hearts, livers, brains, eyes and kidneys just like humans. In fact a tadpole with a fully functioning heart, which can be observed beating using non-intrusive methods, develops from a fertilised egg within 4 days. Embryos produced will be used to study questions of cell communication and migration using a variety of methods. Therefore, what we learn in tadpoles about basic cellular and molecular developmental mechanisms will enhance our understanding of development in humans especially with respect to abnormal or disease situations.

Typically, what will be done to an animal used in your project?

Female frogs from whom we need to obtain eggs are injected with PMSG 4-7 days before the eggs are needed in order to prime the animal to generate good and healthy eggs. The day before an experiment the females are further injected with HCG (Human Gonadotrophic Hormone) which induces them to lay their eggs 12-18 hours later. Each female is very gently massaged to get her to lay her eggs in a petri dish. This procedure is carried our 1-6 times over the course of a day with a minimum of 1 hour rest between squeezes. The female is then observed for a further 12-18 hours to make sure they are fine before being returned to the frog facility.

Males (laevis and more commonly tropicalis) are injected with HCG to make them more fertile before they are sacrificed and the testes removed in order to carry out in vitro fertilisation of the eggs.

Note - Commercialy bought Frozen sperm are increasingly being used which means that over time the number of Males being used will decrease.

With respect to embryos generated we will be manipulating genes by loss of function methods (Morpholinos or CRISPR) or gain of function methods (injection of mRNA coding for a gene of interest) to determine their effect on the developing embryo.

What are the expected impacts and/or adverse effects for the animals during your project?
The procedures used are mild and next to no adverse effects are expected with the procedures used.

For any affected tadpoles there will be diverse adverse effects including potentially: heart or circulation defects, craniofacial defects, altered behaviour, gut defects limiting the ability to feed properly and there may even be alterations in overall body structure. Any tadpole showing adverse effects will be humanely killed. Only healthy embryos will be allowed to continue to develop.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the procedures on the female Xenopus and male Xenopus during induction of laying of eggs and fertilisation of the eggs is mild. When used for natural mating the females and males can be reused after a suitable recovery time (minimum 3 months) They can be used in this way multiple times until they reach an age when they no longer produce eggs of a suitable quality (approx 10-15 years of age). At this time they are euthanized. The proportion showing an adverse effect is approx. 0.5-1%.

With respect to genetically altered tadpoles we envisage mild severity in 80-100% and they will be euthanized by stage 45 of development.

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of the proposed work is to obtain fundamental knowledge on the development of a vertebrate organism. This requires working with the whole organism.

Which non-animal alternatives did you consider for use in this project?

Tissue culture, organoid culture, computer simulations

Why were they not suitable?

In development responses and changes occur due to interactions between different cells and tissues. Cell based assays generally use only one cell type so are not a good model in this respect. Organoid cultures can sometimes include more than one cell type but are still limited and do not include a functioning vasculature.
Computer simulations are increasingly being used in development but in all cases in vivo experiments do at some point need to be done to validate and test predictions and hypotheses

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These are based on the numbers needed from past experience and from preliminary experiments, which have effectively been pilot studies for this investigation.

Tadpoles: For each gene we are studying we will keep 50 tadpoles up to the protected age in each experiment, this allows for the natural death rate of tadpoles and to have 30 animals for phenotype analysis. We perform 3 biological replicates of each experiment. For the actual test experiments we will re-create 50 mutations, each requiring 150 tadpoles; 7500 tadpoles in total. In some cases where we are generating founder lines for specific mutants or reporters healthy individuals (approximately 50 tadpoles in total) will be kept until adulthood.

Adult Animals: When the lab is running at maximum efficiently we plan to do 1-2 Frog experiments a week. One frog experiment involves priming, inducing and collecting the embryos from 3-6 frogs. We usually collect eggs most weeks (approx 40 weeks a year). Frogs can be used after a minimum of 3 months. Therefore over a year we would use up to 12 frogs per week for 40 weeks = 480. Frogs can generally be reused 3 times in a year so 480 divided by 3 = 160. So at maximum efficiently we would look to use 160 female frogs in a year.

We do fewer Xenopus tropicalis experiments (approx 20 per year) so need fewer frogs and use fewer tadpoles.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Each week we have a lab meeting of all the Xenopus users at which we determine what people are planning for the following 1-2 weeks. This way we can plan experiments where personnel share the eggs/embryos produced and so maximise the efficiency of one experiment. Occasionally experiments will be delayed or bought forward in order that one day of egg collection can be carried out instead of two.

At this current time we are transitioning to using commercially bought frozen sperm instead of live males for in vitro fertilisation of eggs. This will not fully replace using Males but will drastically reduce the number of Males we do use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our Xenopus facility is designed to keep the frogs as healthy as possible. The healthier the frog the more likely she will produce good quality eggs. If we can be sure of obtaining good eggs we can reduce the number of females we inject for each experiment. We are continually looking for ways to improve the care of the frogs in a cost effective manner. We are planning over time to initiate the chipping of the frog colony. This will enable detailed records to be kept for each frog. those that routinely provide bad quality eggs will be culled to improve the efficiency of the system.

The Xenopus community in the UK and the rest of the world routinely discusses issues of care and welfare for the animals at meetings such as the British Xenopus group meeting and once a year for the International Xenopus meeting or Xenopus PI meeting in the USA. Web sites such as http://www.xlaevis.com/ also provide updated information. I am in routine contact with colleagues elsewhere in the UK and the rest of the world who provide help and assistance on best practice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Xenopus laevis, Xenopus tropicalis We will use Xenopus because:
Large numbers of Xenopus embryos are produced externally and obtaining them requires only a mild procedure (injection of HCG into the female).

We will use tadpoles prior to metamorphosis, when the brain is poorly developed and lacks the region that, at least in man, generates the distress associated with pain. The tadpoles are largely transparent, allowing simple observation of many of the phenotypes produced without invasive methods.

Why can’t you use animals that are less sentient?

We are studying vertebrate development and require embryos to do this. Xenopus laevis and Xenopus tropicalis embryos/tadpoles develop outside the mother which is beneficial compared to mice.

The frog's genome is very similar in structure and detail to the human one and more than 80% of the currently-identified human genetic disease genes are found in it. To use a less sentient animal in which the genome is sufficiently well annotated for these studies means using zebrafish or Drosophila. The latter, in many cases, lacks sufficient protein identity to humans to make it possible to re-create human disease phenotypes. The structure of the zebrafish genome is very different from that of humans/frogs.

In terms of developmental stage, we use the earliest possible for all experiments but have to judge this on a case-by-case basis depending on the cell type or organ affected by introducing the mutation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We mainly propose to use Xenopus laevis and Xenopus tropicalis for our experiments as they are a well characterised and well used model organism for vertebrate development. They are relatively easy to keep and the adults are subjected to only mild procedures.

As mentioned before we are gradually transitioning to using frozen laevis and tropicalis sperm for in vitro fertilisation. This will in time lead to needing less males in our facility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Online protocols are published by many Xenopus labs and are often available on lab websites. Xenbase and the Xenopus Stock Centres in the UK and the United States also publish standard protocols. Online forums and the biannual International Xenopus Meeting and Xenopus PI Meeting also allow for free exchange of knowledge and best practice.

In addition Cold Spring Harbor Protocols publishes may papers in the 'Xenopus Collection' (http://cshprotocols.cshlp.org/cgi/collection/xenopus) which provide an up to date resource.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am in regular contact with colleagues in the UK and the rest of the world from whom the latest news and advances in Xenopus research can be learnt. The Xenopus community has an online news magazine called Xine from which news is obtained. In addition the Xenopus community in the UK and the rest of the world routinely discusses issues of care and welfare for the animals at meetings such as the British Xenopus group and once a year for the International Xenopus meeting or Xenopus PI meeting in the USA. Web sites such as Xenbase (http://www.xenbase.org/entry/) and http://www.xlaevis.com/ also provide updated information.

70. The role of hormones, genes and diet in diabetes in rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Diabetes, Genes, Diet, Metabolism, Therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to understand how interactions between hormones, genes, environment and diet lead to diabetes in rodent models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Type 2 diabetes mellitus (T2DM) currently affects ~5% of the UK population, with a rising incidence. Patients with T2DM do not live a normal healthy lifespan, instead suffering a number of complications and living on average 10 years less than someone without the disease. Complications include blindness, amputation, nerve problems, kidney problems, as well as increased risk of developing cancer and heart disease. Despite this, the

mechanisms underlying the onset of T2DM are still not well known. This might be in part because T2DM research receives just a fraction of the funding devoted to cancer and heart research. At its most simplistic, T2DM occurs in genetically susceptible individuals exposed to a permissive environment (e.g. diet, lack of exercise). Over the last two decades, rodent models have made important contributions to our understanding of how genes and environment interact to cause T2DM. This is because we can precisely control the environment of rodents, as well as manipulate specific genes. Thus, rodents have uncovered how risk genes contribute to T2DM, and have shown how diet and obesity influences the development of the disease. Moreover, 'preclinical' rodent models have been used to test responses to diabetes therapy, with a number of these treatments now used widely in the clinics (e.g. incretin-mimetics). The present project aims to use the latest rodent models of diabetes to provide new insight into how genes and environment influence T2DM, and how this can be treated. The results are directly relevant for human medicine and will go on to inform new treatments for T2DM.

What outputs do you think you will see at the end of this project?

The studies will identify a number of new genes that contribute to T2DM risk. In addition, the effects of environment, in particular diet, upon gene function will be better understood. This new information is important for understanding why some people develop T2DM, why others don't, and how we treat the disease. New findings will be published in the scientific literature, where they can be accessed by others. We will also work closely with stakeholders (i.e. patients with T2DM and the general public) to present our findings, for example through online webinars, lab tours and involvement in research planning. Should we identify genes with direct relevance for drug therapy, we will protect the intellectual property before working to translate the findings into human benefit. Lastly, we anticipate the development of new mouse strains which will: 1) provide new information about T2DM and how can we treat it; 2) be used in drug development programmes; and 3) reduce the number of animals used in drug testing (e.g. by allowing us to screen beta cell mass non-invasively and longitudinally).

Who or what will benefit from these outputs, and how?

Publication of new results and animal models will be important for others who may want to adopt similar approaches (3 years). Development of animal models for more refined drug screening is attractive, since methods to longitudinally measure responses to treatment are more powerful and require fewer animals (5 years). The general public will benefit over the longer term, since the project will provide a better understanding of the causes of T2DM (10 years). Finally, clinical trials or therapy may be informed by the studies here, leading to better outcomes for T2DM patients (10 years).

How will you look to maximise the outputs of this work?

Positive and negative results will be shared with the wider scientific and clinical communities through presentation at conferences, publication on free-to-view servers or open-access scientific journals. New techniques and protocols will be rapidly posted online and shared with the field. New animal models will be freely distributed to academics and industry so that they can be further validated, at the same time informing the results of our own work. Where the results have the potential to impact human health and wellbeing, we will seek to protect the invention so it can be brought to market. Lastly, we will also engage with the public, focusing on people with lived experience of T2DM.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used, since we need to perform genetic alterations for which this species is most amenable and well characterised. Moreover, the study is based on research already performed using mice. Mice will be studied as neonates and juveniles to understand pancreas development. Mice will be studied as adults, since this is the most relevant model for the study of T2DM and is reflective of the disease in humans.

Typically, what will be done to an animal used in your project?

Genetically-altered (GA) mice and their control littermates will be bred using established crosses and husbandry techniques. Most GA mice will possess the gene deletion/overexpression from birth, but in some cases we will need to administer a single injection or special diet to induce gene deletion/expression in adults (for example because the gene affects pancreas development). Some mice will develop diabetes on normal diet, but the majority will need to receive a diabetes-causing diet or diabetes-causing drug, typically delivered in the drinking water or via injection. Some mice will act as controls and receive normal diet or placebo. Diabetes progress is monitored by taking blood samples every 2-4 weeks to measure glucose/insulin/glucagon in response to glucose/insulin/pyruvate, as in humans. Mice will be treated for diabetes using drugs used in human medicine, administered in the drinking water, gavage or via injection. Responses to treatment are monitored by taking blood samples every 2-4 weeks to measure glucose/insulin/glucagon, as in humans. Mice may be humanely killed before and after diabetes induction and treatment, to allow detailed in vitro examination of the pancreas.

What are the expected impacts and/or adverse effects for the animals during your project?

Genetically-altered mice might spontaneously develop diabetes. Diabetes is well tolerated in rodents and is associated with excess urination. Blood sampling for glucose/insulin/glucagon is associated with mild discomfort and transient pain during the collection of samples. Administering diabetes-causing diets can lead to excess urination. Diabetes-causing diets can lead to skin irritation due to a greasy coat, although this is rare as animals are fed from bowls on the cage floor rather than from a hopper above. Administration of diabetes-causing drugs is associated with mild discomfort and transient pain due to injection. Administration of diabetes medication is associated with mild discomfort and transient pain due to injection. The estimated duration of these effects is 8-12 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category

(per animal type)?

About 25% of mice will undergo a combination of procedures, like diabetes-causing diet, blood sampling for glucose/insulin/glucagon levels and diabetes treatment. This will be classed as moderate severity.

The remaining 75% of mice will only be used for breeding and/or will be used as tissue donors, and will not undergo a combination of procedures. This will be classified as mild severity.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We investigate how genes and environment contribute to the development of T2DM. This is a complex disease which perturbs many systems involved in regulating blood glucose levels and can only be examined in mammals. Indeed, humans and rodents regulate their blood glucose levels using conserved mechanisms and it is because of this that rodents have gone on to be the most widely used preclinical diabetes model.

Which non-animal alternatives did you consider for use in this project?

Primary and immortalized cultures, as well as computer simulations, have guided the studies proposed here and will continue to be used. Islet-like structures derived from human embryonic stem cells (hESC) have also been considered.

Why were they not suitable?

Cell lines cannot be used alone, since they lack proper cell-cell interactions present in the native pancreas and they are unable to replicate the in vivo mechanisms that regulate blood glucose levels. Computer simulations are helpful for setting parameters and modelling system dynamics, but rely on in vivo data as input and can’t replace in vivo models. Islet-like structures still function poorly, since the derived cells are not as mature as those in primary islets. Moreover, use of hESC presents its own set of ethical challenges.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

First, we define the exact measure that we will analyse (e.g. blood glucose, body weight etc). We then determine what the independent replicate is (each cell, each animal, each day?). Expected effect size (i.e. how big the change is) is determined through our previous studies, consultation of the literature, cell culture based in vitro analysis or through small pilot experiments when possible. Finally, from these pieces of information we can accurately calculate the number of animals required to produce a statistically robust result.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs Experimental Design Assistant to design experiments and taken advice from researchers who have performed similar research projects in the past.

The minimum number of animals required to give a valid result has been calculated using careful statistical analysis. Moreover, animal use will be minimised by validating the majority of experiments firstly in vitro, or by using computer simulations to refine experimental parameters. Throughout, we take steps to reduce subjective bias, as well as undertake the most appropriate statistical analysis. In general, experiments will involve a factorial design that will maximise the information obtained from a minimal number of animals. Furthermore, data can be obtained from the same animal at different time points, which increases experimental power and reduces the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Inbred mouse strains will be used to minimise genetic variability and skilled technicians and lab members will be used for animal handling. Breeding strategies will be optimized to avoid animal wastage. Tissue not used in the present project (e.g. liver, gut) will be made available to other investigators who investigate T2DM. All tissue will be stored and made available to other researchers in the field, including posting of imaging and genetic datasets on public databases. A PREPARE guidelines checklist will be completed before each new experiment. Data from the experiments will be published in accordance with the ARRIVE guidelines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Lower vertebrate models, such as zebrafish, are not relevant for the studies here, since they do not share the same mechanisms of blood glucose regulation to humans and rodents. Similarly, immortalized mouse and human pancreatic cell lines do not recapitulate the interactions that exist between different cell types in the pancreas. Stem cells from

humans can be made to form islets, but these do not function well, and therefore, one of the aims of our research is to understand why, using animal models. The scientific literature will be reviewed on a regular basis to identify any novel technologies and models that could be adopted to replace in vivo animal use. Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use. As such mice present the most refined model to understand diabetes.

Glucose, insulin and pyruvate tolerance testing are similar to those used in human medicine and are less invasive than hyperinsulinemic-euglycemic clamps, which produce high quality data but require anaesthesia and implantation of catheters. While continuous glucose monitoring via a wireless implant is becoming available in humans, the technology is still in its infancy in small animals and is beset with a number of issues including inaccurate data capture and the need to surgically implant the monitor.
Nonetheless, we will keep abreast of innovation in this arena and switch once the balance of harm is less than the methods already in use. To minimise adverse effects during these tolerance tests, only sterile solutions will be injected, syringes will only be used once and a local anaesthetic (EMLA) will be applied to the blood sampling site. Hormone concentrations will be measured using ultrasensitive assays, minimising blood volume used. Where possible, animals are handled in cardboard tubes, which minimises stress. Animals are habituated to being handled for 1-2 weeks preceding any experiment. Physical restraint is only needed during the initial access to the vein to avoid harming to the animal. For animals on diabetes-causing diet, softer bedding and more absorbent material will be used to avoid excessive grooming. Food will also be provided in bowls on the floor to avoid distribution onto the animals and into the cage. Diabetes-causing drugs, labelling compounds and diabetes therapy are all based upon standardised protocols and the lowest doses will be used to induce a measurable effect.

Why can’t you use animals that are less sentient?

Lower vertebrates, such as fish, and invertebrates, such as flies, are not relevant here, since they regulate glucose differently to humans. Moreover, fish and flies are not amenable to metabolic phenotyping (hormone measures from blood are difficult/impossible), and do not possess islets of Langerhans like in mammals (rather a small organ of 20 or so cells). Foetal mice cannot be used, since their pancreas only develops fully after birth, specifically following the transition from milk to carbohydrate/protein-rich diet. Lastly, terminally anaesthetised mice cannot be used because anaesthesia influences hormone release and blood glucose levels (i.e. the primary measures here).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We keep abreast of and rapidly adopt any advances in the field which lead to refinement. Examples of this include:

Use of highly-sensitive hormone assays for insulin and glucagon that allow smaller blood volumes to be more reliably tested.

All animals may receive local anaesthetic cream before blood sampling, which decreases stress/discomfort and improves the reliability of hormone and glucose measures.

Where possible, mice are acclimatised to handling before conducting any measures. This

decreases stress, as evidenced by a reduction in basal blood glucose measures.

Where possible, mice are handled using cardboard tubes to avoid stress associated with being picked up by the tail.

Generation of animals that allow longitudinal monitoring of beta cell mass using minimally-invasive techniques.

Where possible, drugs are administered in drinking water, which leads to robust responses without the need for injections.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult the literature for experimental design, best practice, and humane endpoints for metabolic and diabetes research in animals. We will also consult Simon Bate's book, 'The design and statistical analysis of animal experiments', for experimental design, statistical analysis, and sample size calculations.

Prior to all experiments, we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment (PREPARE: guidelines for planning animal research and testing.
Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE 2.0 guidelines published by the NC3Rs.

The LASA guidelines: RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

Jones HRP, Oates J, Trussel l BA (1999) An applied approach to assessment of severity. In: Humane End points in Animal Experiments for Biomedical Research (Hendriksen CFM, Morton DB, eds).
London: Royal Society of Medicine Press, pp 40±7.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will perform literature search, attend vendor’s information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.

We will comply with the ARRIVE guidelines 2.0 (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research. We will sign up the NC3Rs newsletter and attend relevant 3Rs events.

71. Breeding and Maintenance of Genetically Altered Animals for Regenerative Neuroimmunology Research

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Mouse Breeding, Genetically altered mice, Colony Maintenance

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The breeding, generation, and maintenance of mice with genetic modifications. These mice will supply project licenses within our group with the appropriate mice needed to carry out the experimental work.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

When mice are used in the study of human diseases, they are frequently selected because of their similarity to humans in terms of genes, as well as brain structure and function. Additionally, mice are the most widely used animal species in experimental research. This is because it is relatively easy to induce disease models like human diseases, and to manipulate their genes (i.e., genetic modification) in a way that allows studying specific mechanisms of disease. Here, genetically-manipulated mice are

produced for the experimental licenses in our group. These will help us understand how cells of the immune system can affect the healthy, diseased, or injured brain's structure and function.

What outputs do you think you will see at the end of this project?

Outputs will be a steady supply of appropriate mice for studies on other projects.

Mice produced in this licence will be used to study aspects of the human disease multiple sclerosis and human spinal cord injury. These mice will help us understand how cells of the immune system and the brain talk to each other. The mouse behaviour will be studied.

New-born mice in this license will also be used to get immune system and brain cells to grow in lab dishes.

Who or what will benefit from these outputs, and how?

The projects receiving these mice will have a reliable source of mice to use for their experiments.

How will you look to maximise the outputs of this work?

Lab members will meet and design a breeding plan to make sure the right number of mice are produced to match the needs of the experiment. Mice with genetic modifications will be made available to other labs we work with. All mice used on projects carrying out experiments within our group will be described in our publications. If we make a mouse with a genetic modification that does not work as expected (i.e., what is generally defined a negative result), we will look to also publish the negative results as appropriate. The licenses this work is supplying will benefit from good maintenance of the colonies to supply the mice we need at the appropriate times. Lastly, we will look to share tissue (i.e., cells and tissue) with other groups as appropriate and as needed.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice because currently they are the most commonly used animal in human disease research.

We are using adult mice as they need to be sexually mature for breeding purposes. Adult mice will supply project licenses within our group with the appropriate mouse models needed to carry out the experimental work.

We are using new-born mice to collect cells to grow and keep in a dish to do experiments.

Typically, what will be done to an animal used in your project?

Female mice will be given substances to make more eggs that are collected in the mouse ovary (i.e., superovulation). Substances will be given across two injections approximately 48 hours apart.
Substances will be injected into the abdomen (i.e., intraperitoneal). Mice will be killed at the end.

Male and female mice will undergo surgical procedures using appropriate anaesthesia. For male mice, they will undergo a surgical procedure to render them sterile (i.e., vasectomy). For female mice, they will experience a single surgical procedure to place embryos, or fertilised eggs, into their reproductive tract. Female mice may also undergo non-surgical placement of embryos into their reproductive tract.

This involves inserting a small thin tube into the uterus of the mouse to insert embryos directly.

Male and female mice will be housed together and allowed to naturally mate. This will produce mice with and without genetic modifications using standard breeding methods.

Some mice offspring (<50 total offspring per year) up to five days old will be collected and will be killed by removal of their head (i.e., decapitation). We will then collect cells of from the brain. These cells will then be grown in the laboratory and used for experiments.

Adult female or male mice will first be terminally anaesthetized. Then we will remove the blood by flushing it out of the mouse using a pump. Then we will collect the organs and store them in a solution that prevents the tissue from being destroyed. This allows us to store the tissue for long periods of time. Then, we will use the tissue for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Female mice that are breeding, receive injections for superovulation, or undergo a non-surgical procedure are likely to experience mild pain (i.e., that equates to the insertion of a needle beneath the skin), suffering, or distress. These individual procedures will not result in the significant impairment of the well-being or general condition of the mice.

Mice that undergo surgical procedures will experience short-lived (i.e., less than 24 hours) post- operative pain and discomfort. These impacts are not expected to last for more than 24 hours.

Mice undergoing terminal procedures will be completed under general anaesthesia. This will keep the mice in a state of sleep/unconsciousness for the length of the procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse: Subthreshold 98%

Mouse: Mild 1%

Mouse: Moderate 1%

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice are widely used in pre-clinical research. This is because their genes, biology, and behaviour are similar to humans. We can then use mice to study many of the causes and effects of disease or injury seen in human patients. Some things we can study are tissue damage and the presence of inflammatory immune cells. These are types of cells that release chemicals and molecules that prevent the damaged area from being fixed. We also use genetically modified mice. These mice allow us to turn on or turn off specific genes that are involved in the injury or disease. We can then study proteins and cellular activity and how they work in the injured or diseased brain.

Which non-animal alternatives did you consider for use in this project?

Over the years our group has refined and improved our use of cells grown and maintained in plastic dishes. Using these cells, we have exposed them to experimental treatments to understand if they have a positive or negative response. This way we can test their safety before then testing them in a mouse.

Additionally, we have developed a new way to grow and maintain human cells in plastic dishes that does not involve the use of mice. We can then use these cells to perform experiments that test our ideas about how human cells respond to treatments without having to use cells from mice beforehand. This new way of testing cellular responses in plastic dishes is closer to the response of these cells in a living human. This will be help us in being able to predict which aspects of the cell in humans are the most important to study using our mouse models.

Why were they not suitable?

Cells grown in plastic dishes are useful for studying some aspects of human disease. However, they do not fully capture the complex changes that happen to cells in a living mouse or human. Using mice allows us to study these complex changes in a setting that is more like the human disease or injury.
This way, we can understand the true function of these cells in their normal setting.

Cells grown in plastic dishes behave differently to those found in a living mouse or human. Cells in plastic dishes lose their diversity and the ability to communicate with other cell types.

Therefore, it is necessary to use mice to assess the complex biological and behavioural responses of cells following an injury or disease. This is also important when testing a potential therapeutic treatment. There is also a requirement to demonstrate that a treatment is safe and effective in animals before progressing to human application.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mouse numbers were estimated based on a combination of the retrospective review, annual return of procedures, and the estimated animal usage needed to supply the experimental project licenses with our group for their duration.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The National Centre for the Replacement Refinement & Reduction of Animals in Research (NC3Rs) website provides excellent resources for implementing colony management best practices. This includes important considerations to create suitable breeding strategies to reduce the production of mice not carrying the genetic modification of interest for use on other projects. This resource is used as a reference to design breeding strategies prior to the mating of genetically modified animals. This will avoid the excessive waste of mice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding of mice colonies will be planned with care to avoid the creation of surplus stock by carefully and consistently tracking the number of mice.

Any line of genetically modified mice not actively being used in our experimental work will be removed from active breeding and the line frozen down to prevent the generation of surplus stock.

Breeding mice will be replaced before their reproductive performance declines. This will be done by maintaining breeder mice of various ages by replacing a percentage of them monthly.

Non-productive breeders, i.e. those female mice that have not produced a litter within 60 days of mating or since their last litter, will be replaced. Breeding mice will be young, sexually mature male and female mice as younger mice generally breed better than older ones.

Where possible, experienced males will be housed with size matched young females to improve breeding performance and prevent injury to the female mice during mating. Additionally, to produce offspring with the same age we will house females together in

pairs to sync up their reproductive cycles. Then, these female mice will be housed with individual males which will result in the maximum number of pregnancies.

We will keep meticulous and accurate breeding records to evaluate the breeding performance of the mouse colony. This will allow us to detect problems sooner so that they can be corrected.

We are also coordinating with other groups to share animal tissues – including tissues from genetically modified mouse lines and post-mortem tissues - in order to further reduce overall animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using a non-surgical method to increase the number of viable embryos that are released from female mice to be available for fertilization.

We will be using a surgical method under anaesthesia in which mouse embryos are placed into the uterus of a female to establish a pregnancy.

We will use a non-surgical method in which mouse embryos are placed into the uterus of a female to establish a pregnancy.

We will be using a surgical method under anaesthesia in which male mice will undergo a vasectomy to render them sterile.

We will be mating and breeding male and female mice to produce offspring for use in our experimental licenses.

These methods are standard in the breeding and maintenance of mice for scientific purposes and have been routinely updated and optimised to cause the least pain, suffering, distress, and lasting harm to the mice.

Why can’t you use animals that are less sentient?

We are extremely limited in the use of non-mammalian species (i.e., invertebrates (e.g., worms), fish, or amphibia). These non-mammalian species are not fully suitable for the study, development, and testing of treatments for use in humans (i.e., mammals). In fact, while some work is done in non-mammalian species, the complexity of the interactions in an organism can only be studied in mammals (e.g., mice). This is because they have similarities in organ, tissue, and cell structure with humans.

We need mice with cells that have reached a mature stage of development. This is to

make sure it is similar to the cells present in adult humans. The use of mice during the beginning stages of life will be restricted to the collection of cells to grow and maintain on plastic dishes to perform experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Female breeders will only be allowed to have six litters of newborn mice or only breed for six months, whichever comes first, before she is retired.

Stock mice that are required to maintain a live colony will be kept to a minimum to ensure appropriate mouse numbers for experimental purposes. This will avoid producing more mice than is necessary and reduce the wastage of mice.

If a strain of genetically modified mice will not be used for research purposes in the next six months, it will be archived through cryopreservation of female embryos and/or male sperm. This will preserve the genetic background of the strain until it is again needed for use in our experimental licenses.
Cryopreservation involves the collection of non-implanted embryos from female mice and/or sperm from male mice followed by long-term storage in extremely cold temperatures (i.e., -80^{o}C). This saves significant space and mice care resources. Ultimately, it allows us to better manage our colonies being actively used to supply our experimental licenses.

We will select the most appropriate breeding strategy on a per strain basis. For example, if a manuscript is under review, and a colony is being maintained in the event that reviewers request further experiments, an intermittent breeding strategy will be used to avoid animals being wasted. This is where we would reduce the number of active breeding pairs. For example, if we needed 6 breeding pairs to supply our experiments, we would reduce this number to 2 breeding pairs while the research is under review.

Our breeding strategy for mice with genetic modifications will be to set up male and female mice either in pairs (i.e., one male and one female) or in trios (i.e., one male and two females. The use of trios increased breeding efficiency to produce the mice with the desired genetic modification. A well- designed breeding strategy will lead to the largest number of offspring with the expected genetic modification. This will reduce the wastage of mice that do not have the genetic modification.

We have also designed our breeding strategy to produce offspring that either have the genetic modification or do not have the genetic modification. When these mice are supplied to our experimental licenses, they allow us to determine if the changes we have made are real.

Female mice with offspring, called pups, will be provided soft nesting material to keep the pups warm and protected. As the mice develop and approach the weaning stage (i.e., the removal of the offspring from the mother), wet mash will be provided to ensure the pups do not suffer from malnutrition.

Mice undergoing surgical procedures will be administered pain medication immediately before and after the procedure. Mice will be kept under anaesthesia during the entirety of the procedure. They will also be placed on a heating pad to maintain normal body temperature for the entirety of the procedure. Following all surgical procedures, the mice

will be placed into individual cages with a soft, grippable bedding to allow ease of movement. The mice will also be provided with access to a diet gel to maintain hydration. The cages will be kept in a heated chamber to maintain a stable body temperature. Mice will be monitored until they are awake, alert, and active (i.e., moving freely in the cage) and then returned to their home cage. Mice will be monitored daily for 7 days to ensure the surgical site remains closed, there are no development of clinical signs of distress and suffering, and to minimise the chance of post-surgical complications. Pain medications will be provided as needed to mice through either intraperitoneal (e.g., into the abdomen) injections or as a palatable substance (e.g., in the drinking water).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidance provided in the ‘Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes’ and the Jackson Laboratory. We will also use the resources available for colony management and breeding strategies on the ‘National Centre for the Replacement Refinement & Reduction of Animals in Research’ and ‘Laboratory Animal Science Association’ websites.

In addition, we will refer to the Jackson Laboratory resource manual on ‘Breeding Strategies for Maintaining Colonies of Laboratory Mice’ as well as the many manuals and guides available on their website for continued guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The National Centre for the 3Rs (NC3Rs) will be the main reference to understand whether our experiments match the highest standards of 3Rs. We will adapt our protocols if the recommendations evolve throughout the duration of this project. Regular consultations on the latest practical guidance from Laboratory Animal Science Association (LASA), Institute of Animal Technology (IAT), and the Royal Society for the Prevention of Cruelty to Animals (RSPCA) will provide additional sources of new recommendations and advances in animal techniques and clinically applicable models.

As a license holder, it is my own responsibility to stay updated on published best practices. I will do this by consulting information for license-holders provided by our establishment and by speaking to other project license holders.

72. Anticancer Drug Discovery, Target Validation and Experimental Therapeutics

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Therapy

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to identify and validate new molecular targets and pathways which cancers rely on for survival and growth and then to discover drugs or new combinations of existing drugs, which exploit the targets and translate this into new treatments for cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is now the major cause of death from disease in all age groups in the United Kingdom with approximately 300,000 new cases and 150,000 deaths each year. The

lifetime risk of developing cancer is currently 1:3 and this is expected to rise towards 1:2 as life expectancies increase. Despite improvements in early diagnosis, the majority of patients present with disease which has spread from the original site to other areas of the body (metastatic disease) and hence cannot be cured by surgery and local radiotherapy. Drug therapy (chemotherapy) is currently the only modality with curative activity against metastatic disease, notably certain childhood tumours, haematological malignancies and rare adult cancers, and it can also significantly improve quality of life of patient where cure is not possible (palliative effects) in multiple common tumour types. Nevertheless, currently available drugs do not cure the majority of patients and there is an urgent need to develop new chemotherapies with significantly greater activity than those available. The current application seeks to allow the identification of new cancer drugs.

What outputs do you think you will see at the end of this project?

The expected benefit is the identification of new drugs for the treatment of human cancer, where there is a high unmet need for new therapies. The studies will not only help to select agents for clinical evaluation, but will also inform on their optimal use. In addition to the potential therapeutic value of these agents, the studies will also provide data that will inform basic research into the targets of the agents studied.

Who or what will benefit from these outputs, and how?

In the short term our target identification and validation studies will produce data supporting or rejecting the particular target which will help the cancer research community to exclude targets which will not produce anti-tumour effect and give, well validated, new potential areas of research to concentrate on.

Early drug discovery may identify tool compounds which will help the field further investigate the pathways involved in cancer development examples of this are CDK2 inhibitors which have been widely used by many groups in the field.

In the longer term, which may be beyond the life of this licence (for example PARP inhibitors took 10 year to go from the first preclinical studies with the early lead to the first clinical trial), we would hope to bring new drugs to the clinical which will directly benefit patients.

How will you look to maximise the outputs of this work?

We have entered into a strategic alliance with an industrial partner in order to optimise our drug discovery processes. This involves our partner being briefed on our target validation studies at the earliest stages of in vitro investigations.

This allows us to not only get independent scientific feedback from their scientific advisory board on our target strategies but also access to their resource and drug discovery expertise on projects they wish to take forward with us.

We endeavour to publish all our findings both successful and unsuccessful in high quality journals and present at both national and international meetings. Publication on successful project can sometimes be delayed due to patent protection but such studies are published as soon as commercial considerations have been addressed.

Species and numbers of animals expected to be used

- Mice: 9800
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The majority of animals used will be adult mice although rats will be used where there is scientific rational suggesting rats better reflect humans or for practical reasons when the size of rats make them a better model.

Typically animals will be immune compromised to allow the growth of human tumour xenografts (tumours formed from human cells in an animals models, literally meaning foreign graft, or biological material in the form of cells, organs or fragments of tissue grafted from one species to another) in order to study the pharmacology (the study of drugs and how they work) of cancer treatments and discover new treatments.

Where mice are genetically altered (other than immune compromised) this is usually in order to better understand human diseases and seek new treatments.

Wild type mice may also be used to assess toxicity or be implanted with syngeniac (from the same species eg mouse tumour grown in mice) tumours to study the involvement of immune response in cancer treatment.

Typically, what will be done to an animal used in your project?

Typically mice on most of the protocols will be used to assess well new drug treatments or combinations of treatments work or the pharmacology (pharmacokinetics (how the body deals with the drug in terms of absorption from the gut, distribution around the body and elimination (excretion) and pharmacodynamics (how the drug effects the body in terms of desired effects (efficacy) and undesirable or side effects (toxicity)) of these treatments in mice bearing tumours.

In order to do this it is essential that animals develop tumours. Tumours may occur naturally due to an inherited abnormality (<4%) or may be induced by implantation of tumour cells either under the skin (sub cutaneous ~76%), intravenously (by injection into a vein <4%) or surgically (~16 %) into and specific site such as the liver (<4%), bone marrow (leukaemia) (<4%), pancreas (<4%) or bladder (<4%).
Growth and development of tumours may be monitored using medical imaging techniques including but not exclusively MRI, CT ultra sound etc.

In order to aid the development of tumours some animals may receive whole body, irradiation e.g. treatment with x-rays(<5%).

Some animals may also undergo castration (<5%) or ovariectomy (>5%).

In total these studies would account for approximately 85% of all the animals used.

The remaining 15 % would be used in pharmacokinetic or toxicity studies and would be split into:-

wild type mice or rats used in toxicity studies in MTD studies of new pharmacophores (the core chemical structure around which new drugs are built) (~3% of total)

or mice which are wild type (normal) and genetically modified (GM) (GM mice have been modified to have an alteration to their genetic make up which makes them susceptible to a particular cancer, an example of this is the breast and ovarian cancer related gene BRCA in humans) paired where studies may be performed to check the involvement of the target in any toxicity (side effects) observed (~2% of total).

or wild type mice or rats used in pharmacokinetic studies to determine biodistribution (how the drug moves around the body to different organs) bioavailability (how much of the drug actually gets into the body after an oral dose) and metabolism (how the body breaks down the drug) and elimination (how the drug is excreted) (~8 % of total).

or mice which are wild type and GM paired where studies may be performed study the pharmacodynamics and develop specific biomarkers for target engagement (~2% of total).

Imaging techniques may be used to follow the pharmacokinetics of drugs over a 8 hour period in a single animal.

What are the expected impacts and/or adverse effects for the animals during your project?

Generally animals may show signs of sickness e.g. hunched posture, diarrhoea, ruffled fur, look pale or feel cold. Supportive care and pain relief will be given and if the clinical condition does not improve within 24h mice will be humanely killed. Tumour models: Sub cutaneous models where tumour grow under the skin may cause minor discomfort. they may grow upto ~1.5 cm in diameter but will not be allowed to break through the skin.

Orthotopic models where tumours are grown in the organ in which they would naturally occur (all of the surgical models:- liver, leukaemia in bone marrow, bladder and pancreas) and naturally occurring spontaneous tumours due to an inherited abnormality would be expected to show adverse effect associated with the site of implant eg jaundice for liver tumours, careful monitoring of tumour growth will ensure such events are rare however, if such effect are observed then additional supportive care and pain relief will be given and if the clinical condition does not improve within 24h mice will be humanely killed.

Surgical models: adverse effects due to surgical complications may include bleeding or inadequate anaesthesia. Supportive care such as fluids, soaked diet and a warm environment will be provided. Pain relief is always given in surgical models.

Mice may be sick and lose weight after irradiation (e.g. treatment with x-rays) but will recover once the immune system has been replaced.

Imaging: mice may experience a small weight loss post imaging but this should recover within a few days.

Therapy, we do not anticipate therapies will cause significant adverse effects. In all models pain relief is given when needed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severity over 5 years

Moderate < 8800 ~ 89%, < 450 rats ~90 %

Mild approximately somewhere between 900-950, 9-16 %, ~45 rats ~10 %

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Use of animals is needed to address the issue of the therapeutic index of a new agent (i.e. the amount of a medicine that gives the desired effect compared to those which cause un wanted (toxic) effects. In addition the effects of medicines on the whole body both in terms of how the body takes in the medicine, how the medicine moves around the body and how the body get rid of the medicine (pharmacokinetics) and what the medicine does both to the tumour, which may be affected by the site of the tumour and the cells which make up the tumour, but also the normal tissues (pharmacodynamics) cannot be predicted in human tissue/cells or cell culture systems (in vitro models) because of the complex nature of the way the body's systems work together.

Which non-animal alternatives did you consider for use in this project?

Wherever possible, we will use human tissue/cells or cell culture systems to replace animal models of organ fibrosis and cancer. The group have accumulated archival tissue banks of frozen and formalin fixed tissues from our previous models and human normal and diseased tissues. These samples are used in multiple on going projects to minimise the number of animal disease models used. We routinely use human cells in culture (including cell lines) to understand and model the biological processes involved in causing tissue fibrosis and cancer or to perform drug testing.

We currently collaborate with a commercial company, where compounds are screened, in order to get in vitro predictions of pharmacokinetics such as bioavailability and metabolic stability and some common toxic liabilities (eg HERG inhibition). All compounds are screened in house for their activity against their target and where possible screened against related targets either in house or more commonly by a commercial screening company.

Why were they not suitable?

Whilst these are useful tools, there are limitations of cell cultures systems, these include;

Cells grown in petri-dishes sit on plastic, which change their behaviour and they become "super sensitive" or fail to do the job they would in the body. These abnormal behaviours could lead to the identification of non-relevant pathways or fail to predict identify drugs which are likely to be ineffective in the disease.

The in vitro screen and systems we use prior to animal studies are extremely useful for aiding our basic knowledge and for initial drug screening, and we use these systems to reduce animal use however they cannot fully recapitulate the behaviour of a drug in a complex biological system..

Reduction

How have you estimated the numbers of animals you will use?

We have performed audits of our previous research studies and assessed research plans of current projects and proposed new targets to predict use under this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Only after the above rigorous in vitro development and selection experiments are animal experiments considered, and animals are never used as a random screen. In addition, all experiments are designed to use the minimum number of animals to generate a statistically valid result.

The development of the new imaging based methods may allow real time monitoring of drug levels and drug action in animals reducing the number of animals required to assess the pharmacology of some agents. In addition we have entered a collaboration to help develop in vitro pharmacokinetic prediction methods. Use of these in vitro and in silico models will further reduce the number of compounds for which full pharmacokinetic evaluation in vivo is required.

Following consultation we have modified our toxicity studies to reduce the overall number of animals used by avoiding pure toxicity studies in non-tumour bearing mice where possible. This has worked well, and has led to no increase in adverse events over those that were observed prior to this change.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Statistical analysis is performed to determine the minimum numbers of animals need to generate biologically meaningful data. With pilot studies performed, if this is not possible, to reduce numbers and inform future studies going forward.

Tissue is regularly shared between projects to maximise outputs from animal procedures and minimise numbers of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use rodent models that have been consistently shown to reflect human toxicity (side effects) and provide a robust background for the development of new therapies in cancer research. The majority of studies being in mice with rats used where either their larger size is necessary for practical reasons or where the pharmacology of the drugs to be studied has been found to be better reflected by rats physiology in the in vitro studies which precede in vivo studies.

The majority of anti-tumour of tumour pharmacokinetic/pharmacodynamics studies will be carried out in immune deficient mice bearing subcutaneous (sub.cut.) human tumour xenografts. Although not without its weaknesses, this model has be shown to be robust in its ability to produce good reliable data both in terms of antitumour activity and modulation of tumour biomarkers. In addition recent studies at our establishment have demonstrated that this is a relatively mild procedure producing no real evidence of pain in mice.

Orthotopic models (models in which the tumour are grown in the organ of origin eg pancreatic tumours grown in the pancreas) can address some to the challenges associated with the tissues and organ structure in the areas of the tumour (tumour microenvironment) and the ability to get medicines to the tumour in these places (tumour drug disposition). However, whilst studies in bladder and intrafemoral tumours have shown these also cause little evidence of pain behaviour in mice (at least until tumour burden becomes such that it interferes with normal physiological processes) tumour in other sites may cause pain and discomfort. It is therefore important that the growth of such tumours is carefully assessed and characterised in order to reduce potential harms to the absolute minimum. In order to do this and to quantify the growth of orthotopic tumours imaging techniques are required, for example CT or ultra sound, these technique require the use of repeated general anaesthesia to immobilise the animals. whilst these imaging technique will help reduce potential harms from the tumour and its growth, general anaesthesia is not without its own risk of adverse effects. For these reason orthotopic tumours will only be used if there is strong evidence that a new therapy may have a potential role in the tumour type, for example if the drug target is over expressed in the particular tumour type. Even in these cases it would be normal practice to test the drug in a subcutaneous tumour model (where the tumour is grown under the skin) first.

Why can’t you use animals that are less sentient?

Many groups now use the zebrafish model to investigate the mechanisms of oncogenesis (the process of normal cells transforming into cancer cells). Whilst this is a useful model and can provide an insight into the development of cancer and help identify targets that may be used in drug discovery it is not an appropriate model for our drug discovery research. In order to exploit targets for clinical development we need to study human cancers with a well-defined molecular- and histo-pathology, first in vitro and then in in vivo

in a mammalian setting, where we can interrogate drug exposure, tolerability and efficacy.

Zebrafish embryo's are also used to look at growth of human tumours however these are short term models as the embryo's develop immunity. These models may be useful in showing is a gene or target pathway drives a cancer in a way similar our xenograft studies but we would then still have to validate the model to use in later studies thus no reduction/refinement would result. Zebrafish embryo's have also been used to screen drugs however like in vitro studies these studies don't encapsulate the complexities of the mammalian system. Development of the embryo further complicates the picture in terms of looking at the long term effects of tumour which may appear to have been cured. So whilst these models may be useful to run along side studies in mammals they cannot generate the data we would need to take our drugs forward

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals, regardless of disease model are checked regularly and supportive care is readily provided to minimise distress or suffering and improve animal welfare.

For surgical models we use good surgical techniques and operating theatres/equipment to minimise the risk of infection. Mice receive pain relief and a high level of post-operative care including soaked diet, a warm environment and fluids as required to minimize stress and suffering.

Our procedures are designed with animal welfare at the forefront to ensure the minimum suffering and distress to the animal to which end we are collaborating with the animal welfare group in order to assess any pain caused by experimental tumours and facilitate the appropriate use of analgesia. We have also actively engaged in a program to assess how tube handling can reduce the stress in experimental models, which has now been adopted as standard practice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all models and optional procedures good practice guides will be used to help refine the model as described in the ARRIVE guidelines and Laboratory animals special article 2015, 49 (s1).

LASA Working Party guidelines on assessment and control of severity will be used throughout the project to determine if any animal is suffering distress.

Workman et al in 2010. British Journal of Cancer (2010) 102, 1555–1577 NCRI guidelines will be used to perform and monitor cancer studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

There are many sources in which provide information regarding 3Rs advances, these include; the NC3Rs website, NC3Rs seminars/events and emails, scientific publications and published guidelines as well as continued professional development e.g. local seminars, regular communication with the NACWO and veterinary team and academic collaboration with the welfare group.

As information on welfare or technical improvements, alternative less severe models or new non-animal model systems becomes available an appropriate strategy within the research group and veterinary teams will be implemented to ensure that animal use and suffering is minimised. This will include testing new models (animal or non-animal) and modifying procedures.

73. In Utero Therapy for Congenital Blood Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

In utero Therapy, In Utero T Reg Therapy, Stem Cell Transplantation

Animal types	Life stages
Mice	embryo, neonate, pregnant, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To Treat Congenital Blood Disorders before Birth (prenatally) using cell therapy

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diseases inherited through families, such as those affecting the genes in red blood cells, e.g. sickle cell disease (SCD), are not very common but can severely affect lifelong health. I am working to see whether correcting the faulty red blood cell gene (sickle cell gene) in the developing baby whilst still in the womb could correct or reduce the problem before the baby is born. Approximately 400,000 births per year are affected by SCD. It is inherited as an autosomal recessive condition caused by haemoglobin beta-globin gene mutation.

Without appropriate treatment, SCD is often fatal in childhood. In low to middle-income countries where 90% of SCD cases occur, an estimated 50 to 90% of children born with the condition are dying within or not reaching their 5th birthday. This project will address the need to promote the correction of SCD before birth. We will use advanced gene medicine with nanoparticles or genetic vehicles to target the defective blood-forming cells in the fetus before they begin their final journey to the bone marrow. We will assess the safety and feasibility of this approach using a well-described mouse model of SCD. In addition, we will test the gene medicine on human cells collected from the cord of SCD at birth.

What outputs do you think you will see at the end of this project?

Diseases which are inherited through families, such as those affecting the genes in red blood cells e.g. sickle cell disease, are not very common but can have a serious effect on lifelong health. We are working to see whether correction of the faulty red blood cell gene (sickle cell gene) in the developing baby whilst still in the womb could correct or reduce the problem before the baby is born. In this project, we will aim to "reprogram" the early fetus by using new technology which will allow the recognition of the donor cells with the corrected genes as 'self'.

This project will address the need to maximise the efficacy of stem cell (HSC) transplantation and to promote the correction of gene disorders in utero. Currently, researchers in the USA are conducting an in-utero stem cell transplantation trial using maternal stem cells transplanted into the fetus. This involves maternal stem cell mobilisation, isolation and fetal transplantation, which comes with risks to the mother herself. Suppose the mother has sickle cell genes on both chromosomes in her DNA, for example. In that case, this also requires correction of the gene defect in the laboratory using gene editing approaches, which makes the process complicated and very expensive. Our project is novel in addressing the role of immune cells known as Tregs in helping the fetus accept the HSC containing the corrected gene. It will complement and enhance the current local transplantation research programme in defining the contribution of these cells to facilitating the survival of fetuses given the HSC. This has the dual purpose of targeting a niche not currently being studied by the global scientific community. In addition, using a clinically relevant sickle cell disease model meets the translational challenge of promoting the correction of single gene defects prenatally.

We work especially closely with the basic science focused Treg biologists and the clinical maternity services, although ultimately, we envisage that our findings will augment other research groups' activities through the provision of specific immunology expertise focused on tissue regeneration, samples and models and sharing of high-level scientific technology.

Prenatal diagnosis is available across the UK and worldwide. Currently, parents have only two choices when faced with a prenatal diagnosis of sickle cell or thalassemia, either to accept an affected baby or termination of pregnancy. This treatment will be offered as a third option to the couple who currently have a difficult decision, termination or continuing with the pregnancy and, if available, postnatal treatment.

If successful, treating an affected fetus would avoid the need for postnatal treatment. This would have a huge impact, especially in those countries such as Africa, the Middle East and the Far East, where termination of pregnancy may not be available, blood transfusions are prohibitively expensive, and where blood disorders are most prevalent.

Who or what will benefit from these outputs, and how?

Impact on the Society

- Offer the option of prenatal treatment to parents.
- Reduce pregnancy terminations
- Reduce the enormous economic impact, which an illness like Sickle Cell has on health systems. In England alone, between 2010- 2011, 6077 admissions were recorded associated with sickle cell disease. The total cost for these admissions was £18798255-the price increases with age, with children staying longer than adults.
- Off-the-shelf treatment, to be made available in low resource settings

Impact on the Scientific community

- Scientists can use the pre and post-gene editing sequencing datasets for further analysis and compare the efficiency of corrections with their research.
- Repeat the experiments by following the detailed experimental design and data, which will be made available via an open-source data archival system.
- Bioengineers working on fetoscopic therapy tools can better understand the size of the delivered gene-editing tools to develop appropriate fetoscopic instruments for human use.

How will you look to maximise the outputs of this work?

The findings will be disseminated at national and international meetings such as The European Society of Gene and Cell Therapy, the American Society of Gene and Cell Therapy (ASGCT), and the International Society for Stem Cell Research (ISSCR). We hope to publish our findings in high impact journals such as Blood and Molecular Therapy. We will also be involved in the Sickle Cell Society and organise public engagement events, with the involvement of the MRC, to disseminate the results to patients and relatives. We will be participating in various fundraising events, such as the Prudential Ride, the London marathon, allowing us to publicise our research.

We aim to present our findings at national and international meetings such as The European Society of Gene and Cell Therapy (ESGCT), the American Society of Gene and Cell Therapy (ASGCT) and the International Society for Stem Cell Research (ISSCR).

We aim to interact with people who are affected by the disease and obtain their thoughts, on the future presence of definitive treatment (Sickle Cell Society UK). This will allow us to understand whether patients would be willing to allow clinicians to deliver stem cell therapy in utero instead of terminating the pregnancy or wait for postnatal management. By establishing patient support, this will also increase the popularity of the study among scientists and sponsors who will be interested in getting more actively involved.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using these animal models because they recapitulate human disease (Sickle Cell Disease). We will be injecting these animal's fetuses at E13.5-E14 because at that point the main haematopoietic organ is the liver which contains most haematopoietic progenitors prior to bone marrow migration. This will maximize therapeutic engraftment.

we are using the FoxP3 mouse where enhanced green fluorescent protein is expressed in FoxP3+ T cells. These mice may are useful in our proposed studies of regulatory T cell function in the induction of tolerance.

Typically, what will be done to an animal used in your project?

All the experimental mice will be housed in a single cage after plugging.

The pregnant mouse mothers will be anesthetised and dressed using sterile drapes. The skin hair of the mouse will be removed, and the abdomen will be disinfected.
A midline laparotomy incision will be carried out to expose the pelvic cavity and the pregnant uterus. The liver and vitelline vein of each embryo will be identified. A total of 10-20µl of the solution containing the prepared cells/gene vector will be delivered either intravenously, intraperitoneally, or intra-cardiac using a 34 gauge needle attached to a microinjector system.

The uterus will be kept wet in warm sterile normal saline. The uterus will be repositioned in the abdomen. The abdomen will be closed with continuous suturing for the peritoneum and subcuticular suture. A local anaesthetic will be infiltrated around the incision.

The dams will be transferred to a warm cage for initial recovery and then to a regular cage. The dams will be checked daily and given wet food.

The transplanted pups, when born, will be cross-fostered to time-mated CD1 dams on Day 1 to avoid maternal cannibalism and antibody response from the mother. The mother will be killed using a schedule 1 method after cross-fostering.

The recipients will go under venepuncture for engraftment analysis at specific time points. Postnatal tail injection of stem cells or substances to boost the therapeutic effect might be needed in some recipients.

What are the expected impacts and/or adverse effects for the animals during your project?

Anaesthesia

For general anaesthesia, the appropriate depth of anaesthesia often depends upon the strain. Therefore, under- or over-anaesthesia will be minimised/avoided by continual monitoring of breathing rate. Adult mice will only receive inhalation anaesthesia, usually isoflurane. Injectable anaesthesia will be used only very rarely.

Hypothermia is a common adverse effect of general anaesthesia for surgery in rodents.

Therefore all anaesthesia will be performed while keeping the animal on a thermally-regulated pad or in a thermally- regulated chamber. After anaesthesia, animals will be observed until they are awake, in a heated recovery box before being returned to their cage to prevent such an effect.

Surgery

The animal will be monitored continuously until it has fully recovered. They will be allowed to recover in a warmed chamber not exceeding 32°C. Possible pain during/after surgery will be minimised using appropriate analgesia, as recommended by the NVS or NACWO. Where signs of distress are observed (lack of mobility, discomfort, hunching or piloerection) via video/physical observation post-surgery, analgesia will be administered as required. Animals may show signs of distress immediately post- surgery; they will be assessed closely one hour after surgery, at the end of the day, and the following day. If they are still showing signs of distress, they will be culled.

Complications, including infection and wound dehiscence, may rarely occur due to surgical manipulations. This will be minimised by the use of the appropriate aseptic technique. After the procedure, frequent observation will be undertaken to ensure that wound healing and recovery are free from bleeding and infection. In the unlikely event of wound breakdown, the animal will be culled using a schedule 1 method. Any evidence of bleeding during surgery will necessitate gentle compression until bleeding is stopped. In the rare event of bleeding from the wound or signs of infection, animals will be removed and killed under Schedule 1

Surgery for in-utero therapy may result in the maternal cannibalisation of newborn pups. This varies from strain to strain and between animal houses. Strains will be crossed onto the CD1 background where cannibalisation is uncommon (<5% of litters). In addition, the NVS/NACWO will be consulted for possible husbandry strategies to improve mothering e.g. co-caging of gestation-matched experimental and CD1 pregnant dams. As a last option, a caesarean section of the mother and cross-fostering of the pups may be performed.
Vector-related adverse effects

The vectors under investigation are not known to induce any adverse side effects. However, overexpression or ectopic expression of a transgene may, hypothetically, induce unpredictable adverse effects. If these are observed, subsequent experiments will use a diluted vector, dropping 3-fold or more at each round.

Expected severity categories and the proportion of animals in each category per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The only strain experiencing moderate/severe phenotype is the Sickle cell model. Mice homozygous for the alpha-globin null allele, homozygous for the beta-globin null allele and carrying the sickle transgene (Hba0/0 Hbb0/0 Tg(Hu-miniLCRα1GγAγδβS) are called sickle cell mice (Berkeley model).
They exclusively express human sickle hemoglobin, and do not express mouse Hba or Hbb. Although chronically anemic, most of these mice survive for 2 to 9 months and are fertile. A significant percentage of sickle cell mice do not survive to adulthood. These mice

display the major genetic, hematologic and histopathologic features observed in humans with sickle cell anemia; including irreversibly sickled red blood cells, anemia and multiorgan pathology. Typically, ~20% of sickling mutant mice die between weaning and 14 weeks of age.

In the event that signs of infections occur (such as ≥15% body weight loss, lethargy, piloerection, hunched posture, difficulty moving, pallor), mice will be euthanized using a schedule 1 method.

Infection should though be a rare occurrence.

Any bleeding after blood sampling vial peripheral tail vein bleeds will be controlled by the application of local pressure.

Blood sampling will not exceed 15% total blood volume in any 4-week period. Adverse effects of blood sampling are however unlikely.

Adverse effects of the injection are unlikely, but there may be mild discomfort at the site of injection.

In cases of significant inflammation, ulceration or swelling sufficient to cause distress, animals will be killed by a Schedule 1 procedure.

Agents transferred to promote engraftment:

No specific side effects of immunosuppressive agents, cytokines or antibodies are anticipated. Mice will be routinely assessed for signs of ill health, such as weight loss greater than ≥15% of body weight, diarrhea, isolation, hunched appearance, piloerection etc, and any animal displaying any of these signs will be killed using a Schedule 1 method Immunosuppressive protocols. The immunosuppressive protocols reduce but do not abolish immune responses.

The animals' water consumption and hydration status will be monitored daily until it has been established that the animals are hydrating well.

Topical antibiotic cream with or without systemic antibiotics will be applied in such instances to treat the infection. Any animal that develops ulceration or skin infections that cannot be effectively treated within three days, or is in distress, will be killed using a schedule 1 method.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will use in vitro assays as much as possible to replace in vivo experiments. Initially, in

vitro and ex vivo assays may provide insight into the cellular mechanisms involved in the induction of tolerance and allograft rejection. However, they cannot adequately model the complete array of important immunological factors and cells in vivo. Therefore, further in-vivo work is required.

In vivo studies also avoid artefacts that can occur when immune cells are removed from their environment and subject to strenuous purification procedures.

Which non-animal alternatives did you consider for use in this project?

Alternative techniques that could replace the use of animals in our in vivo experiments can be applied such as in vitro assays. This has already been accounted for, and the minimum number of animals will be used in this section. Unfortunately, we cannot replicate the in vivo system, so the final experiments are needed for confirmation.

In the case of in utero transplantation, unfortunately, this requires in vivo testing.

in addition, we aim to collaborate with the researcher who designs the “Virtual Assay” software developed in a research institution. This uses computer models based on human data, which potentially could be a more effective alternative to some of our in vivo experiments, probably the postnatal stem cell transplant study.

Why were they not suitable?

As explained above, unfortunately, we cannot replicate the in vivo system, so the final experiments are needed for confirmation after in vitro testing.

In the case of the in utero transplantation, unfortunately, this requires in vivo testing.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

As noted above, we will endeavour to use in vitro assays wherever possible thus limiting the numbers of mice undergoing experimental procedures.

Although experimental mice will not be used on multiple protocols (other than breeding), to reduce mice usage, donor mice may be used for multiple experiments. For example, a mouse culled by schedule 1 that is used to collect donor skin, may also be used as a cell donor, or spleens and bone marrow for in vitro assays.

The sizes of experimental groups and the number of repeated experiments will be kept to a minimum while ensuring that reproducible results are obtained with clear biological significance. When preliminary data is available, power analyses will be used to determine the minimum numbers of animals and repeated experiments that are required to meet statistical significance. The number of mice that are required varies depending on the

model used.

I have been carrying out murine in utero transplantation since 2012 I have, in collaboration with the NVS, refined these techniques to minimize the numbers of mice lost due to surgical errors.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have been carrying out murine in utero transplantation since 2012. We have, in collaboration with the NVS, refined these techniques to minimise the numbers of mice lost due to surgical errors.

Prior to any animal testing the NC3rs experimental design assistant https://www.nc3rs.org.uk/experimental-design-assistant-eda will be used to reduce animal numbers.

Breeding of the transgenic colonies will be done in collaboration with the BSU and a minimal number of breeding pairs will be kept to avoid unnecessary culling of unwanted animals. In addition, we will use a commercial genotyping service to avoid any delays in identifying homozygote sickle cell animals and wild types.

We are planning to publish our results according to the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
Before the proposed study, a feasibility study (n=3), will be done to test logistics and gather information prior to proposed for larger study, to improve the latter's quality and efficiency.

This will be used to reveal deficiencies in the design of a proposed experiment or procedure and these can then be addressed before animals, time and resources are expended on large-scale studies.

Before conducting the pilot study, a systematic review of the literature will be done to fine-tune the number of cells and techniques before animal testing.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen mice, as we are principally studying models of inherited genetic blood disease and mouse models are available for most of them. In addition, mice have an immune system of comparable complexity to human. For these reasons, mice are the

most frequently used animals in studies of the human immune system.

Where possible, we attempt to prevent the onset of the disease, rather than treat it once the disease phenotype has been displayed; this prevents undue suffering.

We will use a sickle cell mice, which exclusively express human sickle haemoglobin and do not express mouse Hba or Hbb. Although chronically anaemic, most of these mice survive for 2 to 9 months and are fertile. A significant percentage of sickle cell mice do not survive until adulthood. These mice display the major genetic, hematologic and histopathologic features observed in humans with sickle cell anaemia, including irreversibly sickled red blood cells, anaemia and multiorgan pathology. Typically, ~20% of sickling mutant mice die between weaning and 14 weeks of age.

This project aims to breed transgenic mice for use in biomedical research. These animals are needed to investigate the role of different immune cells and the influence of genetic factors in a transplantation setting. The mouse models are important, not only in providing new insights into the processes that lead to rejection but also as models in which to study novel transplantation therapies.

All the protocols proposed in this application utilise well-established and tried techniques that have been refined to involve minimal suffering. The most invasive procedures will involve in utero stem cell transplantation and gene therapy. Anaesthesia and analgesia will be administered to minimise discomfort and the animals will be assessed daily for any signs of distress. In all the proposed in vivo models, if animals display signs of distress, advice will be sought from the NVS and if distress cannot be alleviated, the animals will be culled by a Schedule 1 method.

Why can’t you use animals that are less sentient?

In protocol 1, the testing will be done using in utero transplantation in an E13.5 fetus; we expect minimal suffering of the fetus. The dam will be under general anaesthetic with local anaesthetic and painkillers mixed with the water will be used postoperatively.

How will you refine the procedures you're using to minimize the welfare costs (harms) for the animals?

We will liaise regularly with the NVS and the NACWO regarding the welfare of the experimental animals and breeders.

A systematic review of the literature will be performed before any in vivo study.

A pilot study will be performed to refine the experimental methods and reduce animal numbers and suffering.

The dams after surgery will be transferred to a warm cage (28oC) for initial recovery and then to a regular cage.

The dams will be checked daily and delivered the recipient mice 6-7 days post-IUT (E20-21). All the operated mice will be given wet food for the first day and regularly monitored for any signs of infection, especially during the first seven days.

The newborn pups will be cross-fostered and were placed in a cage with a CD1 dam, that

will be time- mated and plugged one day before the treated dam. The cross-fostering will be performed ideally at day 1 post-natally to avoid maternal cannibalism.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I am planning to follow the Prescott MJ, Lidster K (2017) Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217 and any future publications by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will stay informed by attending seminars and webinars by www.NC3rs.org.uk the IAT.

I am planning to attend the annual NC3Rs/IAT Animal Technicians' Symposium.
I received the NC3Rs newsletter

In addition, I follow the national centre for the 3Rs Twitter and regularly visit the NC3Rs website. In addition, I am in contact with the supplier, which will be providing the transgenic animals via the supplier and my local BSU.

74. Enhanced Bone Ingrowth

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Bone, Ingrowth, Enhancement

Animal types	Life stages
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to evaluate the safety and effectiveness of new materials and surfaces to be used in orthopaedic surgery. The primary aim of this project is to develop novel therapeutics and surgical techniques to facilitate bone ingrowth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work to be carried out under this project licence will be done to improve the experience of patients undergoing joint replacement. It also aims to reduce costs for the Health Service due to shorter stays in hospital.
These experimental models for studying bone ingrowth need to reflect the biomechanics and the physiology of the particular clinical scenario in humans. The therapeutic materials may be either (a) synthetic, i.e. polymeric (resorbable or non-resorbable scaffolds, or a

combination of both), metallic or ceramic or biologic (growth factors, cells, signalling molecules, placental tissue and bone marrow aspirate).

What outputs do you think you will see at the end of this project?

The primary output of this project is to develop new products/methods to enhance bone ingrowth using existing experimental in-vivo models developed under previous licences. Additionally, this will help gather scientific knowledge and generate publications to better the wider scientific community.

Although, the current set of in-vivo models have shown to translate clinically, there is still an opportunity to expand and increase the clinical relevance of the models available. Therefore, a secondary objective will be to develop new experimental in-vivo models for studying bone ingrowth that better reflect the biomechanics and the physiology of the particular clinical scenario in humans. These new models will in turn, facilitate the development of innovative products, which will improve patient outcomes.

Who or what will benefit from these outputs, and how?

SHORT-TERM BENEFITS (0-3yrs): Although, the current set of in-vivo models have shown to translate clinically, there is still an opportunity to expand and increase the clinical relevance of the models available. These new models will in turn, facilitate the development of innovative products, which will improve patient outcomes. The project will attempt to develop new experimental models of bone ingrowth, which will help advance the frontiers of science in this area for the benefit of clinicians appraising preclinical bone ingrowth studies. It will also allow us to investigate new indications for some of their strategic acquisitions, which could be used to enhance bone ingrowth. These therapeutics will be tested using existing bone ingrowth models developed under previous licences.

LONG-TERM BENEFITS (5-10 years): The project will also provide long term benefits for patients undergoing joint replacement will benefit in the short-term as they should be able to return to a day-to- day life much quicker and experience less pain. Long-term benefits would be the economic benefits which include fewer days lost at work, fewer hospital days and reduced care costs.

How will you look to maximise the outputs of this work?

The outputs of the project will be fully exploited through a number of different mechanisms. For example; (a) product support data, (b) pre-clinical regulatory support data, (c) conference abstracts and posters, (d) scientific publications outlining new experimental models of bone ingrowth. Model development may also involve the support of either academics or clinicians, which will assist with knowledge transfer.

Species and numbers of animals expected to be used

- Sheep: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

SHEEP: Sheep have been selected as a large animal experimental model, given that their anatomical size and skeletal dimensions is similar to humans, and ease of supply. Sheep have also been selected for blood sampling due to the volume of circulating blood available and their greater availability. Skeletally mature sheep are preferred over juvenile and aged animals in this licence for the following reasons; (a) availability from the open market, (b) our current implants and surgical instrumentation also tailored towards the bone of skeletally mature animals, (c) bone ingrowth and remodeling processes are dissimilar between juvenile and skeletally mature animals and so juvenile animals are not considered to be sufficiently representative of the clinical conditions under study. From past experiences, aged sheep are more susceptible to succumbing to complications arising from the surgical procedure and the effects of the general anesthetic. Therefore, for this reason young adults are more suitable.

Typically, what will be done to an animal used in your project?

Surgically, under general anesthesia with recovery appropriately sized defects will be drilled into suitable cancellous bone sites These defects will be filled with either test materials, industry standard controls or left as empty defects. The defects may be created in both hind limbs; up to four defects will be created per animal. The estimated time of the surgical procedure is approximately 1.5 hrs. Once the animal has recovered from the effects of general anesthesia it will be carefully monitored by qualified animal husbandry staff until the live phase of the study is completed up to 3 years later. At the end of the study, the animals will be humanely euthanized.

What are the expected impacts and/or adverse effects for the animals during your project?

The project will involve the creation of a bone defect, which may lead to some degree of discomfort following surgery, although this will be reduced by the use of a minimally invasive technique. Any discomfort will be minimised with the use of appropriate pain relief. At the end of the studies the animals will be humanely euthanised. In addition any animal showing severe signs of suffering whilst on study (e.g. excessive weight loss, signs of uncontrolled pain, significant lameness) will be humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that up to 95% of animals will experience moderate harm in work under this protocol. The remaining 5% or less of animals will be classified as non- recovery by dying whilst still under controlled anaesthesia due to either adverse reaction to the anaesthetic itself or being euthanised due to irreparable surgical complications.

Due to the enforcement of humane endpoints in each protocol, it is highly unlikely that any animals will suffer any severe harm.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals will only be used where there are no alternatives to the use of animals in order to answer the questions that the project requires.

Bone ingrowth is a complex, well-orchestrated physiological process of bone formation involving signaling cascades and cellular repair mechanisms that cannot be studied by in-vitro cell culture studies alone where these complex interaction are impossible to truly replicate. Consequently, bone ingrowth can only be demonstrated with the help of animal models, i.e. no in-vitro methods such as computer simulations or cell cultures can mimic the complexity of an in-vivo environment sufficiently or predict clinical efficacy. The in-vivo models developed under this licence tailored for studying bone ingrowth will attempt to reflect the biomechanics and the physiology of the particular clinical scenario in humans.

In-vivo models will also be required when in-vitro systems cannot provide a reproducible approximation of the real-life in-vivo or clinical setting, e.g. the kinetics of delivery and distribution of drugs or bioactive factors; the biocompatibility and degradation properties of implant materials.

Initial screening and feasibility testing will be carried out in rodent models whereas large animal models, whose bone regeneration is closer to the same processes in humans, will be used to provide translational proof of concept.

Regulatory authorities such as that FDA will also require the testing of novel bone repair therapies in both a small and large animal model before accepting an agent for clinical trials to ensure clinical translation in bone tissue engineering and regenerative medicine through assessment of appropriate efficacy and safety endpoints.

Which non-animal alternatives did you consider for use in this project?

In-silico bone mechanobiology will be used where appropriate for predicting mechanobiological changes to bone tissue and investigating cell mechanobiology. In-vitro cell culture models will be used for studying bone mechanobiology in 2D by applying controlled mechanical stimuli to relevant cell lines and also to establish safety of any technology prior to any in-vivo experimentation. Collectively, these tests will be used for screening out some of the early stage technologies.

Why were they not suitable?

These preliminary tests will be used to screen out novel technologies that lack supportive data. However, in order to provide a sound basis for making determinations about reasonable safety and efficacy, animal models will be required to provide accurate information about how a medical intervention will perform in a human clinical trial. Furthermore, regulatory authorities such as the FDA and MHRA will require evidence of in-vivo safety and efficacy data prior to clinical evaluation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals per species required will be determined from a number of sources:

The experiences gained from previous licences.

ISO standards (ISO 10993)

Our statisticians input at the planning stage of the in-vivo studies to advise on study design, post live phase analysis and to determine the minimum number of animals required to provide sufficient likelihood of a meaningful outcome.

Previous studies or studies reported in the literature will be used to provide variability data to aid this process, or pilot studies will be conducted to generate such data. This will reduce the numbers of animals used in total without compromising the data/information obtained.

Our organisation's AWERB, which will assess all protocols and experimental design prior to the start to ensure a minimum number of animals are used to the meet the study objectives. Our AWERB review every proposed study in addition to reviewing the protocols proposed in this licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our organization will adopt multiple strategies that will help ensure that the fewest number of animals will be used in the research to address the scientific questions outlined in the project.

SUBJECT VARIABILITY: Variability will also be reduced through the procurement of animals of consistent breed, sex, age and weight ranges and through application of animal acceptance criteria for each study.

BIOSTATISTICS/POWER ANALYSIS: Statisticians will be consulted in the planning stage of the in-vivo studies to determine the minimum number of animals required to for statistical analysis and to answer a scientific question being asked. This will reduce the numbers of animals used in total without compromising the data/information obtained.

Consultation with a statistician will comprise setting clear study objectives, and ensuring appropriate output measures are collected and analysed using appropriate statistical methods. Sample sizes will be determined based upon the needs of the study which may be tailored for either welfare, pilot, validation or efficacy/non-inferiority/equivalence. Where powered, historical data will be used to determine the appropriate sample size to achieve the required study power. In order to minimise animal numbers used across the project

every effort will be made to test as many candidates as possible in a single experiment against a single control group. Typically, welfare studies to assess new procedures or technologies under this licence will consist of no more than four animals. Where there is no adequate data to power a study, a pilot will be used to gather sufficient data to design a definitive study. Typically, these will be designed to provide a minimum of 10 degrees of freedom to estimate the error. For example, a study with two groups would have a sample size of 6 per group. Where historical information is available the study size will be determined by the minimum numbers required to provide sufficient power (at least 80%) to achieve the desired outcome.

To further minimise numbers, where possible, one sided statistical tests will be used. The objectives dependent on the outcome measures may be to show superiority to a control, non-inferiority to a predicate or gather device performance data. Sources of variability will be controlled by giving careful thought to potential sources of error, bias and variation in measurements, and making every effort made to minimise them. This will include (a) using well-characterised implants that are within specification, (b) defining the success criteria of the study, (c) adopting a consistent surgical technique across the studies, (d) providing adequate time for acclimatization, (e) training of staff, (f) blinding observers and participants to the study hypothesis, and (g) adopting a randomisation schedule in order to reduce bias and interference caused by irrelevant variables.

LOCAL ETHICS (APPROPRIATE EXPERIMENTAL DESIGN): Our organisation's AWERB will assess all protocols and experimental design prior to the start to ensure a minimum number of animals are used to the meet the study objectives. Our AWERB review every proposed study in addition to reviewing the protocols proposed in this licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

COMPUTER SIMULATIONS: Computer generated models of the anatomy will be generated from CT scans of isolated limbs to create 3D models that can mimic functions of physiology and help determine safe corridors for surgical implantation. These models will also be used to develop customized implants reducing the risk of any surgical complications.

In-Vitro Testing: In-vitro cell culture models will be used for studying bone mechanobiology in 2D by applying controlled mechanical stimuli to relevant cell lines and also to establish safety of any technology prior to any in-vivo experimentation

QUALITY ANIMALS/VETERINARY CARE/PRE-SCREENING: Radiological templating of the animal prior to surgery will help screen out animals that are deemed to be unsuitable for surgery due to either health reasons or unsuitable anatomy. The images collected can also be segmented to create 3D models to assist with implant development. The loss of animals can also be minimized by providing good post-operative care, avoiding unintended breeding, and planning ahead so that the appropriate number of animals needed for the studies are ordered and/or bred.

PILOT WELFARE STUDIES: Pilot studies can be used to estimate variability and evaluate procedures and effects. Where the primary output measure of the pilot study is to establish acceptable welfare of animals subject to either new procedures or technologies under this licence, no more than four animals will be used.

PILOT "POWERING" STUDIES: Where there is no adequate data to power a study, a pilot will be used to gather sufficient data to design a definitive study. Typically, these will be designed to provide a minimum of 10 degrees of freedom to estimate the error. For example, a study with two groups would have a sample size of 6 per group. Where historical information is available the study size will be determined by the minimum numbers required to provide sufficient power (at least 80%) to achieve the desired outcome.

APPROPRIATE USE OF ENDPOINTS - TISSUE SHARING: Where possible, harvested tissues will be recycled for multiple testing, e.g. blood draws, biopsies, CT, histology and biomechanical testing.

SHARING ANIMALS: For instance, animals euthanized by one investigator can provide tissue for use by another investigator on another licence or protocol.

NEW INSTRUMENTATION AND TECHNIQUES: Using new instrumentation or innovative techniques that can improve precision can reduce the number of animals needed for a study. This has the added benefit of also being a refinement technique for the protocol.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A thorough investigation into the most relevant species for simulating bone ingrowth have been obtained from the knowledge gained from previous project licences. Ovine geometry cointained defect and sub-articular defects are widely described and published.

Both models are already developed by our facility. These models and methods have shown that they cause the least amount of pain, suffering and distress to the animals.

HUMAN IMPLANT SCREENING: Both protocols listed in this licence will utilise sheep as this species has bones of the size that are compatible with human implants and surgical techniques. Our facility have accrued a great deal of experience with these animal species from previous licences. This experience has led to refinements in surgical technique, analgesic regimes and post-surgical care. Gait analysis has been used successfully to monitor recovery after surgery and this analysis has been used to improve post-surgical care.

Why can’t you use animals that are less sentient?

Live mammalian vertebrates are required that closely mimic the bone ingrowth pathways and human skeletal system as much as possible to ensure that any data generated can be translated to the clinical situation.

The protocols assigned to the less sentient species (rat, mice and rabbit) are generally intended to be used for the initial/earlier stage assessment of technologies tailored for enhanced bone ingrowth.
However, as the technology progresses through the product design control matrix, there will be a requirement to assess their safety and efficacy in animal species whose anatomy and physiology more closely represent the intended use in humans. These animals (sheep) tend to be of higher sentience.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement applies to all aspects of animal use, from housing and husbandry to the scientific procedures performed on them. Continued investigation into animal refinement will be sought through several sources, e.g. (a) careful choice of animal model, (b) adoption of a multi-disciplinary team with expertise in animal husbandry, housing and care, veterinary science, pain management, engineering and project management, (c) improvements in animal procurement, transportation and quarantine, (d) improvements in animal husbandry such as training of animals and group housing to habituate animals to study procedures to minimise any distress, (e) implementation of housing, e.g. micro- and macro- environment, (f) increased monitoring and surveillance, (g) refinement in surgical techniques, e.g. minimal invasive surgery that minimize animal pain and distress, (h) appropriate anaesthesia, analgesia and sedatives to minimise pain and (i) post-operative care/recovery and (j) pain management (anesthesia, analgesia, drug pumps).

SOPs will also be regularly updated and documented within our Quality Management System, which is accredited to ISO9001. Staff training will also be made available through attending courses and conferences and integrating with key opinion leaders.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice approaches will be used to enhance animal well-being, minimize or avoid pain and distress, and reduce the number of animals required to obtain the desired research objectives. Best practice on animal care and husbandry will also be achieved through several sources including (a) our facility's Animal Welfare and Ethical Review Body (AWERB) with an advisory function on ethical matters, (b) UK Home Office guidelines on Animal Testing and Research https://www.gov.uk/guidance/research-and-testing-using-animals, (c) NC3Rs, which is a UK-based scientific organisation dedicated to replacing, refining and reducing the use of animals in research and testing (the 3Rs) https://www.nc3rs.org.uk and (d) consultation of the Guide for the Care and Use of Laboratory Animals (Source: National Research Council of the National Academy of Sciences 2011).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The subject matter experts that are employed within the animal facility will engage in continuous professional development that will ensure best practices in pharmacology, radiography, animal husbandry and welfare are regularly adopted during the lifetime of the project.

75. Cellular homeostasis and brain development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

neurodevelopment, Brain, Neurons, microglia, neurodevelopmental disorders

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main aim of this project is to understand the role of pyramidal cells, the most abundant excitatory cell in the cerebral cortex, in regulating the development, distribution and maturation of microglia, the resident immune cells, in the developing cerebral cortex.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodevelopmental disorders such as autism spectrum disorders (ASD) affects at least 1% of the population. Currently, there are no known treatment. Furthermore, ASD are only reliably diagnosed late in development, consequently preventing earlier intervention in halting disease progression. The lack of treatment and earlier diagnosis is largely due to our lack of understanding as to how the brain develops. This work aims to remedy this by (i) increasing our understanding as to how brains are formed during development, (ii)

identification of a critical time window during development in which the brain is susceptible to perturbations and (iii) providing insights into how neurodevelopmental disorders such as ASD mayarise during development.

How does this work aim to achieve this?

Neurons are the basic working unit of the brain in which information is transmitted and processed from the periphery to the brain. Pyramidal cells, in turn are the most abundantly found excitatory neurons present in the cerebral cortex. In individuals that have been diagnosed with ASD, pyramidal cells have been known to behave aberrantly (e.g. altered levels of neuronal activity). We hypothesised that despite the different factors contributing to ASD, these factors converge onto a similar molecular mechanism, namely alteration of neuronal activity during early postnatal development. These changes can have an impact on how brains are built, especially on cell types such as the brain immune cell, microglia. Microglia are known to be involved in different aspects of brain development, more specifically in how neurons communicate with one another. Consequently, alteration in how microglia develop, mature or even the amount that are present in the brain can have a significant impact on how the brain functions. In this work, we aim to understand how changes in pyramidal cell activity can impact microglia development and how deviation from normal microglia development may contribute to some of the impairments observed in ASD such as alteration in cognitive function.

What outputs do you think you will see at the end of this project?

Overall, this proposal aims to find new methods of earlier autism spectrum disorder (ASD) diagnosis and intervention by increasing our understanding of the molecular mechanisms involved in brain formation. This will be achieved by demonstrating that although different factors (e.g. genetic mutations, environmental insults such as maternal infection during pregnancy, pollutions) may contribute to ASD, these factors however, converge onto a similar molecular mechanism, namely alteration of neuronal activity during early postnatal development. We hypothesised that this alteration of neuronal activity has a significant impact on how brains are built, especially on cell types such as the brain immune cell, microglia, which are known to modulate cortical function and behaviour. The discovery from this proposal will be key in (1) identifying the role of neuronal activity in modulating microglia development and number, (2) identifying the critical period during development in which the developing mice are susceptible to changes and (3) convergence of molecular mechanisms leading to the phenotypes typically observed in individuals with ASD. These discoveries will increase our basic understanding as to how brains are built during development and provide insights as to what happens during ASD and possibly other neurodevelopmental disorders.

In the long term, application of the knowledge obtained from this project onto human development will allow for (1) understanding as to how alteration of neuronal activity during early development can impact microglia development and number which in turn may explain some of the impairments observed in ASD, (2) earlier diagnosis of ASD based on changes in neuronal activity observed during gestation or during the first few months of life using resting-state fMRI and (3) new therapeutic avenues that might prevent or reduce the impact of changes of neuronal activity during early development.

To ensure that these discoveries and information will be disseminated as far and wide as possible, we will publish these discoveries in peer-reviewed scientific journals and also in talks and posters during conferences (both positive and negative results). Furthermore, the

project involves the generation of transcriptome datasets, which illustrates the changes in multiple gene expression within the microglia population in reaction to altered neuronal activity. This data set will be made readily available through online repository. We will also summarise our findings for the general public and will communicate our discoveries through press releases and also via social media (e.g. Twitter).

Who or what will benefit from these outputs, and how?

According to the latest statistics from the UK government, neurodevelopmental disorders such as autism spectrum disorder (ASD) affects at least 1% of the population. Unfortunately, this is likely to be an underestimation due to the difficulty in diagnosis, especially among young children. Currently, the earliest detection of ASD in humans are approximately 2 years old. More often however, individuals with ASDs are typically diagnosed much later in life. Earlier detection and diagnosis of ASD will enable earlier intervention that may reduce social and cognitive deficits. One possible avenue that may allow for earlier diagnosis and intervention is by increasing our understanding on the aetiology of ASD.

In the short term, the outputs from this project can be seen in the advancement in basic sciences. The discovery from this proposal will be key in (1) identifying the role of neuronal activity in modulating microglia development and number, (2) identifying the critical period during development in which the developing mice are susceptible to changes and (3) convergence of molecular mechanisms leading to the phenotypes typically observed in individuals with ASD. These discoveries will increase our basic understanding as to how brains are built during development and provide insights as to what happens during ASD. The people benefiting from these outputs will include researchers from within and outside the field where they will be able to utilise the scientific discovery made and the training provided (e.g. knowledge gained from the insights and the direct use of the data that will be made available via publication and online repository). Furthermore, new collaborations may be formed based on the data produced by this proposal.

One of the long-term objectives of the lab is to collaborate with clinicians in order to determine how these findings can be applied onto human development. Application of the knowledge obtained from this proposal will allow for better understanding as to the aetiology of ASD and the possibility of an earlier diagnosis among children. Currently, there are no known treatments available for ASD. Identification of new therapeutic targets that can prevent significant alteration in neuronal activity during development may not necessarily cure ASD, but it will halt the deterioration of further impairments that can occur during development. Consequently, earlier diagnosis and prevention will allow for better management of the symptoms.

Finally, if the outputs from this project can be successfully applied onto human development, individuals with high risk of developing ASD (e.g. siblings with known ASD diagnosis) in the long-term, will benefit from this work as earlier detection of this disorder will allow for more efficacious treatments and preventive measures to be done earlier during development. To this end, we are currently consulting with clinicians in order to determine how the discovery from this proposal can be applied onto human development. Together, this will allow for earlier diagnosis and potentially earlier intervention in individuals that have a high risk of developing ASD.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work, we will disseminate the output of the project through publications and preprints. We will also disseminate outputs (successful and unsuccessful approaches) through talks, poster presentations and informal discussions during conferences and meetings. We will also look into building new relationships with clinicians in order to apply this knowledge onto human development. Furthermore, the output of this work can also be further maximised by the formation of new collaborations, both in the field of neurodevelopment and beyond, as the knowledge generated through this project can be easily applied to other diseases, organs and organisms.

Species and numbers of animals expected to be used

- Mice: 5700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use genetically modified mice, both males and females, in this proposal in order to study cell-cell interactions in the developing brain. For this purpose, mice are an ideal choice as brain development in mouse is similar to those in humans the mouse brain contains the same complement of cell types as in humans the availability of genetically modified mice allows for specific cell type manipulation and the induction or deletion of specific gene of interest.

This project will use animals in all life stages. This will allow us to investigate how the brain develops during early postnatal weeks and also to study the consequences of altered brain development in the adult animals.

Typically, what will be done to an animal used in your project?

The bulk of the animals in this protocol will not undergo any further procedures beyond the normal breeding and maintenance procedures (70%).

The remaining animals will undergo at least one (10%), two (15%) or up to three (5%) of the following procedures listed below

Administration of substances peripherally (e.g. via their diet/drinking water, orally, subcutaneously (e.g. under the skin) or intraperitoneally (e.g. into the abdominal cavity)). Substances will be administered maximally for 7 days, twice daily.

Administration of substances directly into the central nervous system of neonates (e.g. intracerebral injections). This procedure will not last more than 30 minutes.

Behavioural tests that aims to measure the different aspects of behaviour that are typically associated with neurodevelopmental disorders (e.g. cognition, compulsion). The maximum length of time the animals will spend performing these behavioural tests will not exceed 24 days.

Brief sensory deprivation/stimulation models aim to elucidate how alteration of neuronal

activity impact on the developmental trajectories of cells present in the developing cortex. These models will be performed maximally for 3 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Previous experience has shown that these procedures do not typically induce any adverse effects. Nonetheless, listed below are possible adverse effects that may arise in this project.

There is a low risk of death occurring from anaesthesia or complications during surgery (<1%)

Other adverse effect from surgeries and substance administration may include weight loss in excess of 15% of total body weight or excessive loss of coat (e.g. piloerection) in rare situations.

Low risk of hypothermia from Morris water maze. This will be mitigated by the use of heating cabinets and by maintaining the water and room temperature appropriately (<1%).

Low risk of pups being rejected by their mothers or foster mothers after administration of substances into the central nervous system (<1%)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities of the animals in this project will be mild (70%) and moderate (30%).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The main aim of the project is to understand the formation of the brain and elucidate the role of neuronal activity in shaping the development and maturation of the various cell types in the developing cortex.
The developing brain undergoes tremendous changes during the first few weeks of mouse postnatal development. Due to the complexity and ever-changing physiological environment during development, the use of mice is necessary as the tissue architecture plays an important role in influencing this process. Currently, it is inconceivable that we will be able to generate computer models that will allow us to study the cell-cell interaction in

an ever-changing three-dimensional structure that is required for this study. For the same reason, this precludes the majority of in vitro models such as primary slice cultures. Nonetheless, we will use organotypic slice cultures whenever possible to reduce the severity of the procedures. In this instance, we aim to use organotypic slice cultures in order to test the efficacy of our pharmacological candidates before testing these drugs in vivo.

Which non-animal alternatives did you consider for use in this project?

As a non-animal alternative, I have considered the use of organoids as a potential in vitro system. Organoids are self-organising three-dimensional multicellular in vitro tissue. Organoids are derived from stem cells that are meant to recapitulate the developmental progression of an organ in vitro.

In addition, I have checked the FRAME website (www.frame.org.uk) and currently there are no other suitable replacement available for this current project.

Why were they not suitable?

The use of organoids has several major limitations in these key areas as they lack:

the correct cellular structure and layers (e.g. the presence of inputs from brain regions outside of the cerebral cortex such as the thalamus is lacking in organoids)

the complex environment is required to study brain immune cell behaviour and neuronal interaction. It has been previously shown that brain immune cells do not fully mature into the adult state when grown outside the organism (e.g. cell culture and organoids).

The brain consists of many different cell types that originate from different lineages during development. Organoids however are grown from cells originating from a single lineage. Consequently, it is currently not possible to study the interactions between cell types from different lineages using organoids.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have estimated the number of animals used based on my previous experience and the current preliminary data obtained where I have performed power calculations. As most of the data required can be obtained from ex vivo analysis, we will be able to use the same samples for multiple experiments in order to address different scientific questions. The bulk of the animals estimated in this project will come about through the breeding of mice for the appropriate genotypes. The number of animals estimated have been calculated based on Mendelian genetics in order to obtain the desired genotypes. Consequently, multiple breeding will be required to obtain animals with the appropriate genotypes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have 10 years of experience using mice as a model system for studying neurodevelopment. I have used this experience together with tools such as the NC3R's experimental design assistant to minimise the number of animals used when testing our hypothesis, including the use of factorial experimental design. Furthermore, prior to the experimental design, I have also taken the online course (www.3rs- reduction.co.uk) and went through the PREPARE guidelines (https://norecopa.no/prepare) in order to minimise the animal used while ensuring high reproducibility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To optimise the number of animals used, all lab members will be required to take an online course designed to minimise the number of animals used (www.3rs-reduction.co.uk).

With regards to animal breeding, we will ensure efficient mouse breeding by maintaining a detailed record of the breeding and colony management. Record keeping in this instance will allow us to identify problems with the colony early on (e.g. the performance of the breeder, rotating breeders on a strict schedule, replacing non-productive breeders). Furthermore, we will also cryopreserve any mice strains that are not in use. We will also have a brain database to ensure that every brain collected will be recorded together with the relevant information (e.g. experiments conducted, age, sex) to ensure that it can be used by the entire lab in addition to other researchers beyond the lab. We anticipate that as the mouse brain is relatively large and quite a substantial number of brain slices can be obtained per animal, this will allow for the maximal use of the tissue collected. In addition, the tissue collected can be used for pilot experiments in which we will test novel reagents such as antibodies. Together, this will reduce the overall usage of mice in our experimental procedures while sharing the resources with everyone in the lab and in the university.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically modified mice to study the function of specific genes in the formation of the brain during development. Some of the procedures that will be used in the project aims to manipulate genes in specific cell types. In the case of neonatal manipulation, we will provide special care to ensure that no pups are deserted after intracerebral injections. In particular, we have previously found that rubbing pups with the bedding reduces the probability of mothers rejecting their pups. This method not only serves as a refinement measure but also lessens the number of animals used, due to a reduction in animal lost. Furthermore, localised administrations and manipulations reduce the adverse effects that are typically associated with systemic manipulations where

multiple organs and cell types are affected at the same time. For all genetic manipulations, animal welfare is our topmost priority and care will be given in terms of anaesthesia, analgesia and recovery monitoring to ensure that any discomfort and suffering will be minimised.

Why can’t you use animals that are less sentient?

The aim of this project is to study brain development which involves a complex choreography of different cell types in an ever-changing environment. Currently, the mouse remains the best options as there are (1) no suitable in vitro experiments that can mimic the in vivo environment, (2) less sentient animals such as drosophila, worms and zebrafish lack a cerebral cortex and in some species (e.g. drosophila) microglia and (3) the brain development process in mice is relatively similar to those in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animal handing and care will be conducted in a manner that minimise stress whenever possible. This would include using techniques such as tunnelling. We also aim to minimise any distress in animals while performing behavioural tasks. In the Morris water maze, animals are subjected to 5 trials per day over 7 days where the aim of the test is for the animals to learn the location of the hidden platform. Each trial last for 1 minute followed by a 30 second interval in which the animals are left on the platform. To minimise distress, the water and room temperature will be maintained appropriately and any animals that failed to find the platform after the 1-minute trial will be guided directly to the platform. For rotarod, transient stress may occur when the animal falls from a short distance from the rotating rod. We will minimise stress and avoid potential injury by padding the surface in which the animals will fall onto.

Special care will be given to all animals after a surgical procedure or prior to any animal behaviour experimentation where they will be gently handled and habituated in order to minimise stress inflicted by the procedures. This will include increased monitoring after any surgical procedure which includes post-operative care and analgesic if required. In addition, we aim to reduce the duration of all surgical procedures. We also aim to minimise the time pups are kept separated from their mothers in order to reduce their distress. All new lab members will be trained on animal cadavers until they are competent to perform the surgeries.

Refinement can also be achieved in the type of mice we used. In full knockout animals, the gene of interest is systemically removed in the entire organism. Sometimes, the global removal of certain genes can induce multiple organ dysfunction that can impact the health and welfare of the animals. By using, specific genetically modified mice in order to manipulate genes in a specific subpopulation of cells when possible, we can mitigate the potential adverse effects that are observed in full knockout animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines and advices provided by the NC3Rs regional manager to ensure that the experiments are conducted in the most refined way. Furthermore, we will follow the guidelines published on the home office websites (https://www.gov.uk/guidance/research-and-testing-using- animals) and the N3CRs

(https://nc3rs.org.uk/3rs-resources).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will be working closely with the NC3Rs regional manager who will be able to advise us on the advances in the 3Rs and implement these advances effectively during this project. Furthermore, prior to the start of any animal experimentations, all lab members are required to undergo a 3Rs training course provided by the NC3Rs (https://nc3rs.org.uk/e-learning-resources) which will provide training on animal welfare assessment, euthanasia, and anaesthesia. In addition, all lab members are expected to be up- to-date on advancement in the 3Rs through literature in journals such as ILAR Journal online and Journal of Applied Animal Welfare Science.

76. Genetics of sex differentiation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

sex determination and differentiation, reproduction, cell fate determination and maintenance, disorders of sexual development, sex hormones

Animal types	Life stages
Chicken	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how cells choose and maintain specific forms and functions (cell states or fates) during development and in the adult animal in specific biological systems, notably the gonads, pituitary and sexually differentiated tissues and how this leads to disease when the processes go wrong.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

During the development of an animal, cells go through a sequence of cell divisions and fate decisions, in which they transition from one cell type to another. These changes are

driven by complex gene expression programs, that respond to their changing environment (external signals). These decisions of cell fate have to be coordinated in time and space to generate functional tissues, organs and the animal. Although some aspects of certain cell fate decisions can be studied i*n vitro*, and we both use and develop such approaches, it is generally essential to study them *in vivo*, using animal models.

The main purpose of the work to be conducted under this Project Licence is to provide fundamental knowledge on gene networks and cell fate decisions in chicken sex determination/differentiation.

Sex determination refers to the process by which a sexually reproducing organism differentiate as a male or as a female. Central to this process is the differentiation of the gonads into either testes or ovaries, which then operate as the niche for the maturation of the germ cells in either sperm or, respectively, eggs, as well as endocrine organs. The hormones produced, the sex steroids, control the fate of other sexually differentiated structures, such as internal and external genitalia and other body features and are also important for fertility.

In mammals sex is dictated by the inheritance of the sex chromosomes (genetic sex determination system, or GSD) to give XX females and XY males. A single gene on the Y chromosome acts as a dominant inducer of testis differentiation. In its absence the ovarian pathway prevails. From its discovery, many other genes have been identified which have allowed to start building the gene networks that regulate the process.

Most of our knowledge derive from the study of mouse models and from the genetic analysis of human patients with disorders of sexual development (DSD): a wide range of conditions present from birth where the development of internal or/and external sex features are, discordant, different from expected, based on the genetic sex (XY or XX); Despite the advances in the field, the molecular cause of the majority of these cases remain unknown.

A critical feature that has emerged and seems to be common to other vertebrates, is that male and female signal networks are mutually antagonistic. One pathway has to be established while the other has to be continuously suppressed.

This makes the system very plastic. For example, in the adult mouse gonad, altering the expression of key male or female promoting genes, such as *Dmrt1* or, respectively *Foxl2*, causes a switch in the gonad sex identity (gonadal sex reversal). Some examples of naturally occurring plasticity have been observed in mammals. For example *Foxl2* has a key role in early embryonic ovary determination in goat, but not in mouse, where it assumes a key role in the ovary only after birth. Seasonal plasticity have also been observed in other mammals. For example in the Spanish mole, the female show sex seasonal variation, as, outside breeding season, part of the ovary produce male hormones, which result in some masculinisation of body features, including a more aggressive behaviour.

Many of the molecular players identified in mammals are conserved in other vertebrates, like birds, turtle, fish, reptiles, however they may be expressed in a different order. This fluidity is quite evident at the top of the sex determination cascade where transitions between different trigger mechanisms have been commonly observed even between closely related species. (e.g. in fish and reptiles it is common to observe transition between GSD and environment-dependent sex determination (ESD)). This means that mechanisms of gonad sex determination are rapidly evolving and therefore are quite

variable across vertebrates, in contrast to most other developmental processes. Even in mammals, that have a stable GSD system, a few species do not have a Y chromosome (e.g. spiny rat), indicating that the regulator may be replaced by other genes downstream in the pathway.

We are far from understanding the sex determination pathways in vertebrates and we need to study different models to understand the core elements of the process.

The chicken has been chosen as, like mammals, it has a stable GSD system (the female inherits the heteromorphic chromosomes (ZZ/ZW system)) and there is a high degree of homology between the chicken and the human genome. It is a versatile model, that is easily accessible for embryo manipulations and now can also be genetically modified. Due to its sensitivity for endocrine disrupting chemicals (EDCs), it has also been proposed as a bioassay for impact assessment of EDCs on reproductive tissues. We aim to understand the molecular mechanism that control chicken gonad sex determination, how the downstream genetic pathways specify male and female different gonadal cell types and how these instructions are coordinate at organ level.

We will use the chick (this PPL) and the mouse (separate PPL) to understand conserved mechanisms and help to construct the networks of gene activity required for ovary versus testis development and reveal how certain genes take critical roles within these network in a species specific manner. By comparing aberrant gonadal fate decision in chicken and mouse models due to variation in genes, developmental programming, or hormones throughout different life stages we will gain understanding on causes of DSDs, on the role of the gonadal sex in controlling the development of sexual dimorphism and the potential consequences of environmental endocrine pollutants on reproduction.

What outputs do you think you will see at the end of this project?

-Improved understanding of the mechanism of chicken sex determination and of the genetic pathways that drive testis or ovary differentiation. We have recently established that the trigger of chicken sex determination depends on the dosage of the Z gene *Dmrt1* and that the gene *Foxl2* is an essential key gene for ovarian determination in the embryo. We now aim to characterize the interactions between *Dmrt1* and *Foxl2* and to identify the networks regulated by these genes in establishing the testis or ovarian pathway. This work may also lead to the identification and characterization of new genes of the network.

Improved understanding of the plasticity of the chicken gonadal sex; by perturbing the expression/regulation of potential key ovary or testis genes in the adult gonad (e.g. *Foxl2*) will lead to new insights into cell fate reprogramming and organogenesis.

Improved understanding of female reproductive function, fertility and premature ovarian failure. We have shown that eliminating one copy of *Foxl2* in chicken results in a phenotype characterized by an eyelid phenotype and, in females, shorter fertility lifespan. These phenotypes resemble the human Blepharophimosis, ptosis, and epicanthus inversus (BPES) syndrome, This model therefore may be used to shed light into human BPES.

-Improved understanding of the hypothalamic-pituitary-gonadal axis. *Foxl2* is a key gene for the adult ovary function, but it is expressed both in the ovary as well as in the pituitary endocrine cells producing the hormones regulating the ovarian cycle. The generation of new chick models where *Foxl2* expression is perturbed in each of these organs separately, will provide new insights into *Foxl2* role in each of these organs and in the sex hormones

local and systemic effects on fertility and may inform new strategies to manage fertility.

Improved understanding of the evolution of sex determination and of the pathways that are conserved.

-Improved understanding of the role of the gonadal hormones and of the sex chromosomes on sexual dimorphism. The chicken model we have generated, carrying a mutation in *Dmrt1*, has shown that ZZ chickens with only one copy of functional *Dmrt1* have gonadal sex reversal (male to female) and sex reversal of the internal and external reproductive organs, but they maintain male body features (e.g. male greater musculature mass, larger combs and wattles, obvious leg spur). This shows that many sexual features of the body in chicken are more influenced by the sex chromosomes of the cells forming the tissues, than by the gonadal hormones. We aim now to analyse the effect of gonadal sex reversal on sexual dimorphism in the opposite direction (female to male, in *Foxl2* knock-out models).

The use of animal models which provide improved understanding of the mechanisms underlying sex bias in human diseases will be of clinical benefit in terms of improved diagnosis and perhaps options for treatments.

We will publish all of our findings in open access journals, with data in a reusable form. Moreover, germ cells from any genetically altered chicken line generated as part of this PPL, will be made freely available to other researchers.

Who or what will benefit from these outputs, and how?

There are likely to be multiple beneficiaries from the outputs above.

-In the short term our studies will shed light into unresolved questions in the field of sex determination and its evolution, opening new ways forward to other scientists working in chicken and other systems. Moreover they will be beneficial also to researchers working on the more applied field of reproductive biology in chicken, but also other birds and mammals

As the chicken is a farm animal, the improved understanding of chicken sex determination will be of relevance to the chicken industry, as it will allow the industry to make more informed decision on issues related to fertility and to sexual development. Similarly our study may be of benefit to conservation programs.
-Our studies on the genetic pathways driving sex determination/differentiation will be of relevance to DSD in humans and have an immediate impact. DSDs represent a major paediatric concern and a significant healthcare burden due to the difficult clinical management of these conditions and, in some, the association with gonadal cancer and infertility. It is estimated that the incidence of new-borns with ambiguous genitalia is 1 in 4,500-5,500 births. More commonly, 1 in 300 new-borns present with some sort of developmental abnormality affecting the somatic sex phenotype. The range of pathologies of DSDs is quite extensive and, as of yet, the molecular cause for the majority of these cases is unknown. Only 50% of the cases receive a definitive clinical diagnosis and only for 20% of those a specific molecular diagnosis. A better knowledge of the genes and genetic pathways involved in the process through the study of animal models is essential to improve the ability of making correct diagnosis of DSDs, and apply the right treatment, which may include surgical intervention and/or lifelong hormonal treatment.

-Improving our knowledge of sex differences may ultimately improve gender based

healthcare in humans, as relevant to the pharmaceutical industry for gender-based drug development In the longer term (perhaps in 5 to 15 years). There are sex differences in food consumption, metabolism and obesity, with concomitant differences in the risk and manifestation of obesity-related conditions such as atherosclerosis and diabetes and in cardiovascular disease and hypertension. It is therefore crucial to determine the factors that lead to the sex differences for the development of novel therapeutics.

How will you look to maximise the outputs of this work?

Alongside the publication of primary research papers in open access journals, we will present our work at meetings, ranging from small focused workshops to large international conferences. Critically, we will communicate negative results and approaches as well as those that are positive.

We collaborate, both internally, within the host Institute, and externally with scientists and clinicians based in the UK and abroad.

We share details of approaches and data generated with our collaborators, which allows for improved development of methods and better synthesis of findings.

Where we develop new transformative methods, we will publish the protocols as papers and post them on bioRxiv.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use chickens for all the projects covered in this PPL. These studies will be complementary to the studies in mice that are covered by a separate PPL. This is done for multiple reasons. First, these studies will improve our understanding of the evolution of sex determination/differentiation.

There is much to learn about sex determination pathways in vertebrates, including even in mice and humans. Data obtained from the chick will indicate additional conserved mechanisms and help to construct the networks of gene activity required for testis versus ovary development and reveal how certain genes take on critical roles within these networks in a species-specific manner.

Secondly, recent advances in the understanding of sex determination/differentiation have raised doubts as to the universality of the mouse as mammalian model of sex determination. For example, studies in mouse have shown that the gene *Foxl2* has a key role in the adult ovary to maintain the ovarian fate, but it is dispensable in the embryo for ovary differentiation. However in another mammal, the goat, *Foxl2* is necessary for early ovary differentiation. Moreover the differentiation of the early ovary in the mouse is atypical, as it proceeds in the absence of any estrogen and the germ cell niche is only

formed quite late, compared to other mammals. It is therefore important to study other model systems to better understand ovary determination and differentiation. The chicken is chosen because, like mammals, it has a genetic sex determination system and it is an amniote. Most genes important for the differentiation of the ovary or testis are conserved, including *Foxl2*.

The chicken has many experimental advantages. The embryo is easily accessible for manipulations, such as tissue ablations and tissue grafts, administration of substances and gene mis-expression. It is particularly suitable to study gonadal differentiation as the gonad is one of the organs that can be easily and specifically targeted in the embryo. Moreover, it is now possible to generate genome modifications that can be transmitted via the germline.

With respect to life stages, our work ranges from early embryo in the egg, all the way to ageing adults. This range reflects, in part, the focus of the lab on certain genes, for example *Foxl2*, that function in cell fate decisions throughout many or all these stages, but also the importance of understanding the effect of changes that take place during organ development in the adult.

Typically, what will be done to an animal used in your project?

The main work covered by this PPL involves breeding, including genetically altered (GA) animals and harvesting tissues from embryos or from post-hatching animals after they have been killed (using a schedule 1 procedure) for detailed analysis of phenotypes.

Some embryos from wildtype or GA lines may be subject to cell/tissue grafting aimed to generate gonadal chimera. A few of them may be hatched and killed at different stages of gonad differentiation.

Some embryos from wildtype or GA lines maybe administered viral particle, marker molecules, or DNA. Most embryos will be killed before the first two thirds of embryogenesis.

We may use substances such as doxycycline, to induce a genetic alteration, e.g. a conditional loss- or gain-of-function of a specific gene, as well as to follow cell fates, or to isolate specific cell types (e.g. by activation of a fluorescent reporter gene).

We may also use signalling pathway modifiers, such as Fadrozole or Estrogen, to interfere with the sex determination process, or challenge the ovarian or testis pathway and/or use labelling agents, to look at cell processes (e.g. EdU or BrdU for cell proliferation) in tissues after harvesting.

These substances may be administered in the egg, or in post-hatch animals in diet or by injection, and may be carried out multiple times over a few days, followed by a variable period prior to the animal being killed and the tissues analysed.

Most of the manipulation work is carried out and terminated in embryos before the first two thirds of embryogenesis.

Some animals may be used as surrogate hosts to transmit exogenous germ cells that may have been genetically modified. Those surrogates may be GA with defective germ line. We may use drugs to kill the endogenous germ cells. These procedures are done at early embryonic stages and the hatched animals are kept as founders for breeding and for

generating embryos for experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

We are investigating the genetic pathways affecting the development of the reproductive organs, secondary sexual characteristics and the fertility of the birds. Therefore we work with lines with specific gene mutations affecting gene expression or regulation which may result in male-to-female or female- to-male gonadal sex reversal and/or sterility. Those chickens should experience no more than mild effects. The birds will be closely observed to monitor any unexpected adverse phenotypes. With mutations affecting some genes, there may be broader phenotypes, which can lead to more severe adverse effects (e.g. Foxl2 knock-out line has also a chronic eyelid phenotype of moderate severity already present in heterozygotes). All those lines with harmful mutations, or leading to sterility, will be normally maintained for breeding as heterozygotes, or whenever possible, will be maintained by cyclic generation of germline chimeras (chicken surrogate hosts carrying modified germ cells of interest).
Some animals may be crossed to generate homozygotes or compound mutations, where stronger phenotypes occur, including embryonic or postnatal lethality, or reduced lifespan. It will be necessary to study embryonic stages and to keep some animals with harmful mutations until the phenotypes develop, in order to study how they arise. We will kill animals before end points for the relevant severity band are reached.

The frequency, type and severity of any adverse event depends on the procedures being used, together sometimes with genetic status, including the genetic background of the strain. We endeavour to minimise the chances of these occurring; for example we will generate new GA lines by designing genome editing strategies that perturb gene expression in a defined temporal window and/or specific tissue, when the gene under study may have roles in multiple tissues within the body. However the cause of adverse effect sometimes may be unknown. This is also the case of the occasional death after administering signalling modifiers (e.g. tamoxifen).

In the case of new GA lines the phenotype will be analysed in steps, starting with the egg at different stages of embryogenesis and then in the hatched chicken at different timepoints. GA lines with known adverse effects will be closely monitored. One such a line is the Foxl2 knock-out line which has a chronic eyelid phenotype of moderate severity developing from hatching even in heterozygotes and therefore affecting the chick welfare for all its lifespan.

Any animal will be killed prior to it reaching the relevant end points as defined in the protocols.

Surgical procedures are generally performed in the early embryo and therefore should not cause discomfort. All embryonic manipulations may have variable success rate which is difficult to predict. However their outcome is normally established by monitoring the embryos growth, and embryos that continue with their normal development may be incubated up to hatching.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category

(per animal type)?

The expected severities for the chicken experiments are:

Mild; about 50% of the animals. Moderate; about 49% of the animals. Severe; less than 1% of the animals.
The germline chimera chickens (chickens derived from embryos injected with exogenous germ cells) and the gonadal chimera chickens (chickens derived from embryos transplanted with tissue that give rise to the gonad) are falling in the mild category. The GA line mutated in the *Foxl2* gene (*Foxl2* knock- out) falls in the moderate category due to an eyelid defect that compromise the ability to blink. Those animals are under eye treatment regime to avoid infections. The severe category includes animals with unexpected severe effects; those animals would be killed if found.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Most, if not all cell fate decisions in the embryo and adult animal take place within a complex environment, where events inside the cells are influenced by a variety of signals, whether these are from neighbouring cells, involve molecules, such as growth factors, cytokines and hormones (which can act over considerable distances), are commensal with the animal, such as gut microbiota, or are part of the environment, i.e. are external to the organism. Moreover, most tissues develop in a complex way in three dimensions over time in a carefully orchestrated manner. Therefore, although some aspects of certain cell fate decisions can be studied *in vitro*, and we both use and develop such approaches, it is generally essential to study them *in viv*o (as a minimum to judge the suitability of *in vitro* systems to give meaningful information).

Several distinct cell lineages give rise to the developing gonads and their continued interactions are required for appropriate gene activity leading to the development of either testes or ovaries. It is currently not possible to mimic all of these cell-cell interactions using cells maintained *in vitro*. Moreover even if we can culture the intact early gonad for periods of few days, which does allow us to follow some events in real time (and reduce animal numbers), this still requires breeding to produce the animals.

To study postnatal gonadal sex reversal, cannot meaningfully be studied in any current *in vitro* system. While it is possible to culture isolated specific type of ovarian cells for a limited time, they tend to lose expression of critical genes and their normal features. The same is true of cells in the testis.
Without a robust and reliable culture system that could maintain the properties of different cellular types, it would be impossible to address the consequences of deleting *Foxl2* in the adult ovary in meaningful way. Moreover, it would not be possible to investigate how other

testicular cell types differentiate, nor the complex morphological changes occurring from ovary to testicular-like structures.

(iii)The pituitary develops through a complex series of events involving different tissues and there are no actual protocols to reproduce its cellular organisation and proper hormonal function *in vitro*.
Progresses have been made in growing pituitary organoids, from stem cells, however also these structures don't have sufficient complexity to model the *in vivo* organ, or to be useful to address the complex interactions of the pituitary with the gonad, to regulate reproduction, ageing and other key physiological processes, which requires whole animal study.

(iv). There is now increasing evidence that many aspects of anatomy, physiology, behaviour, pathologies and responses to treatment, differ between the sexes and even when these appear similar, the underlying mechanisms may be different. These differences are likely to be due to direct effects of sex chromosome-linked genes, to sex hormones made by ovaries or testes, or both. Moreover, these effects can be organisational (i.e. they are established during development, perhaps prior to any obvious difference), or activational (require constant input). Experiments to understand the mechanisms involved, the importance of which have been widely recognised in recent years, cannot be conducted *in vitro*.

The use of the chicken as a model species itself addresses "replacement". The chicken offers advantages over using a mouse model, as the mother does not need to be killed to obtain the embryos and, as germ cells can be introduced in the embryo, there is no need of any surgical manipulation of the hen to generate new GA lines. Moreover the majority of experiments to study sex determination will also be carried out at unregulated developmental stages (before day 14.5 of incubation).

Which non-animal alternatives did you consider for use in this project?

We complement our *in vivo* analyses in chicken with tissue culture models and organ culture.

Why were they not suitable?

We can gain a certain amount of information from these culture systems, but there are serious limitations. It is not currently possible to replicate the complexity of tissue structures in culture models. Moreover such cell and organ cultures cannot permit research on aspects of biology such as reproduction or physiology.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on several factors. It is based on our experience of working with chick embryos and the experience over the past 4 years with generating and maintaining chicken lines (e.g. *Foxl2* and D*mrt1* knock-out GA lines).

We also continually re-evaluate the numbers of animals required for each experiment. This will allow us to determine the number of animals required per experiment to give statistically valid results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing specific experiments within the overall project, we estimate the minimum number of animals required to give robust answers. Most often this can be based on our prior experience, or on published data. Often it is not necessary to use statistics (e.g. three transgenic lines giving the same result shows that this is correct), however, we perform statistical analysis whenever necessary. Where experiments result in consequences, for which we have little or no prior information, usually around 5 or 6 animals per treatment group (which will include sex as a variable when relevant and possible) are sufficient to obtain robust results. The design of quantitative experiments generally follows the ARRIVE guidelines and sample sizes may be set using power analysis. Any exceptions are where there is a degree of variability beyond our control (for example, where minor fluctuations in conditions together with threshold effects require more animals to be examined in order to have statistically significant results). We generally use a significance level of 5% and a power of 80%, estimating standard deviation from pilot experiments. We may include advice taken from local statisticians as well as make use of online tools, such as the NC3Rs' Experimental Design Assistant. For some important questions that we wish to address there can be a choice between using a mild procedure but many animals because the measurable effect is weak, or a moderately severe procedure with few animals because the effect is robust. Our choice will depend on the specific question and available resources, but it will most often be to use fewer animals.

Genetically altered chicken embryos depleted of their own germ cells will be used whenever possible as surrogate hosts of exogenous avian germ cells to produce chicken chimera founders. The transmission rate in these GA hosts is 100% allowing to reduce both the number of chimera founders and the number of offspring for the establishment of the line. This strategy is more efficient than using host surrogate embryos treated with chemotherapeutic reagent to reduce the number of the host germ cells and improved transmission of injected germ cells. Moreover, these germ cell chimeras can be used not only as line founders, but also as regular providers of eggs for experimental studies and may be the method of choice to maintain a line with a harmful phenotype or a phenotype that leads to sterility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We try to keep as few chickens as possible by carefully monitoring our flocks and by good practice.

Whenever possible and when there are no harmful phenotypes (or infertility) we maintain GA lines as homozygotes to reduce the numbers of animals required for experiments and to reduce the need to genotype.

In case of infertility or harmful phenotype we may maintain the line via the germline chimera founders.

We may also make use of fluorescence reporters that can (in some circumstances) avoid the need of genotyping.

The ability to generate transgenic lines using primordial germ cells which can be cultured and frozen down means that lines of chickens would no longer need to be held and bred indefinitely. Frozen germ cells can be used many years later when a particular breed of chickens would be again needed by researchers.

Whenever possible, we pre-screen substances (including molecules to induce gene expression, cell death, mutagens, etc.) and agents such as viruses, in the egg (*in ovo*), or in cell culture (*in vitro*) to determine approximate doses required. We also test genome editing components *in vitro* (e.g. in primordial germ cells), prior to the generation of genetically altered animals.

To maximise information gained from single animals, we use live imaging when feasible (e.g for embryo work), obtain data on as many tests of behaviour as possible on single animals, and obtain relevant tissue samples from multiple sites after killing, where more than one project involves the study of an animal with a particular genotype; for example as *Foxl2* is relevant to studies of the gonad, pituitary and eyelid, we often collect multiple tissues from single animals.

Similarly, when designing new genetic tools, and maintaining animals derived with these, we will, wherever possible, do so in a way to allow them to be shared amongst as many people as possible, including making use of the Institute sharing platform. This efficient use of animals minimizes the number used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

-Cultured germ cells that can be genetically modified to disrupt gene function and used to produce chimera founders is unique to the chicken. The germ cell transplantation to form chimeras are carried out at early embryonic developmental stages (unregulated stages) and in an animal model that does not entail a surgical operation on the mother, or her death, to provide access to the embryos.

Moreover our use of genetically modified surrogate hosts for the generation of germline chimeras results in 100% transmission of injected germ cells, reducing the number of chicklings to be screened and making these chimeras also good providers of fertilised eggs for experiments. The latest refinement of the protocol, which allows to generate chimera founders (G0 generation) from both sexes of GA surrogates, may eliminate the necessity of

breeding the siblings (G1 generation) for line maintenance.
This is particularly important if the genetic modification causes infertility or if it adversely affects multiple tissues.

-Sex determination is an embryonic process so many experiments can be carried out in the egg.

-We choose well-established protocols, known to have minimal harmful effects, whenever possible. Many of the genetic and physiological manipulations, as well as the administration of substances, including gene inducers and repressors, viruses, cells and grafting of tissues, are standard and previous refinements from the literature will be used, if possible. For novel types of manipulation, or where insufficient information is available, small-scale pilot experiments are conducted in order to determine the best conditions to obtain a sufficiently robust and meaningful response from the minimum dose, exposure time, or treatment. These pilot experiments help to minimize any potential suffering.

-Although it is not always possible to predict the nature or severity of any defect that arises from a newly generated genetic alteration, we take steps to minimise unwanted phenotypes and/or the number of animals exhibiting these. For example, we may make use of tissue-specific regulatory elements and whenever practical, we may make genetic alterations that are inducible, so that the animals do not show a phenotype until expression of the candidate gene or a deletion is induced.

-When the experiment is predicted to lead to harmful effects outside the body system under study, we will provide treatments designed to alleviate these; for example the eyelid phenotype present in chickens mutated at the *Foxl2* locus is constantly monitored and regular ointment treatment is provided.

-To minimise stress during breeding and maintenance we follow best practice guidelines, institute refinements and, for some strains, our own specific procedures of husbandry. (e.g. the *Foxl2* knock-out line is in pens layered with horse shavings to minimise dust). In the case of any new strain of animal or application of any new procedure or refinement we pay special attention by increased observation and monitoring starting with the embryo and then in the hatched chicken, until we have become familiar with the phenotype and/or the consequences. If welfare implications are identified they will be acted upon and refinements considered in consultation with the NVS, NACWO and animal technicians.

Why can’t you use animals that are less sentient?

We use the chicken as a model complementary to the mouse, to study sex determination/differentiation, partly for evolutionary comparisons, partly because some aspects of the process may be more similar between chicken and human than mouse and human (e.g some features of fetal ovary differentiation) and partly because certain embryological techniques are feasible *in ovo*, but not in utero. A significant fraction of our research involves studies on chicken embryos *in ovo* prior to two-thirds through embryogenesis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all manipulations, we will adhere to the relevant guidelines that aim to minimise suffering. We examine the animals for signs of pain and discomfort (such as prolonged

lethargy) and monitor body condition, killing the animals if the distress is likely to be more than temporary. Many of the genetic and physiological manipulations, as well as the administration of substances, including gene inducers and repressors, viruses, cells and grafting of tissues, are standard and previous refinements from the literature will be used and added to ifpossible.

For novel types of manipulation, or where insufficient information is available, small-scale pilot experiments are conducted in order to determine the best conditions to obtain a sufficiently robust and meaningful response from the minimum dose, exposure time or treatment. These pilot experiments help to minimize any potential suffering.

Appropriate aseptic surgical techniques, temperature, and fluid therapy, will be applied as necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

These will include publications from the NC3Rs, the Institute for Animal Technology and the BVAAWF/FRAME/RSPCA/UFAW Joint working group, but also relevant articles in scientific journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay up to date via regular communication with animal care staff at the Institute, other scientists in our fields, via e-mail and other updates and publications from, and occasional attendance at meetings held by, the NC3Rs, the Institute for Animal Technology, and the International Society for Transgenic Technology, and through regular visits to their websites: https://www.nc3rs.org.uk/3rs-resources https://www.transtechsociety.org/ https://www.iat.org.uk

77. Modelling Liver Disease for Drug Discovery

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Fibrosis, Liver Cirrhosis, Therapy, Chronic liver disease, Liver damage

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to test the effect of novel compounds in models of liver disease, in order to assist with the development of new therapies where none exist or current treatments are inadequate.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Liver disease is now the third leading cause of premature death in the UK and is the top cause of premature death in individuals aged 35-49 years old. In contrast to heart disease

and cancer, where death rates have remained relatively stable, deaths from liver disease are increasing. If detected early, the effects of liver damage can be reversed successfully with treatment that can allow the liver to regenerate. Unfortunately, the majority of individuals already present with advanced liver scarring, at which point treatment options are limited.

Fibrosis (or scarring) is a result of part of the liver's healing response to damage and often occurs in the absence of any obvious symptoms. Long-term liver damage can lead to progressive fibrosis and eventually cirrhosis, liver failure and premature death. There is an urgent need for new therapies to prevent, slow or reverse fibrosis (and therefore cirrhosis) in patients with chronic liver damage and to ultimately prevent liver failure and death. Despite this need, there are currently no licensed treatments to slow or prevent fibrosis in chronic liver disease. Furthermore, liver transplantation is often the only treatment option for advanced cirrhosis, and with a shortfall in donors for liver transplantation, there is an urgent need for therapies that are able to prevent progression to this stage of disease.

What outputs do you think you will see at the end of this project?

We provide a suite of advanced, mode-of-action models that will allow the pharmaceutical and biotechnology industries to test novel and existing drug candidates for use in many conditions where the immune system plays a role. Information from studies performed at our establishment are used to make decisions about the progression of drug candidates to clinical trials.

Who or what will benefit from these outputs, and how?

In the short term, these outputs will assist the pharmaceutical and biotechnology industries in making key decisions about their drug discovery pipelines and whether to progress a drug candidate towards clinical trial. In the long term, this benefits patients as it prevents exposure to ineffective therapeutic agents and also facilitates the development of novel drug candidates that may have substantial clinical benefits.

How will you look to maximise the outputs of this work?

As work is performed solely on a commercial basis, for biotech and pharmaceutical clients, output will be subject to client confidentiality and therefore collaborative opportunities will be limited and at the discretion of the client, however, some of our previous clients have published our data in peer reviewed journals and presented at Scientific conferences. As dissemination of information may not be feasible, we will maximise the usefulness of the output through high quality experimental design and review of proposed experiments for scientific merit before proceeding with any work.

Species and numbers of animals expected to be used

- Mice: 6350
- Rats: 825

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We shall predominantly use mice, but rats could also be used if the drugs being tested are known to be more effective in rats than mice. The role of the immune system and the mechanisms of disease in these models closely mimic a lot of the aspects observed in the human disease. Therefore, use of these animals for drug development is directly relevant for the clinical treatment of humans.

Typically, what will be done to an animal used in your project?

It is envisaged that the majority of the genetically-modified animals used under this licence will be humanely culled to provide cells and tissues for use in the laboratory and will undergo no further experimentation. Where experimentation is conducted, procedures include manipulation of diet or administration of substances to induce liver injury where clinical signs should be minimal. All animals will be humanely killed at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

To replicate the effects of human chronic liver disease, listed models may lead to clinical signs including jaundice, ascites (abdominal fluid), or weight loss. Animals will be closely monitored throughout for signs of distress and culled humanely if they exceed the predefined limits.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of the animals used will experience mild to moderate effects. Any observed effects should be short in duration, and direct effects from liver injury should be mild. The majority of these effects are associated with weight loss, fatigue or mild discomfort following administration of treatment.

What will happen to animals at the end of this project?

- Culled

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Importantly, many of our assays are performed in the laboratory, rather than in animals. These often use human cells and allows us to test how different cells respond to potential drugs. However, once we have defined the most likely candidate drugs, we must understand whether these can in fact help to dampen the complex biological processes seen in liver disease.

Which non-animal alternatives did you consider for use in this project?

We routinely perform *in vitro* assays using human cells in order to test drug candidates on cells of the immune system. The majority of our work is conducted using these *in vitro* assays, however, animal studies are often required downstream of this in order to test drug efficacy in a living system prior to clinical trials in humans.

Why were they not suitable?

In vitro assays are very useful at measuring the effect of drug candidates on particular cell populations and complex assays can be designed to model a lot of the processes that occur in the body. However, *in vitro* systems currently cannot model all of the aspects involved in liver fibrosis that occur *in vivo*.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is the maximum number of animals predicted. As a Contract Research Organisation, it is difficult to accurately calculate the exact number on animals that will be used as this largely relies upon client requirements and demand. Whilst we offer *in vivo* models as a service, these experiments are ordinarily only performed as a small part of a larger package of work that is primarily focused on *in vitro* models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our emphasis as a company is to use data-rich *in vitro* methods so that clients can select the best compound(s) before moving forward to *in vivo* models. This means that drugs that are unlikely to be effective are screened out at an early, *in vitro* stage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our advanced *in vitro* assays allow us to advise our clients on which of their test compounds are most likely to be effective in *in vivo* studies. This saves time and money and, most importantly, reduces the numbers of animals required for studies.

In addition, pilot/initial studies will be performed using the least invasive protocols and only using drug candidates that have been proven to be effective in *in vitro* experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative

care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our objective is to provide advanced, mode-of-action models that will allow the pharmaceutical and biotechnology industries to test novel and existing drug candidates for use in liver disease. *In vivo* models are combined with advanced *in vitro* assays that allow us to study the effects of the test drugs on the processes involved in the onset and progression of liver fibrosis that often lead to liver failure.

The majority of the genetically-modified mice will be humanely culled to provide cells and tissues for use in the laboratory and will undergo no further experimentation. Beyond our breeding program, the majority of the animals used will experience mild to moderate effects. Due to the often asymptomatic nature of liver disease, the majority of the models of liver fibrosis and injury we will use are also associated with mild effects. Where possible, models that are able to provide the most relevant answers in a short time-frame will be used in order to minimise the duration of any clinical signs.

Why can’t you use animals that are less sentient?

Rodent models are extremely well-characterised and validated for studying the progression and regression of liver fibrosis and for evaluating the efficacy of new therapeutics. They also have the most extensively characterised immune systems, which is relevant for understanding the role immune cells play in the progression of liver disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where necessary, animals will receive appropriate anaesthesia during the procedure and analgesia following surgery. In some experiments animals are at risk of infection. These animals will be kept in a barrier environment and receive appropriate antibiotics. All animals are monitored regularly and any that show signs of ill health receive prompt veterinary intervention. If significant ill health is evident, the animals are humanely destroyed. Any further refinements that can be implemented over the course of this projects will be put in place following consultation with the Named Animal Care and Welfare Officer (NACWO) and Named Veterinary Surgeon (NVS).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to following the ARRIVE guidelines and the best practice procedures recommended by the NC3Rs, regular literature searched will be performed to ensure that the models used are the most refined for each purpose.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

In addition to communications and seminars from our Establishment Veterinary Services, we will routinely access the resources on the NC3Rs website (https://www.nc3rs.org.uk/) and subscribe to the NC3Rs newsletter in order to keep up to date with current developments.

78. Breeding and Maintenance of Immunocompromised and Genetically Altered Mice as a Service

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, breeding, colony management

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project licence is to breed, maintain and supply high quality immuno-compromised and genetically altered mice for use in cancer research under the authority of other project licences at our establishment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our breeding programmes can be managed in dedicated facilities and closely monitored to minimise over-production and to produce a high quality healthy animal. We work within guidelines which are taken from the Genetically Altered breeding initiative from the Home Office in relation to colonies which will be held under this service licence. Our experienced animal technologists supply the specific expertise necessary to provide the optimum

husbandry conditions, the highest level of health and welfare as well as accurately maintaining the minimum colony size to produce the animals required for research.

As a direct result of the work that is carried out in our facility using these strains of mice, major and innovative developments in the treatment of breast, testicular, lung and gut cancers have been made in human patients. These have been widely publicised in the media in recent years.

What outputs do you think you will see at the end of this project?

A single centralised breeding project will be managed by someone with specialised technical expertise in the required breeding methods and with stringent colony management. This is administratively efficient and has welfare benefits such as reduction in animal numbers by effective liaison with end- user projects. This will also ensure that appropriate strains of the desired specification are bred (best model for the disease areas), with minimal wastage and sharing of animal lines and/or tissues by several research programmes.

There has been a proven record of efficient generation and breeding of Genetically Altered Mice and this Licence will continue and improve the provision of high quality animals to researchers whenever such strains are not readily available from commercial breeding establishments.

Who or what will benefit from these outputs, and how?

As a direct result of the work that is carried out in our facility using these strains of mice, major and innovative developments in the treatment of breast, testicular, lung and gut cancers have been made in human patients. These have been widely publicised in the media is recent years.

How will you look to maximise the outputs of this work?

We will utilise published best practice guidelines for the breeding and management of genetically altered mice.

In addition we will liaise closely with research teams to plan their colony production to provide the numbers of animals they require whilst reducing the over production of animals.

Species and numbers of animals expected to be used

- Mice: 27550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents that lack a fully active immune system are a valuable research tool in cancer research enabling human tumour material to be grown. Genetically Altered mice are also a

valuable research tool enabling mice with specific targeted genes to be bred and maintained for use in many areas of cancer research. Many of the research projects will involve the use of laboratory systems such as cell culture, human tissue assays and computer modelling to complement the animal work. However, Laboratory assays cannot adequately replicate many of the complex molecular, cellular, physiological and behavioural properties necessary to fully understand how genetic modifications result in normal or abnormal tissue growth.

For this project adult mice will be bred in efficient colonies. The offspring of these breedings will be transferred to other Project Licences at the Establishment for use in cancer studies.

Typically, what will be done to an animal used in your project?

For this project, adult mice will be bred in efficient breeding colonies. The offspring of these breedings will be transferred to other Project Licences at the Establishment for use in cancer studies.

Typically, the only procedure these animals will be exposed to is identification by ear marking.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the genetic alterations will cause tumour growth in some animals and these will be closely monitored for typical signs of pain or distress. Mating of mice does not typically have any adverse effects. Occasionally, young pups are injured or killed by their parents. This we try to reduce by providing an enriching environment and ensuring that weanlings are removed before new pups are born. Occasionally we remove Male animals to reduce the likelihood of injury

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity of all animals in these protocols is Mild

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals in cancer research remains a vital tool in improving our understanding of how biological systems work in disease, and in the discovery and development of new

medicines, treatments and technologies. This licence aims to breed and maintain animals with impaired immune systems and genetically altered animals for use in research projects at the establishment.

Detailed justification for the particular programmes of research is provided by the individual scientists in their own licences that must always be approved by the Home Office.

Which non-animal alternatives did you consider for use in this project?

Many of the research projects will involve the use of laboratory systems such as cell culture, human tissue assays and computer modelling to complement the animal work.

Why were they not suitable?

Laboratory systems cannot always adequately replicate the complex molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal tissue growth.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Research into the causes and subsequent treatment of a wide range of cancer types requires the use of specific strains of mice including those with impaired immune systems and animals with specific genetic modifications that are relevant to the genetic pathways now known to be associated with tumour development.

We estimate that we will breed and supply 5000 immune deficient mice each year, approximately 500 Genetically Altered mice per year and very small numbers of approximately 10 animals for Superovulation per year.

These figures are based on projected animal supply to other project licences at the Institute. Supply and demand vary considerably however and historical data is also used to estimate future trends in usage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Using the latest good practice guidelines on the breeding and management of laboratory mice will allow us to maintain the lowest number of breeding animals to produce the required number of study animals.

Unfortunately due to the complex genetics involved in the breeding of Genetically Altered mice, there will be animals produced that we are unable to use for our studies. These we will humanely killed at the earliest opportunity or used for collection of tissue and blood products for further use in laboratory research.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Unnecessary production or import of genetically altered animals will be avoided by searching cryobanks and databases. Examples of resources available include:

NC3R's breeding and colony management: https://nc3rs.org.uk/breeding-and-colony-management

Animal Welfare Management Discussion Group (AWMDG): An email network for Named Persons to share ideas

RSPCA Animals in Science Resources:
https://science.rspca.org.uk/sciencegroup/researchanimals PubMed:
http://www.ncbi.nlm.nih.gov/
Web of Knowledge: https://wok.mimas.ac.uk/

Jackson laboratory: http://www.jax.org/ & http://jaxmice.jax.org/index.html

Home Office Technical Advice: https://www.gov.uk/guidance/animal-research-technical-advice

The strain used for generating a new colony will be carefully considered to avoid producing unwanted mice. Animals will only be bred if a user requirement has been established, and the breeding programme will be subject to regular review to optimally meet anticipated demand. Spare animals will be made available for use on other scientific projects.

Breeding will be optimised, wherever possible, to produce only the genotype required e.g. Homozygous breeding pairs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are universally used for work involving genetic alterations. The standard protocols, methods and reagents have been optimised for this species and there are acknowledged benefits from their use.
Careful analysis of the genetics of the animals allows us to only breed those animals that will not experience any adverse effects during their breeding life. For example we would not breed female animals that are predisposed to develop spontaneous tumours.

We also maintain all animals under strict environmental conditions to prevent infections

from unwanted pathogens. The methods chosen are all standard for this type of work.

Why can't you use animals that are less sentient?

Much of the work carried out at the Establishment is designed to mimic disease in human patients. Indeed much of our work involves the use of human tissue to see how novel treatments can be used to provide a clinically relevant treatment regime for patients with that type of disease. This can only be replicated in live mice as the tumours will only grow when complete body systems are supporting them.

There is also a great deal of laboratory analysis that can also be carried out that would not require the use of a live animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Routine health screening of the existing colony and careful examination of the health status of any new animals acquired from external collaborators ensures that the health quality of the colony is maintained at a high level.

Where there is a need to identify the mice , refined methods of tissue sampling will be employed ie: ear- marking and surplus tissue used for genotyping.

Some of our strains of mice have impaired immune systems due to their genetic modification. This allows the growth of human and other non-mouse tissue as the animal's natural immunity is unable to reject the foreign material. These animals demand special care and our husbandry and care routines ensure that these animals are maintained in a healthy environment

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Published guidelines for best practice will be followed, including:

Refinement and reduction in the production of genetically modified mice; Laboratory Animals Vol 37, Supp 1 July 2003.
Breeding and Colony Management (NC3Rs) https://nc3rs.org.uk/breeding-and-colony-management Assessing the welfare of genetically altered mice. Wells et al (2006) Laboratory Animals 40(2), 111-114 Home Office Technical Guidance: https://www.gov.uk/guidance/animal-research-technical-advice
How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Wherever we can we replace the use of animals in research, refine experimental procedures and minimise the number of animals used in experiments. We work closely with organisations such as the National Centre for 3Rs (NC3Rs) to work on new approaches and technologies to minimise the use of animals and improve animal welfare.

79. Xenopus as a model for drug development and toxicology

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Xenopus, Drug Development, Toxicology, Cardiotoxicity

Animal types	Life stages
Xenopus laevis	adult
Xenopus tropicalis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

As part of the drug discovery pipeline a new drug's potential toxicity is tested at the whole animal level in mice. This uses a lot of mice and is costly. In the spirit of the NC3Rs we are developing protocols that would use frog embryos to test toxicity and so flag up harmful/toxic compounds at an earlier stage in the drug development process.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Toxicology research may lead, in the long term, to fewer experiments on higher vertebrates such as mice and rats as the methods developed will identify and flag potentially toxic drugs earlier in the drug development pipeline.

This project will therefore be important in many areas of biomedical research including stem cell biology, cancer biology and toxicology

What outputs do you think you will see at the end of this project?

We hope to develop new assays to look at compound toxicity. These assays will be presented to Pharmaceutical companies either in the form of publications or personal talks with the idea that they may adopt the assays as part of their drug discovery programs.

Who or what will benefit from these outputs, and how?

In the short term the beneficiaries of our work will be students and other researchers trained in the lab to be the scientists of the future.

Our work will also be of interest to researchers working in the fields of Drug evelopment, Cell Biology, Cancer Biology and Toxicology. In addition some of our projects have direct implications on the NC3Rs.

How will you look to maximise the outputs of this work?

I will endeavour to publish the groups work wherever possible in appropriate journals. Myself and others in my lab will attend relevant conferences and present our work in the form of invited talks or posters.

I am in touch with some colleagues working in the Pharmaceutical Industry. I will reach out to Pharma with respect to our drug discovery and development objectives.

Species and numbers of animals expected to be used

- Xenopus laevis: 25-50 adults.
- Xenopus tropicalis: 20-50 adults

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using the tadpoles of Xenopus laevis (the African clawed frog) and Xenopus tropicalis as model organisms. We use Xenopus because the females can be induced by a simple injection to lay eggs all year around when kept in an ideal environment and this provides us with a source of embryos (frog spawn). During the course of a year a colony of approximately 150-200 frogs will be induced to lay eggs 1-3 times. The better the quality of care of the frogs the better the quality of the eggs/embryos they produce. To therefore minimize having to repeat experiments it is essential to have healthy animals.

The Xenopus embryos develop outside the mother and they are large which makes observation and manipulation relatively easy. Tadpoles have hearts, livers, brains, eyes and kidneys just like humans. In fact a tadpole with a fully functioning heart, which can be observed beating using non-intrusive methods, develops from a fertilised egg within 4

days. This makes them ideal for studying the effects of compounds on organ function. Embryos produced will be used to study questions of toxicity using a variety of methods. Therefore, what we learn in tadpoles about drug/compound induced changes to basic cellular and molecular developmental mechanisms will enhance our understanding and identification of toxicity in humans.

Typically, what will be done to an animal used in your project?

Female frogs from whom we need to obtain eggs are injected with PMSG 4-7 days before the eggs are needed in order to prime the animal to generate good and healthy eggs. The day before an experiment the females are further injected with HCG (Human Gonadotrophic Hormone) which induces them to lay their eggs 12-18 hours later. Each female is very gently massaged to get her to lay her eggs in a petri- dish. This procedure is carried our 1-6 times over the course of a day with a minimum of 1 hour rest between squeezes. The female is then observed for a further 12-18 hours to make sure they are fine before being returned to the frog facility.

Males (laevis and more commonly tropicalis) are injected with HCG to make them more fertile before they are sacrificed and the testes removed in order to carry out in vitro fertilisation of the eggs.

Note - Commercialy bought Frozen sperm are increasingly being used which means that over time the number of Males being used will decrease.

Tadpoles that are treated with various compounds will be killed humanely after less than 10 days.

What are the expected impacts and/or adverse effects for the animals during your project?

The procedures used are mild and next to no adverse effects are expected with the procedures used.

For affected tadpoles there will be diverse adverse effects including potentially: heart or circulation defects, craniofacial defects, altered behaviour, gut defects limiting the ability to feed properly and there may even be alterations in overall body structure. These tadpoles are normally killed humanely after less than 10 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the procedures on the female Xenopus and male Xenopus during induction of laying of eggs and fertilisation of the eggs is mild. When used for natural mating the females and males can be reused after a suitable recovery time (minimum 3 months) They can be used in this way multiple times until they reach an age when they no longer produce eggs of a suitable quality (approx 10-15 years of age). At this time they are euthanized. The proportion showing an adverse effect is approx. 0.5-1%.

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

With respect to our chemical screens and toxicity work the use of the whole organism helps with identifying compounds that have toxic or other effects which might not be the case with screens involving simple biochemical, cell based and organoid assays.

Which non-animal alternatives did you consider for use in this project?

Tissue culture, organoid culture, computer simulations

Why were they not suitable?

Responses and changes in response to toxic compounds can occur due to interactions between different cells and tissues. Cell based assays generally use only one cell type so are not a good model in this respect. Organoid cultures can sometimes include more than one cell type but are still limited and do not include a functioning vasculature.

Computer simulations are increasingly being used in toxicology but in all cases in vivo experiments do at some point need to be done to validate and test predictions and hypotheses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These are based on the numbers needed from past experience and from preliminary experiments, which have effectively been pilot studies for this investigation. Importantly many of the embryos that will be used in this project can be deemed as spare embryos leftover from experiments being carried out in the lab on other projects. In which case the numbers of animals used will be significantly lower than would otherwise have been.

Adult Animals: When the lab is running at maximum efficiently we plan to do 1-2 Frog experiments a week. One frog experiment involves priming, inducing and collecting the embryos from 3-6 frogs. We usually collect eggs most weeks (approx 40 weeks a year) for our research on early development.

Spare embryos not used in these experiments will be grown to stage 38 where they will then be used for this project. Frogs can be used after a minimum of 3 months. Therefore over a year we would use up to 12 frogs per week for 40 weeks = 480. Frogs can generally be reused 3 times in a year so 480 divided by 3 = 160. So at maximum efficiently we would look to use 160 female frogs in a year.

We do fewer Xenopus tropicalis experiments (approx 20 per year) so need fewer frogs and tadpoles

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Each week we have a lab meeting of all the Xenopus users at which we determine what people are planning for the following 1-2 weeks. This way we can plan experiments where personnel share the eggs/embryos produced and so maximise the efficiency of one experiment. Occasionally experiments will be delayed or bought forward in order that one day of egg collection can be carried out instead of two.

At this current time we are transitioning to using commercially bought frozen sperm instead of live males for in vitro fertilisation of eggs. This will not fully replace using Males but will drastically reduce the number of Males we do use.

With respect to the numbers of tadpoles used to develop screening protocols we will be driven by what is required statistically. We will discuss with statisticians and determine the minimum number of tadploes required for each procedure to make the result significant. This is ongoing work. As the assay is developed we will then be able to fine tune it for maximum efficiency and thus reduce the number of tadpoles used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our Xenopus facility is designed to keep the frogs as healthy as possible. The healthier the frog the more likely she will produce good quality eggs. If we can be sure of obtaining good eggs we can reduce the number of females we inject for each experiment. We are continually looking for ways to improve the care of the frogs in a cost effective manner. We are planning over time to initiate the chipping of the frog colony. This will enable detailed records to be kept for each frog. those that routinely provide bad quality eggs will be culled to improve the efficiency of the system.

Importantly many of the embryos that will be used in this project will be spare embryos leftover from other experiments being carried out in the lab as part of other projects. In which case the numbers of adult animals used will be significantly lower than would otherwise be predicted.

The Xenopus community in the UK and the rest of the world routinely discusses issues of care and welfare for the animals at meetings such as the British Xenopus group meeting and once a year for the International Xenopus meeting or Xenopus PI meeting in the USA. Web sites such as http://www.xlaevis.com/ also provide updated information. I am in routine contact with colleagues elsewhere in the UK and the rest of the world who provide help and assistance on best practice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Xenopus laevis, Xenopus tropicalis We will use Xenopus because:
Large numbers of Xenopus embryos are produced externally and obtaining them requires only a mild procedure (injection of HCG into the female).

We will use tadpoles prior to the protected age, when the brain is poorly developed and lacks the region that, at least in man, generates the distress associated with pain.

The tadpoles are largely transparent, allowing simple observation of many of the phenotypes produced without invasive methods.

Why can’t you use animals that are less sentient?

We are studying the effects of compounds on animal physiology and require embryos to do this. Xenopus laevis and Xenopus tropicalis embryos/tadpoles develop outside the mother which is beneficial with respect to observing phenotypes compared to mice.

The frog's genome is very similar in structure and detail to the human one and more than 80% of the currently-identified human genetic disease genes are found in it. To use a less sentient animal in which the genome is sufficiently well annotated for these studies means using zebrafish or Drosophila. The latter, in many cases, lacks sufficient protein identity to humans to make it possible to re-create human disease phenotypes. The structure of the zebrafish genome is very different from that of humans/frogs.

In terms of studying toxicity. Zebrafish only have a two chambered heart compared to the 3 chambered heart of Xenopus. the Xenopus heart is therefreo closer in morphology and function to mammals compared to zebrafish and therefore a likely better system for identifyig toxicity that would also be found in mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We mainly propose to use Xenopus laevis and Xenopus tropicalis for our experiments as they are a well characterised and well used model organism for vertebrate development. They are relatively easy to keep and the adults are subjected to only mild procedures.

The compounds that will be tested on the tadpoles will have already come through preliminary screens for toxicity such as tests on cells lines and organoids grown in culture and computer based predictions. Any tadpole(s) which show undue stress when exposed to a compound will be humanely euthanised. The experimentwill then be evaluated and reviewed accordingly

As mentioned before we are gradually transitioning to using frozen laevis and tropicalis sperm for in vitro fertilisation. This will in time lead to needing less males in our facility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Online protocols are published by many Xenopus labs and are often available on lab websites. Xenbase and the Xenopus Stock Centres in the UK and the United States also publish standard protocols. Online forums and the biannual International Xenopus Meeting and Xenopus PI Meeting also allow for free exchange of knowledge and best practice.

In addition Cold Spring Harbor Protocols publishes may papers in the 'Xenopus Collection' (http://cshprotocols.cshlp.org/cgi/collection/xenopus) which provide an up to date resource.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am in regular contact with colleagues in the UK and the rest of the world from whom the latest news and advances in Xenopus research can be learnt. The Xenopus community has an online news magazine called Xine from which news is obtained. In addition the Xenopus community in the UK and the rest of the world routinely discusses issues of care and welfare for the animals at meetings such as the British Xenopus group and once a year for the International Xenopus meeting or Xenopus PI meeting in the USA. Web sites such as Xenbase (http://www.xenbase.org/entry/) and http://www.xlaevis.com/ also provide updated information.

80. Mechanisms influencing mammalian digit tip regeneration.

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Regeneration, Digit Tip, Blastema, Stem Cells, Mammalian

Animal types	Life stages
Mice	neonate, adult, embryo, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to identify the signals in the environment that are important for successful regrowth of the tips of fingers and toes (called digits) that have been amputated in mammals and to understand how cells in the digit respond to those signals. I aim to learn if we can use this information to promote regeneration in tissues where it doesn’t normally occur.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are over 25,000 people in England currently living with limb amputations mainly as a result of illnesses such as diabetes or traumatic injury. If you cut off a person’s arm, it won’t grow back. Instead, the wound will heal and you will be left with a scar. Surprisingly, however, removing the end portion of a person’s fingertip does not scar. It will completely regrow all of the missing tissue. Understanding why these two different responses occur in a human could help provide insight into how we can regrow other parts of the body.

What outputs do you think you will see at the end of this project?

The main aim of this project is to study how cells in the mouse digit tip respond to injury. We are trying to understand how these cells are able to regrow the digit tip perfectly in order to uncover the basic principles that guide successful regeneration. The results of this study will help us understand how some tissues heal without scarring and will help other scientists working in the regenerative medicine field.

This project will likely result in new information and publications about the following:

Understanding how cells in the mouse digit tip communicate with each other and the cells that surround them (tissue regeneration). The mouse digit tip, which regrows upon amputation, is a powerful system for investigating how tissue repair and regeneration works. This process is similar to human fingertip regeneration and functions as an excellent substitute. In both mice and people, digit tip regrowth depends on how much of the finger or toe is removed. If you remove more than 60% of the end of the digit, it will fail to regrow. This is because a key structure made up of a clump of cells capable of growth fails to form. This key structure is called a blastema and it contains all the cells that will regrow the missing parts of the finger or toe. This project will aim to understand which growth factors or molecules in the injured digit tip environment are important for telling cells to form the blastema, and where these signals come from.

Understanding how the DNA is modified (epigenetic changes) during mouse digit tip regeneration (development & tissue regeneration). Most vertebrate embryos have the ability to regenerate their limbs. After birth, as animals and humans mature, this ability is gradually lost. There is, however, one exception to this rule. In both mature rodents and humans, regeneration occurs when the end of the digit tip is removed. One reason for this remaining regenerative capacity may be due to changes to the DNA, called epigenetic modifications, that allow genes to be turned "on" or "off". This project will aim to understand the epigenetic modifications that occur in response to injury and how these differ from early embryonic development.

Who or what will benefit from these outputs, and how?

One challenge for scientists is to take the knowledge that they discover and make it into therapies that benefit people. The first step in this process is to identify which factors promote regeneration in mammals. Then we need to determine if we can add these factors to the injury or help the person to produce them naturally so that their body will regenerate. This study will aim to answer these important questions. *In the short term,* new information that comes from this study will be presented through publications and conference presentations, or shared with organizations such as Diabetes UK. This will mostly benefit the scientific community. *In the long term,* this information could be used to develop therapies to improve repair and regeneration in human tissues. This research is expected to provide targets for use in regenerative medicine. These targets may be important for people who suffer with diabetes mellitus (Type 1 diabetes) who need to have their fingers/toes and/or limbs removed because their illness was not managed well.

How will you look to maximise the outputs of this work?

To gain the most from this work, we will do the following:

- We will share all experiments and results with the scientific community, including both

successful approaches and unsuccessful approaches. This information will be shared by publishing it, presenting at scientific conferences and giving workshops.
- We will share the results of this project with the public. This will allow people who are interested to learn about the research that is being carried out on tissue repair and regeneration.
- We will share results from this work before or at the same time that we send them to be published. This will make sure that the work is available to other scientists sooner and will help other laboratories avoid repeating the same work unnecessarily.
- We will work together with other scientists and/or research and development companies. We will share knowledge, skills and techniques that may result in exciting scientific discoveries.

Species and numbers of animals expected to be used

- Mice: 17332

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this study we are using mice to study tissue regeneration. This is because the mouse digit tip and the human fingertip are very similar. Both digit tips are made of skin, nerves, blood vessels and bones. Both naturally regrow the tip when injured as well. The things that they have in common make the mouse digit tip an excellent replacement to studying regeneration in humans as it makes us confident that any results we get will also be useful for people. Additionally, all the genetic tools that we need to help us understand how regeneration works are already available in mice. Our first experiments will use cells of interest to us taken from baby mice (less than 14 days old) that will be grown in the laboratory. This allows us to reduce the number of animals we need because we can increase the number of cells we have by growing them. Most of the animal experiments will use adult mice (more than 8 weeks old) however as we need to understand why many animals have the ability to regenerate tissues when younger but in adults this ability is limited. By studying this process of regeneration in adult tissue we can ensure that all of our findings will have the widest clinical application.

Typically, what will be done to an animal used in your project?

In order to study digit tip regeneration, animals will normally have a surgical procedure. During this procedure we will do one of two things. We will remove 1-2 mm of the end of the digit, which will fully grow back. In a human this would be the same as removing the tip of your finger starting from midway through your nail. Otherwise, we will remove 3-4 mm of the end of the digit. This type of injury will not grow back but will heal and the mouse will have a shorter digit. In a human this would be the same as removing the tip of your finger up until the first joint. A small number of animals will also be injected with various substances that will help discover at the cellular level what is happening during regeneration. Animals are subsequently humanely killed and tissue samples taken after death.

To study what certain cells are doing during the process of digit tip regrowth, we will make, breed and use genetically modified animals in some experiments. These animals will receive injection of substances which will either make cells in the digit tip glow, delete a gene in cells affecting their function or make a small number of cells die. In all cases, the mice will be killed humanely and the tissue samples taken after death. We are then able to study what effect this had on digit regrowth under the microscope.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the mice used in this project are not expected to display any harmful changes that affect the animal's day to day life. Amputation surgeries will only be performed on the middle three digits of one or both feet in order to make sure the injury does not affect the animal's ability to move and groom itself.
Surgeries will only be carried out on hindlimbs (feet). The forelimbs (hands) of the mice will not be touched. All surgeries are carried out under anaesthesia and animals receive pain medication that will remove any discomfort during the surgery and in the recovery period. Mice normally recover from surgeries within 10 - 15 minutes and display normal behaviour. When baby mice receive surgery, immediately afterwards, they are returned with their brothers and sisters to their mother. The mother has always been observed to welcome her babies back. Mice that had 3-4 mm of the tip of the digit removed, in which the digit doesn't regrow, will display a small amount of swelling in the digit. This appears at 7 - 14 days post amputation and will naturally disappear following this period. This swelling has not been observed to cause the mouse distress or impact their normal behaviour. Genetically altered mice that are given the drug, tamoxifen, may lose up to 10% of their weight. This sometimes occurs during the first 1 - 2 days that they are given tamoxifen. These mice normally gain the weight back to normal in the next 5 days and do not show any other harmful side effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This project will use mice. 44% of the protocols are classified as mild and 56% of the protocols are classified as moderate.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The digit tip is a complex structure being comprised of many different cell types. When the digit is injured, it needs to be able to tell all these different cells to regrow a toe over

several months. These cells also need to respond to instructions coming from the surrounding cells which tell them where to go and what to do during the regeneration process. It is therefore important to study this process in a whole organism because the response of the different cell types depends on which cells surround them and what instructions they receive from these cells. Today, there are few models that can imitate fingertip or toe regeneration in the laboratory. Those that do, first require the researcher to obtain cells directly from the animal. Additionally, most techniques that work with cells outside of living animals do not fully reflect their normal behaviour over long periods.

Which non-animal alternatives did you consider for use in this project?

In recent years scientists have developed a new way of growing (culturing) cells in 3 dimensions. They allow scientists to carry out their research without using animals. This is because they can be made using human or mouse stem cells. They are also very exciting for researchers to use because the cells mimic the structure of a small organ and can be grown for long periods of time. These cultures are called "organoids". So far, scientists have been able to make "organoids" that resemble the brain, kidney, lung, intestine, stomach and liver.

Why were they not suitable?

Despite the excitement around this new way of growing cells in three dimensions, scientists have not yet developed an "organoid" that models the human digit tip. Current "organoid" cultures cannot be grown together with supporting blood vessels and immune cells (cells that keep our body safe from infection) as well. This technology, therefore, cannot be used to model how the environment communicates with and directs the cells of the digit tip to regenerate.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The predicted number of animals needed for this project has been based on the following:

Animal numbers have been worked out by talking with a trained statistician. This is to make sure experiments are designed properly and have also been based on the number of studies that we expect to carry out each year. It is important to make sure that experiments use the proper number of mice so that the results of the experiments are accurate.

We have asked for advice from experienced researchers to help us work out the number of genetically altered mice needed. We have also predicted the number of animals needed from our own past experience. We have carefully considered the best way to make sure we keep the lowest number of different types (strains) of mice for breeding. At the same time, we have also made sure that we have enough mice to use for experiments.

We have considered the type (strain) of mice that we are working with to estimate the number of young animals that we can expect each time they give birth. For example, mice that are brown normally give birth to 6 - 8 animals. However, white mice give birth to 10 - 15 mice normally. Animal numbers will also be reduced because we will be buying in a large number of them. By doing this, we can control how many mice we have and will not waste any extra that are born and cannot be used.

Test experiments, called pilot experiments, will be used to calculate the amount of a substance that we can safely inject into the animal. It is important to find the smallest amount of the substance that has an effect but that won't harm the animal in anyway. This will then allow us to perform the intended experiment using enough mice to be sure that the results we obtain are right.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To work out the number of animals required for each experiment we used the NC3R's Experimental Design Assistant. This makes sure that the number of animals used in this study will produce data that is reliable and accurate. We have also taken the advice received from a local, qualified statistician. This will make sure that each experiment includes methods of reducing the chance that we unfairly interpret our data. We will also use a type of mathematics, called statistics, to help us calculate the chance that our ideas, called a hypothesis, are correct. Where possible, all experiments are designed to get the most information using the least number of animals possible. For example, we can give the digits on one side of the mouse the treatment and digits on the other side of the mouse can be given the control. Additionally, all experiments were designed taking into account the PREPARE guidelines (a document that gives scientists advice on how to plan animal research and experiments).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to use the smallest number of animals that will give us useful results, we will do the following:

- We will try and breed our genetically modified mice in a way so that none are wasted. Any types (strains) of genetically modified mice that are not being used for scientific study will be frozen as embryos.
- Where possible, we will do test (pilot) experiments. For example, when working with substances that stop cell function, we want to use an amount that will have an effect. These test experiments will help us to work out how much this amount is but will only use a small number of animals. We will only work with substances that we know. These substances will also have been used in the past for experiments and will have been shown to have an effect before when other scientists used them.
- We will try to work with other scientists and share tissue from the mice that we have removed the digits from. This will reduce the need to breed more mice.
- We will keep up to date with any new techniques that allow us to replace the experiments where we use animals with different experiments that do not use these.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use mice to study the naturally occurring process of digit tip regrowth. The procedure of digit tip amputation will be carried out in two different ways. Amputations that only remove 1-2 mm of the tip of the toe will result in regrowth of the digit to its original shape after approximately 30 days.
Alternatively, amputations that remove 3 – 4 mm of the tip of the toe will result in wound healing and scar formation. Additionally, digit tip amputations in mice only affect the skin, the very tip of the bone, minor nerves and nail. This injury does not damage muscles, tendons, glands or joints. Because these amputations only affect a small amount of tissue, the digit is able to heal quickly. It does not affect the ability of the animal to move or it's day to day activities. This project will also use genetically altered mice. Using these animals, we are able to follow cells or kill cells that we are interested in. These genetically altered mice have been used by other researchers before. They are not expected to show any harmful clinical signs.

Why can’t you use animals that are less sentient?

The mouse is a good system for studying naturally occurring regeneration. The process of mouse digit tip regrowth mimics human fingertip regeneration. In this project, most of the time we will be studying adult mice. The reason for this is that many animals have some ability to regenerate when they are young. When the animals reach maturity however, this ability is lost. In mice, the end of the digit tip is able to regenerate throughout the mouse's life. This also occurs in humans and we would like to understand why this is so. Mice were also chosen for this study as this is the only type of animal in which all of the genetic tools needed are available. Regeneration in classes of animals that are less aware (sentient) such as amphibians,, fish fish or worms have been shown to act through different mechanisms to mammals. These animals can produce and use specialised proteins which mammals can't make.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All methods in this project will use techniques that reduce animal stress and make sure the animal does not suffer as detailed below:

- We will make sure that animals suffer as little as possible during surgical procedures by giving the animals medication to manage their pain. All digit tip amputation surgeries and injections into the digit tip will use anaesthesia. Pain medication will be given before the surgery and where necessary after the surgery. We will talk with the Named Veterinary Surgeon to make sure we do this correctly.
- We will make sure to watch the animals before and after surgery to make sure they are healthy and not distressed. We will record what we see on a chart. If the animal needs anything such as more pain medication, we can give this to them. We will

always talk with a Named Veterinary Surgeon and get advice if the animal shows any signs that are outside its normal behaviour.

- Surgery will be carried out in a clean manner (using aseptic technique). We will make sure to meet the level set out in the Home Office Minimum Standards for Aseptic Surgery and the LASTA Guidance on Preparing for and Undertaking Aseptic Surgery (2017).
- We will make sure to use the best care methods to improve the quality of life for the animals. Mice will be placed in cages with other mice that they get along with. The mice will be given enough bedding material and at least one shelter (e.g. cardboard tube or plastic house). This will encourage the mice to explore and give them a refuge so they can escape the other mice when they want to.
- We will make sure to kill any animals before they suffer too much. This is called a Humane
- Endpoint. We are not expecting animals that undergo any procedure in this licence to suffer very much or for very long. If an animal does begin to look unhealthy, we will look at it and decide if it needs to be killed. If the problems cannot be relieved with pain medication or other methods, the animal will be killed.
- Some substances have to be given to animals by specific routes. We have therefore asked to use several different routes (e.g. intraperitoneal [injection into the abdomen], oral and subcutaneous [injection under the skin]) in this project. We will always use the least harmful route possible to give an animal a substance, which is normally under the skin (subcutaneous). This is to make sure we cause the smallest amount of discomfort or pain to the animal.
- All animals that are brought into the animal facility will be allowed at least 7 days to get used to their surroundings. This process is called acclimatisation. We will also allow them to get used to their handlers prior to use. This will reduce the amount of stress the animal experiences and will improve their well-being.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To make sure experiments are done in the best way, we will follow the Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE) and Animal Research: Reporting of *In Vivo* Experiments (ARRIVE) guidelines. For surgical procedures we will follow the Laboratory Animal Science Association (LASA) Guidance on Preparing for and Undertaking Aseptic Surgery (2017) and the Home Office Minimum Standards of Aseptic Surgery. For the breeding of genetically altered mice, we will follow the guidelines provided by the Home Office and the NC3Rs Resources on 'Genetically altered mice' detailed in:

- https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file
- /773553/GAA_Framework_Oct_18.pdf https://www.nc3rs.org.uk/GAmice
- Additionally, for making sure that chemical inhibitors or ligands are given in the best way, we will refer to the following resources:
- *"Refining procedures for the administration of substances. Report of the BVAAWF/FRAME/RSPCA/UFAW Joint Working Group on Refinement. British Veterinary Association Animal Welfare Foundation/Fund for the Replacement of Animals in Medical Experiments/Royal Society for the Prevention of Cruelty to Animals/Universities Federation for Animal Welfare". Morton DB et al. Lab Anim. 2001 Jan;35(1):1-41*

- *"Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider". Turner PV et al. J Am Assoc Lab Anim Sci. 2011 50(5): 600–613*
- *http://www.procedureswithcare.org.uk/lasa_administration.pdf*

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

In order to stay up to date about advances in the 3Rs, I will use the following methods:

- I will make sure that I have regular talks with the Named Persons and animal technicians at my Institute. This will help me to go over current approaches and remain informed if there are any new 3R opportunities.
- Sign up for the NC3Rs e-newsletter. This is where information on the latest NC3R publications is promoted. I will also attend NC3Rs events or workshops.

- I will regularly use our Institutional 3Rs search tool. This contains a database of information that is frequently updated about ways to reduce or replace the number of animals we use in experiments. It also contains information about the best ways to perform experiments that will reduce stress on the animal.
- I will regularly search published literature to stay informed about the latest techniques and approaches that may be used that will allow me to replace, reduce or refine my experiments that use animals.

To make sure that I can use any new techniques properly, I will collaborate with other scientists or staff members that already know these new techniques. This will make sure that all scientists working under this licence receive proper training and are qualified in the new procedure. Test studies will be performed for any refined methods to make sure these new methods do not cause the animal any more pain, suffering or distress. If any of these new methods occurs in a procedure that requires authorization (regulated procedure), permission will be sought before any experimental work is started.

81. Anthropogenic impacts on migratory fish

Project duration

5 years 0 months

Project purpose

- Basic research
- (e) Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

migratory fish, barriers to migration, life history variation, environmental change, fish pass

Animal types	Life stages
European eel	adult juvenile
Salmonids	adult, juvenile
Marine Species representative pelagic and benthic species native within UK waters, excluding those listed in Annex A to Council Regulation (EC) No 338/97	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to, first, identify and quantify key components driving patterns of fish behaviour and movement ecology and, second, define and test measures to mitigate for the impacts of selected anthropogenic activities on fish behaviour, migration and survival.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Migratory fish that need to move between different habitat types to complete their lifecycle are particularly susceptible to the impacts of human-induced environmental change. These include over- fishing and habitat degradation, habitat alteration and loss. Since 1970, populations of migratory freshwater fish have plummeted, with an estimated 76% decline

globally and a 93% decline in Europe. Many migratory species such as Atlantic salmon, sea trout and European eel are both ecologically and commercially important and there are strong legislative drivers to conserve their stocks. Understanding how fish biology and behaviours are affected by environmental changes and how we might mitigate for any negative impacts is urgently needed in the face of ongoing declines.

Addressing barriers to migration by installing fish passes and protection technologies is one measure to help conserve imperilled fish. There remains a lack of effective designs for many species and/or lifestages of fish and robust tests are urgently needed to ensure new pass technologies are fit for purpose and cost-effective. By using telemetry to track fish movements at a biologically relevant scale, this research will inform water managers about how well fish passes and other fish protection measures operate and provide recommendations for design improvements.

Other studies within this programme of work will focus on gaining a better understanding of fish behaviour and movement patterns as they migrate within and between freshwater and marine environments, primarily to identify human impacts. Our work will be used by policy makers, regulatory authorities and fisheries and aquatic habitat managers to inform effective management of freshwater and marine habitats (e.g. defining protected areas, implementing restoration efforts), and conservation actions for fish stocks (e.g. setting fishing quotas, licensing aquaculture activities). While studies are focused within the UK and will derive site-specific benefits, the wider research questions being answered are highly transferable to many other systems throughout these species' ranges.

What outputs do you think you will see at the end of this project?

The anticipated outputs will include:

- Quantitative assessments of the functioning of various designs of fish passes and protection technologies. Our results will help regulatory authorities and fisheries managers to identify the most effective solutions for improving fish passage and protecting fish at structures. Our recommendations for design improvements will be fed back to pass developers and manufacturers so they can more effectively meet the needs of this sector. Findings will also be disseminated as peer-reviewed scientific literature so will contribute more widely to fish passage science, including in other countries.
- Beyond specific fish pass designs, publication in the scientific literature of the findings from our studies of fine-scale eel movement data in relation to the detailed hydrodynamics they encounter in fish passes. These data are urgently needed to advance fish passage and protection science by 1) providing fundamental and robust design criteria, and 2) assist the switch towards a future predictive modelling approach to fish pass assessment and improvement, thus removing the need to conduct tests of every design with live fish
- An improved understanding of the contribution of factors that drive the movement patterns of migratory fish in freshwater and near-shore areas. We will be investigating a wide range of factors, both those intrinsic to the fish (e.g. physiology, genetics), and external (e.g. human activities, predation). This information is needed by local catchment and fisheries managers so they can implement appropriate measures to help reverse the decline in migratory fish stocks. With regards to estuarine and near-shore areas in particular, this information is also urgently required by the national regulatory authorities to inform their policy-making.
- The communication of findings to local, national and international stakeholders, and the

general public, through workshops, meetings, presentations and publications.

Who or what will benefit from these outputs, and how?

Short term benefits – years 1-5

- Robust assessments of novel fish passage and protection technologies to inform imminent spending decisions on how to meet UK legislative obligations and targets
- International collaboration through working groups and non-formal research networks
- Raised awareness of the issues causing declines in migratory fish through stakeholder engagement

Long term benefits: > 5 years

- New and improved designs for fish pass protection and passage technologies
- Improved guidance on the suitability of fish pass protection and passage technologies for certain species/lifestages/sites
- New information for policy makers tasked with managing the impacts of human activities on salmonid and other fish in transitional waters
- Evidence-based predictive tools to optimise policy and management decision making
- Contribution to wider scientific knowledge on the drivers of life-history strategies in salmonids
- Contribution to datasets on salmonid population abundance and size structure in the study systems. Information that is used to generate stock assessments, inform policy and measure the efficacy of management interventions

How will you look to maximise the outputs of this work?

- We collaborate closely with partners in Government, catchment managers, utilities (water & power), Rivers Trusts and Wildlife Trusts, commercial and sports fisheries and fisheries enforcement agencies. These collaborations help inform our research direction to maximise tangible outputs
- We contribute to national and international working groups for the study species. We work directly with Government policy makers and regulators to shape the future direction of management and conservation, particularly within the fields of anguillid and migratory salmonid conservation.

- Our organisation hosts regular conferences, species working groups, and conservation special events. We actively disseminate our work to a wide audience through these channels.
- Even though our work is of greatest importance nationally and therefore is often disseminated through internal reports and stakeholder workshops, we have a strong track record in publishing our findings in the wider peer-reviewed scientific literature. In this way it contributes to a global knowledge base and minimises the risk of others replicating the same work.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The chosen species are of specific interest because they have undergone population declines and are the subject of legislation aimed to bring about stock recovery. The lifestages are selected based on where the need to fill knowledge gaps is most pressing.

Typically, what will be done to an animal used in your project?

Fish will either be tagged and/or marked so that their movements can be tracked. Tagging entails anaesthetising individuals then either making a small incision through which the tag is gently pushed into the peritoneal cavity or attaching it externally using thin wires passed through tissues near the dorsal fin. Some tagged individuals will also be externally marked by inserting a needle close to the dorsal fin and attaching a small T bar anchor tag. This is so they can be easily recognised as tagged fish by 3rd parties who may capture them (e.g. anglers or commercial fishers).

Some individuals will be sampled for blood before they are anaesthetised and tagged. This entails inserting a needle close to the tail of the fish and withdrawing a small quantity of blood (maximum 10% of fish mass blood volume). It is a quick procedure that typically takes less than 3 minutes. Some individuals may be sampled for fin tissue after they are tagged and while they are still anaesthetised. This entails using a sharp pair of scissors to snip off the top section of the adipose fin. Juvenile fish too small to be tagged will be marked using a dyed compound that glows under UV light. For this procedure, the fish is anaesthetised and a small amount of the compound (0.01 - 0.02 ml, fish size dependent) is injected just under the skin using a hypodermic needle.

The maximal duration of all the surgical steps combined will not typically exceed 15 minutes. After surgery, the fish is transferred to a holding cage in the river or an aerated holding tank for recovery. In some studies, fish will be released into the wild after recovery. In other studies, fish will be retained and used in trials to test fish pass designs before being transported and released into the wild.

What are the expected impacts and/or adverse effects for the animals during your project?

A possible adverse effect could be infection of the tagging wound. Infection risk will be minimised by taking adequate infection control measures (e.g. antiseptic precautions) during tag implantation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All procedures are classified as either mild or moderate severity.

What will happen to animals at the end of this project?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The study programme is focussed on advancing our understanding of the behaviour of actively migrating fish. There is no appropriate replacement for wild fish because at present there is insufficient existing knowledge on fish behaviour to accurately predict and model the natural movements of wild fish.

Which non-animal alternatives did you consider for use in this project?

An alternative approach we considered to test barrier mitigation strategies (e.g. fish passes) for eels is to use computer modelling approaches such as individual-based models.

Why were they not suitable?

The current state of the science makes them insufficient for this purpose. The best available approaches (e.g. Padgett et al, 2020) fail to capture the complexity of eel movement because eels interchangeably use swimming and climbing during the ascent of structures and models fail to incorporate climbing behaviours. Further, there is currently a dearth of data with which to parametrise the models; Padgett et al. (2020) used burst swim data dating back to 2004 that was based on a very small sample size of eels.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of fish represent the minimum required to obtain statistically robust results, based on the scientific literature, previous research experience and statistical tests.

For controlled tests of barrier mitigation technologies under different treatments (e.g. flow rate, fish pass slope), numbers are derived from power calculations based on treatment effect size informed from our previous work. Specifically, we will mark with visible implant elastomer a maximum of 3100 juvenile eel, which represents 20 individuals per trial. Larger juvenile eel will be PIT tagged. Unlike marked fish, PIT tagging allows for definite individual identification, so the within tank (i.e. between individuals) variance will be more accurately defined, and is likely to be lower than in our previous studies. We calculated that 5 replicates per treatment (i.e. 50 eels) are sufficient to detect the estimated treatment effects above the expected levels of variability/noise. For tests of European eel passage

and protection technologies in the field, we aim for 30 tagged fish per release group, and a minimum of 3 replicates per test condition. Prior experience indicates that this is the minimum required to gain meaningful entrance and passage efficiency metrics, allowing for the fact that a proportion of the fish released may not approach the pass. For the studies of European eel fine scale movements and responses to flow cues in lentic waterbodies, our target number of 60 tagged fish per year is strongly informed by our previous work in a reservoir that employed the same positioning telemetry system, and our previous fine-scale eel tracking in an intake forebay. Across all studies, the maximum total number of eel to be tagged is 6,300.

For studies on the behaviour of free-ranging fish, the telemetry methods being employed maximise the likelihood of gaining high quality and quantity data from each individual, thereby minimising the number that need to be tagged to gain meaningful results. Additional logistical constraints such as the numbers of fish likely to be captured in the study systems, staff time and the cost of tags are also contributory factors in decisions on study design, including tagging numbers. However, past experience and published studies were the primary information used to ensure that the numbers will enable sufficient inference to achieve our objectives.
For the studies of salmonid life history variability, our target is to tag 30 fish per year from each minor river and 60 fish per year from each medium to large waterbody, giving a maximum of 3750 fish. These numbers take into account our anticipated acoustic receiver array efficiency and return rates based on previous studies and should allow us to generate accurate estuary/marine survival rates in addition to movement patterns. For studies of marine species, we will tag a maximum of 800 individuals, comprising 200 individuals per system, over four discrete studies. This, based on the detection rate achieved in previous similar studies, is the minimum required to achieve robust assessment of the impact of anthropogenic pressures in large marine environments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We conducted detailed literature reviews to inform our decisions in situations where we had no relevant previous or pilot studies. Power and sample size calculations were used in the planning stage to ensure our experiments can meet our objectives. Further, we have designed our studies to always optimise the data quality and quantity obtained from each individual through using state of the art methods to achieve our objectives, rather than relying on bulk, low quality information.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Tissue samples collected for genetic analysis can be preserved for long periods. Any tissue remaining after our own analysis will be retained for future use by ourselves or fellow researchers in our network, thereby reducing the need to go and sample more wild fish in the future.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime

of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All proposed fish capture, handling equipment and methods are specifically designed to minimise stress and avoidable harm e.g. adequate through-flow of water, soft knotless nets, appropriate mesh/bar size for species, smooth edges to frames, nets, tanks etc. All nets, traps and equipment will be used by competent staff with prior experience of the proposed methods. The proposed capture and handling equipment and techniques result from extensive testing and refinement by fisheries scientists around the world including UK government science and monitoring agencies. Nets/traps will be checked regularly (minimum every 24h) with captured fish removed immediately and placed in suitable holding facilities. Electrofishing will only be conducted by certificated experienced staff and is deemed an efficient non-harmful method employed for repeated long term fisheries monitoring programmes.

Specific procedures within this project are:

- Tagging with a tracking/monitoring device by insertion into the peritoneal cavity- The surgery required will only be carried out by the principal investigator and co-investigator(s) who have extensive experience using the proposed methods on the proposed species. The incision that will be required to insert the tag will be on the ventral surface in an area chosen to minimise the chance of puncturing any major blood vessels. All tagging apparatus including sutures and tags will be sterilised using appropriate sterilisation fluid and antiseptic precautions will be used throughout the procedure.
- Attachment of an external marker tag - Markers are chosen so that the monofilament or wire section inserted in the fish is of small (<1 mm) diameter, minimising the risk of an adverse tissue reaction to the tag, and tags are of a suitable size relative to the fish so that the effects of additional drag during swimming are minimal. A small number of scales (approximately 3 to 5) will be removed from an area at the point of insertion to reduce impact on surrounding tissues. The tag will be inserted at an acute angle to the body and will be in line with the body when the fish swims, thereby reducing resistance and tag movement. The tag will be placed behind the pterygiophores to reduce the likelihood oftag loss.
- Visible implant elastomer marking - This was chosen because it's among the most effective and minimally invasive ways to mark fish with translucent skin, requiring only one insertion of a narrow gauge hypodermic needle. Replacement of the needle between animals further minimises the small risk of infection at the injection site and reduces tissue trauma because the needle is always very sharp.
- Removal of the adipose fin to obtain tissue - This is the chosen location to sample tissue because it minimises pain as few nocireceptors are located on the fins, and the adipose fin is the smallest fin and is considered functionally redundant in the study species.
- Blood sampling - Blood will be withdrawn from a single needle inserted in the caudal region. The quantity is small and scaled on fish body mass, so smaller fish will not be disproportionally impacted. Antiseptic precautions and replacement of the needle for each fish minimises any risk of infection and reduces tissue trauma because the needle is always very sharp.
- Scale sampling - The removal of scales represents a reliable and minimally invasive

way to age our study fish and provide information on past life-history. Only 3-5 scales will be removed for this purpose and the sampling location, on the dorsal flank, away from the lateral line which has a high concentration of neuromasts, is selected to minimise distress and suffering. The scales will regrow causing no lasting harm.

When fish undergo any procedure with recovery, they will be monitored for an appropriate period to assess any adverse effects and ensure minimum suffering. It is the most likely outcome that fish subjected to the procedures and released to the wild will suffer no long-term impairment.

Why can’t you use animals that are less sentient?

The species and lifestages of fish chosen are of specific interest so they cannot be replaced with other lifestages. We are capturing wild fish and none of the experiments require the fish to be killed, therefore terminal anaesthesia is not appropriate both because we don't want to deplete wild stocks and because the data we hope to gain from the fish relies on tracking their behaviour post-procedure.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our proposed procedures represent the most refined methods based on current knowledge, and we actively keep up to date with advancements in the field.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We keep up to date with animal welfare literature and practices. Our fish capture and transport methods follow Environment Agency best practice guidance. All activities involving the housing and husbandry of animal within our institute are reviewed and refined by veterinary staff.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am part of a global network of researchers who conduct similar research and through collaborative studies and workshops we actively exchange ideas and learn from each other's approaches. For example, we share developments and findings through specialist groups such as the Oceans Tracking Network, European Tracking Network, International Conference on Fish Telemetry, and the International Bio-logging Science Symposium. We, as a community, always strive to reduce and refine our use of animals. Rapid advancements in tracking technologies and non-fish surrogates (e.g. robot fish) offer the most promise for achieving this. Staying informed about the opportunities to use computer modelling in place of, or in combination with, animal experiments is also something I and my team actively do. At my own research institute, I am a member of the 'Biotelemetry: advancements in technology and methods' review group, which includes both researchers and veterinarians.

82. Transcriptional regulation of erythropoiesis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

red blood cells, anaemia, transcription factors, leukaemia, proteomics

Animal types	Life stages
Mice	adult, embryo, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how the process of generating red blood cells in our body is controlled and how these control mechanisms can go awry in blood diseases, such as anaemia. We will focus on the study of a protein called GATA1, which is a critical player controlling the process of red blood cell generation.
Importantly, mutations affecting GATA1 functions have been linked to blood disease, including leukaemia.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will allow us to understand basic control mechanisms in the generation of red blood cells in our body. This is important because it will provide us with new knowledge that will help us understand how these control mechanisms go awry in diseases such as anaemias (sickle cell anaemia, thalassemia etc.), porphyrias and leukaemia. Specifically,

the project will involve the use of genetically modified mice to study the fundamentals of GATA1 function, particularly during blood cell generation in the foetus. This is important as it has been shown that specific GATA1 mutations are strongly associated with anaemia in the foetus, which can be fatal, and with leukaemia in Down syndrome babies. Studying GATA1 in the blood cell generation in the foetus cannot be modelled or recapitulated in simpler animal models or in cellular models.

What outputs do you think you will see at the end of this project?

The work to be performed will provide new information on the role of GATA1 in red blood cell production in our body and on how mutations in GATA1 result in blood diseases. This information may lead to the development of new therapeutic approaches in the treatment of haematological disease such as anaemia. Our work will also result in the development of novel methodology for analysing proteins, that we expect will have many applications and which may lead to commercial products and/or services. We also expect our work to be disseminated through presentations at international conferences and through scientific publications in peer-reviewed journals.

Who or what will benefit from these outputs, and how?

The red cell and haematology research communities will benefit initially from the outputs of this work. In addition, the outputs of our work will go some way in helping us understand the involvement of GATA1 mutations in haematological disease. In the long term, this will help in the development of effective treatments. GATA1 belongs to the GATA family of proteins which includes a total of 6 members with important roles in different organs, including the immune system, the heart, the pancreas and others. Mutations affecting other GATA proteins have also been implicated in disease, for example, GATA2 in leukaemia and GATA3 in breast cancer. As such, the outputs of the work described here will also broadly benefit research on GATA proteins and, in the longer term, will help develop more effective therapies for GATA protein-associated disease.

How will you look to maximise the outputs of this work?

We will collaborate with researchers in Germany for the proteomic characterization of GATA1 protein functions and with researchers at our University for the analysis of genomic data, which will identify the genes that GATA1 controls in red blood cells. Our work will be presented at conferences (American Society of Hematology Congress, GATA Meeting, Haemoglobin Switching meeting etc.) and published in relevant journals. Data will be made available by depositing in appropriate public repositories.
Detailed protocols and unsuccessful approaches will also be submitted for publication to inform the broader research community.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use different genetically modified mouse models that will allow us to directly examine the functions of GATA1 in red blood cell generation and of GATA1short, i.e. a GATA1 mutation that has been associated with leukaemia in Down Syndrome children and with the rare haematological disorder Diamond-Blackfan Anaemia. The mice have been genetically modified through the addition to the GATA1 protein of a small “handle” that will allow us to efficiently and cleanly purify GATA1 and GATA1short proteins directly from red blood cells in order to characterize their functions. As the haematological disorders associated with the GATA1 mutations (i.e., GATA1short) first appear in the foetus, our work will focus mostly on the collection of embryos at specific stages of gestation that correspond to the foetal stages that are relevant to our key scientific questions.

Typically, what will be done to an animal used in your project?

Animals in our project will be primarily used for breeding, blood sampling and collection of embryonic tissues. Mice will be ear clipped for identification and genotyping. Successful breeding pairs will stay together for no more than 4 breeding cycles. Females used in timed breeding will be killed humanely. This is necessary in order to retrieve embryos at specific developmental stages (embryonic day 11.5- 14.5). Use of general anaesthesia is not recommended as it can affect the physiology of the embryos and the experimental outcomes of the study. Male and female mice will be used for tail vein blood sampling.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect any adverse impacts or effects for the animals during the project. We will only conduct minimally invasive procedures where the procedure occurs without terminal anaesthetic, such as ear clipping and blood sampling. The expected impact of ear clipping and blood sampling is expected to be minimal. Aseptic technique will be used to minimise risk of adverse effects following blood sampling. Analgesic cream will be applied to site of ear clipping and blood sampling, when required. Even though no adverse effects are expected from these procedures, mice will be monitored for 24h following sampling. Animals exhibiting any unexpected harmful phenotypes will be killed humanely. Embryonic tissue will be collected from mice following schedule 1 protocols and are therefore non-recovery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: tissue biopsy for genotyping mice in breeding; also for blood sampling. Female mice will be culled by a humane method for embryo collection.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We aim to study the physiological functions of the GATA1 protein in red blood development in the foetus and how these functions are disrupted by the GATA1short mutation. We need to use mice to study the early window in the development of the blood system in the foetus, which appears to be particularly susceptible to GATA1 dysfunction. As this work involves mammalian foetal developmental, it cannot be carried out using lower vertebrates (e.g. zebrafish) or cultured cells as surrogate models.

Which non-animal alternatives did you consider for use in this project?

Alternative non-animal models considered include cultured red blood cell types derived from leukaemic samples, or from the differentiation in a petri dish of embryonic stem cells or of induced pluripotent stem cells. All methods to be used in the project will initially be carried out and optimised using cellular models so as not to use animals unnecessarily.

Why were they not suitable?

Working with red blood cells in a petri dish cannot recapitulate the events taking place during the generation of red blood cells in the mammalian foetus. The sites of red blood cell production change as foetal development progresses. The red blood cells generated as these sites shift, differ in their properties so as to better suit the specific demands of the growing foetus. In addition, the niche, i.e. the cells surrounding the changing sites of red blood cell generation in the foetus, play a critical role. All these parameters cannot be recapitulated in any of the existing cellular models for red blood cell production.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
We have estimated the total number of mice based on:

the number of mice we will need to crossbreed to homozygosity and to maintain the different genetically modified strains used in the project. We will need to maintain colonies for the following transgenic lines (six in total):

Homozygous BioGATA1/ROSA26-BirA double transgenics

Homozygous BioGATA1/UCOE-BirA double transgenics

Homozygous BioGATA1short/ROSA26-BirA double transgenics

Homozygous BioGATA1short/UCOE-BirA double transgenics

Homozygous ROSA26-BirA single transgenics

Homozygous UCOE-BirA single transgenics

We will need to maintain for each homozygous line a minimum of 4 males and 6 females (60 mice per breeding cycle for all lines) that will be used to increase colony stock as required for experimentation, assuming that homozygous transgenic lines will be replenished every 4 months (3 breeding cycles per annum). Taking also into account the number of crosses that will be required to obtain the homozygous double transgenic lines, we estimate for this part of the project that we will need a total of 7500 mice for the five-year duration.

the number of mice we will need to carry out our experiments using mouse embryos. For our studies we will need to collect embryos between developmental stages E11.5 and 14.5 using the different transgenic mouse strains given above. In estimating the number of animals we will use for embryo collection, we took into account an average litter size of 8 embryos, the amounts of experimental material that we will obtain at each embryonic stage and the need to carry out all experimental assays in quadruplicates for reproducibility. Taking all these factors into account, we estimate a total of 800 mice for this part of the project.

The number of adult transgenic mice that we will need to obtain blood samples from the tail vein. We estimate that we will need a total of 200 mice for this part of the project.

Grand total: 7500+800+200 = 8500 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The main determinant of which animals and how many animals are used in this project is the genotype of embryos from which we will obtain tissues for analysis. Heterozygote and homozygote breeding pairs will be used for timed pregnancy experiments to (i) initially collect all required samples for analysis including controls and to subsequently maximise the generation of embryos with the specific genotypes required and avoid wastage of females and embryonic tissue. Embryonic genotyping requires the humane killing of pregnant females. Experimental data are also restricted by the number of cells available in specific tissues at specific developmental stages (i.e. earlier developmental time points will yield less starting material). Improvements in experimental technique and design have maximised the amount and improved the quality of data obtained from a reduced number of cells, thereby reducing the number of mice required for experiments. Lines will be frozen down and re-derived as required to restrict maintenance breeding. Maintaining lines as heterozygotes and homozygotes only will reduce the number of non-genetically modified mice generated.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animals will only be used when absolutely necessary. In order to minimise the number of mice used in this project, we will breed heterozygous mice which will generate all required controls for the analysis (i.e. wild type mice, single transgenics [BirA or bioGATA1/bioGATA1 short] and double transgenics).
Initial proteomic and genomic analyses of the control samples will generate sufficient reference data for subsequent experiments. This will allow use of homozygous double transgenic lines to collect additional samples, thus reducing the number of animals used

per experiment. Once double transgenic lines have been established, we will look to cryo-preserve the single transgenic lines to reduce the number of mice we maintain for the project. Whenever scientifically feasible, we will seek to switch to using cell lines to further test, validate and extend the data obtained using mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically modified mouse models. The mice carrying these modifications already exist and are viable with no adverse phenotype or lasting harm. We will isolate embryonic tissues at specific developmental stages (E11.5-14.5) that coincide with the transition from primitive to definitive erythropoiesis. Embryos will be isolated at developmental stages prior to the last third of gestation.
Pregnant females will be killed under a schedule 1 method. In rare instances, it will also be required to collect bone marrow. Again animals will be killed under a schedule 1 method. These methods are not expected to cause pain or suffering, distress or lasting harm.

Why can’t you use animals that are less sentient?

We will be using primarily embryos up to 14 days of gestation. Zebrafish and lower vertebrates are also used for developmental hematopoiesis studies, however a mammalian model still remains necessary to provide key insight and understanding of the disease-associated phenotypes that form part of this project and of their physiological effects in complex developmentally regulated processes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Best practice will be used for all procedures. All cages will be enriched with nesting materials. Daily non-intrusive monitoring of all animals will be performed by BSU staff and/or scientific researchers. Animals will also be observed through handling in order to train the animals in this procedure. Animals undergoing a terminal procedure (e.g. schedule 1 and embryo collection) will do so away from the sight and sound of other animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will closely follow the best practice guidance of ASPA. We will regularly consult the RVC and NC3Rs websites and look to our AWERBs and NACWOs for current best practice guidance.

How will you stay informed about advances in the 3Rs, and implement these

advances effectively, during the project?

Best practice will be used for all procedures. All cages will be enriched with nesting materials. Daily non-intrusive monitoring of all animals will be performed by BSU staff and/or scientific researchers. Animals will also be observed through handling to train the animals in this procedure. Animals undergoing a terminal procedure (e.g. schedule 1 and embryo collection) will do so away from the sight and sound of other animals.

83. The role of CSF1R in rodent macrophage biology

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Macrophage, Microglia, Neurodegeneration, Development, Disease

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Increase knowledge of macrophage biology in health and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

This project is focused on expanding our understanding of the role of macrophages (a cell of the immune system) in immune function, growth and development, as well as health

and disease. It is becoming increasingly clear that macrophages are influential in many physiological processes and diseases. Therefore, this is a significant area of scientific study that will contribute to our understanding of basic physiology and may lead to the development of new therapies important for human health.

What outputs do you think you will see at the end of this project?

We will achieve a greater understanding of macrophage biology in development and disease.

This is important because macrophages are found in all tissues of the body. They are essential for normal development but are also involved in many diseases such as cancer, arthritis, osteoporosis and white matter diseases of the brain.

By the end of this project we hope to identify new drugs that can be used to treat or prevent osteoporosis.

We also aim to explain why mutations in a macrophage-specific gene cause the neurological disease Adult-onset leukoencephalopathy with axonal spheroids and pigmented glia (ALSP).

We will publish all of our results in open access journals.

Who or what will benefit from these outputs, and how?

In the short-term, our experimental outputs will inform other researchers and will likely result in the establishment of new collaborations so that common scientific goals can be tackled more effectively.

A deeper understanding of the role of macrophages in development and disease may provide insight into developing novel treatments/preventative measures for a range of macrophage-related pathologies.

In particular, we hope to provide osteoporosis patients with a new treatment and provide patients with Adult-onset leukoencephalopathy with axonal spheroids and pigmented glia (ALSP) more information about what causes the disease.

How will you look to maximise the outputs of this work?

All of our research is performed in partnership with scientists who are experts in their particular field. We will disseminate new knowledge with our collaborators worldwide via meetings and publications.

Species and numbers of animals expected to be used

- Mice: 6200 (including colony maintenance)
- Rats: 6200 (including colony maintenance)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use freshly isolated macrophages from humanely killed animals to investigate macrophage properties in vitro and we will continue to use this approach wherever possible and scientifically valid. However, in vitro assays cannot adequately model the complete role of macrophages during development, inflammation or disease as macrophages are just one of a massive number of cell types involved in inflammatory responses and immunity. Therefore, in vivo work is also required to understand how macrophages function in their proper environment.

We use animals at all life stages as macrophages play important roles throughout much of development, adulthood and ageing.

Typically, what will be done to an animal used in your project?

The majority of our experiments involve investigating macrophages from humanely killed animals. For our other experiments, animals are typically:
injected with a compound and blood sample/s taken (range 1 day to 6 weeks). OR
injected with a compound prior to infection (range 1 - 5 days). OR injected with donor cells blood sample/s taken (range 1 - 12 weeks).

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect any adverse effects for the majority of experiments as all the compounds/cells have been used extensively in our laboratory and others.

Some of our genetically altered rodents have adverse phenotypes. These include osteopetrosis (thicker bones) and the absence of teeth. These animals are fed a liquid diet and housed with as few animals are possible to prevent any injuries to their (more fragile) bones. These animals are typically analysed whilst young and are not aged.

We use behavioural tests to determine the role of macrophages in diseases such as Adult-onset leukoencephalopathy with axonal spheroids and pigmented glia (ALSP).

One of our experiments will involve surgery on pregnant rodents (under general anaesthetic). This may result in mild discomfort whilst the incision heals and animals will be given pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold 75% - The majority of our experiments involve investigating macrophages from humanely killed animals

Mild 20% - A mild severity is expected where animals are injected and subsequent blood samples taken.

Moderate 5% - A small percentage of our GA rodents have a harmful phenotype due to

the absence of macrophages.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use freshly isolated macrophages from humanely killed animals to investigate macrophage properties in vitro and we will continue to use this approach wherever possible and scientifically valid.

However, in vitro assays cannot adequately model the complete role of macrophages during development or inflammation as macrophages are just one of a massive number of cell types involved in inflammatory responses and immunity. Therefore, in vivo work is also required to understand how macrophages function in their proper environment.

Which non-animal alternatives did you consider for use in this project?

We have previously used cell-lines in the majority of our experiments. The promising results obtained have led to this application for in vivo work.

Why were they not suitable?

The non-animal alternatives were suitable for the initial studies. However, macrophages functions are defined by environment-specific factors, such as other cells and local signalling molecules in every tissue of the body. These environments cannot be accurately modelled using non-animal alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers were estimated based on our previous 10 years of experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We optimise the numbers of animals used by:

- performing pilot studies when required
- breeding efficiently to ensure we have control and genetically modified animals for each experiment
- storing all organs from killed animals following an experiment - for use by ourselves at a later date or to provide organs to other researchers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use genetically modified mice and rats in order to study a particular gene which we know is important for macrophage development. Most of these animals do not have any harmful symptoms. Analysis of these rodents includes behavioural tests to see how the absence of macrophages affect learning and memory. These tests do not cause any suffering or distress.

One of our genetically modified rat lines develops thickening of the bones (due to the absence of macrophages). These animals are monitored daily and housed with as few animals as possible to prevent injury.

The majority of our experiments involve injection of substances which do not have any adverse effects. We do this to either increase or decrease the numbers of macrophages in wild type rodents. For example, we want to determine if reducing macrophage numbers can prevent age-related bone loss (osteoporosis) and if increasing macrophage numbers can prevent neonatal infections.

We will use a neonatal rat infection model to see if increasing the maturity of the immune system (by increasing macrophage numbers) can prevent serious infection. These are very short-term experiments (<5 days) and we will analyse the rats at the very earliest stages of infection before clinical symptoms appear.

Why can’t you use animals that are less sentient?

Our studies do involve animals that are less sentient - for example we use embryonic rodents or rodents under terminal anaesthetic wherever possible.

We cannot use lower organisms such as zebrafish as they contain two copies of the gene we study. This means that they are not similar to humans. They also lack a specific region

of the gene which we know is important for macrophage development in higher organisms.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At the beginning, researchers will frequently be exposed to the animals so they can learn the differences between normal and abnormal behaviour and appearance. Animals will be provided an enriched environment and they will be handled frequently to reduce their stress. When animals are required to perform a specific task, they will be familiarised with the new environment before the test. If surgical procedures are performed, we will do regular checks to assess recovery and pain. If there are signs of pain, analgesics will be provided.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on the Operations of ASPA, https://www.nc3rs.org.uk/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed of the latest news by consulting resources such as: ARRIVE and PREPARE guidelines, https://www.nc3rs.org.uk/, https://www.gov.uk/research-and-testing-using-animals, www.understandinganimalresearch.org.uk, www.frame.org.uk and http://www.procedureswithcare.org.uk.

We also receive regular updates and advice from our named vets and the Home Office.

We implement these updates via regular evaluation of our study request forms by the named vets.

84. Understanding the mechanisms and pathophysiology of heart failure and atrial fibrillation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

heart failure, myocardial infarction, atrial fibrillation, therapy, comorbidities

Animal types	Life stages
Sheep	adult, aged, juvenile, neonate
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Diseases of the heart including heart failure, myocardial infarction and atrial fibrillation are major causes of premature death and ill health. Many people with these diseases are elderly and also have a variety of other conditions including high blood pressure and obesity which are thought to contribute to disease onset and progression. However, the underlying mechanisms causing these associations are poorly defined. This project will firstly investigate how these various factors act to cause these cardiovascular diseases and, secondly, investigate how novel treatments might work in these diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

- Diseases of the heart lead to ill health and premature mortality.
- There are no fully effective treatments for these diseases with five-year survival for key heart disease in Western society being worse than that of the commonest cancers e.g breast and prostate cancer.
- A key factor for the lack of progress in finding effective treatments and preventative measures for some of these cardiac diseases remains a lack of understanding of the underlying mechanisms responsible for their development.
- We know that ageing, high blood pressure and being overweight are associated with the development of many cardiovascular diseases but the mechanisms by which these cofactors act to increase disease prevalence are poorly understood.

To address these issues we will investigate key mechanisms that cause the development of heart disease and why heart disease leads to an increased risk of death. We will study the impact of heart disease on the function of the heart at both the whole animal and isolated cardiac muscle cell levels.

From these studies we will gain a better understanding of the mechanisms that lead to various cardiac diseases (the pathophysiology of disease) and from these findings we expect to reveal novel therapeutic targets.

What outputs do you think you will see at the end of this project?

The major output anticipated from the programme of work is an increase in our understanding of the pathophysiology (disease mechanisms) of key cardiac diseases and the role of significant cofactors (ageing, obesity and high blood pressure) in the development of heart disease.

We will also build on our recent findings, by furthering mechanistic understanding, where we reported that a class of drugs normally used to treat erectile dysfunction were highly effective at treating heart failure and reversing some of the changes that occur in the diseased heart.

From the increased understanding of the pathophysiology of heart disease and the role of key cofactors in the development and progression of these diseases, we anticipate that we may be able to develop more effective therapies for heart disease.

We will generate 'large' datasets from experiments where changes in protein abundance and gene expression are investigated.

From these studies we anticipate identification of new and more effective therapies for heart disease.

Who or what will benefit from these outputs, and how?

The major beneficiaries of these outputs in the immediate term (lifetime of project) will be within academia and the pharmaceutical industry.

The increased mechanistic understanding we generate will drive further investigational studies by the wider scientific community and pharmaceutical industry. We anticipate that these 'secondary' studies will commence once our initial findings become publicly available via publications and conference presentations (3 - 7 years).

We would reasonably expect that a successful outcome of our pharmacological interventions could, within a 5 - 10 year period lead to in-human trials. Should these preliminary in-human studies show benefit, the next expectation would be for large scale clinical trials and ultimate adoption of the therapies into standard clinical practice (beyond 10 years).

How will you look to maximise the outputs of this work?

We will maximise accessibility of outputs via open access publishing and depositing large datasets in public databases. This will allow other individuals and groups to use the available information and datasets with minimal delay and thus to greatest effect.

Any software for analytical work that is developed for this programme of work will be made available either through the journal associated with the data or open access sites such as GitHub upon publication

We will also communicate work (subject to intellectual property considerations) as widely as possible via scientific meetings and interactions with commercial partners via workshops and in response to calls for potential collaborations.

We also host a series of public (schools and adults) and patient engagement events within the host institution and contribute to these routinely to maximise the public understanding of our work. We will look to maximise the reach of this work by establishing an online web resource for patients and members of the public as well as for sharing our scientific discoveries with the wider academic and industrial communities.

We are committed to sharing best practice via open access publications. In the event that studies are unsuccessful our intention is that this information is also made available through appropriate channels including appropriate publications and open access repositories.

Species and numbers of animals expected to be used

- Sheep: 1430
- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

The principal animal model used is the sheep with mice used in some experiments. The sheep is a highly translationally relevant animal model for understanding disease processes in the cardiovascular system. The sheep heart is more similar to the human heart than is the case for species such as the rat, mouse or zebrafish. These similarities include structure, size, heart rate, response to various stimuli and stresses and the way in which the parts of the heart are supplied with blood. An important consideration for our studies is that we are able to employ standard clinical practices and devices to best reproduce what would be undertaken in patients. Due to availability arising from standard farm animal practices and potential welfare issues centred around single versus group

housing, studies using sheep will only be performed using female animals.

Our experiments will mainly be conducted using fully grown adult animals. In a few experiments we will use aged animals and a small number of younger animals. The use of fully grown adult animals means that we are reducing confounding factors such as growth which is a neglected consideration in many other studies. In experiments where we will use aged animals, this is because in some experiments we are studying the role of cofactors in disease and age is a one such key factor. Similarly, in some experiments we will use young animals, this is because in the young animal heart there are still processes occurring such as changes in cellular structure which we may wish to validate and target as a therapeutic approach in the disease model and therefore the young animal model may help inform these choices.

Where mice are used, both genders will be studied. The reason for using the mouse in some experiments is that we will be able to take advantage of genetic modifications. This will allow us to understand the role of specific genes and their protein products where they have either been knocked out or over expressed. In all cases, we will use adult mice.

Typically, what will be done to an animal used in your project?

The typical experiment where animals have a surgical intervention will involve a number of non- invasive assessments of heart function in conscious gently restrained animals where we will measure their electrocardiogram (ECG), blood pressure and heart function by echocardiography (ultrasound measurements of heart function). We may also take blood samples during these procedures either by direct insertion of a needle into a vein or from a catheter that has been placed in the vein.

The majority of animals will then undergo a surgical procedure where we implant a cardiac pacemaker and pacing leads into the chambers of the heart in the same way that is used for patients who have a pacemaker inserted. In some of these animals this will be combined with either using an angioplasty balloon placed in one of the arteries in the heart to induce a myocardial infarction (heart attack). These procedures may also be combined with measurements of the electrical activity of the heart either using the implanted cardiac pacemaker or by leads that are temporarily inserted into the chambers of the heart using the same vessels into which the cardiac pacing leads are inserted or additional devices.

Typically only one device approximately the size of a small box of matches will be implanted however, in a small number of animals a maximum of four devices (normally less than half the size of a box of matches) may be implanted to remotely monitor cardiac function (e.g. heart rate or blood pressure), activity or, to stimulate the vagus nerve in the neck. We will also take several blood samples during the anaesthesia period.

In a small number of animals where a vagal nerve stimulator is used, when this is activated we expect it will lead to a periodic cough and change in vocalisation when the nerve is actively being stimulated (a few seconds every few minutes). These changes will resolve spontaneously over the course of a few days and have no long-lasting effect.

In studies of heart failure we will, following recovery from surgery and a period of monitoring the animal to ensure full recovery from the surgical procedure, activate the cardiac pacemakers to cause the heart to beat faster and induce heart failure. Some of these animals will receive treatments (typically a tablet given orally every day) and some will also have a small blood sample taken weekly.

We will monitor the animals for signs of heart failure and once this becomes evident they will be terminally anaesthetised and a final set of measurements of the electrical activity of the heart made before the animal is killed and tissues harvested for a series of in vitro experiments.

The maximum duration over which any animal will be monitored following its first surgical intervention will be six months.

However, not all animals (approximately two-thirds) will undergo a surgical procedure. Here, animals will only be give a single injection of heparin to prevent blood clotting a few minutes before they are killed for tissue harvest for in vitro experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect animals to make a full recovery from surgical interventions with recovery from anaesthesia and do not anticipate anything more than transient and mild discomfort from procedures performed on conscious animals.

In those experiments where we are studying the mechanisms that are altered in heart failure we do expect animals to develop signs of heart failure which can include increased breathing effort, coughing or tiredness. We monitor animals carefully for the development of these signs and they are humanely killed (as the end of the experiment) once these signs become evident and impact on normal behaviour.

In some experiments we may expect animals to develop abnormal heart rhythms in the main chambers (ventricles) of the heart; the large majority of these will be experienced in anaesthetised animals.
However, there is a small possibility that these abnormal heart rhythms may develop spontaneously in conscious animals. If these are significant, we might expect the animal to rapidly lose consciousness and as such do not expect them to cause pain.
Beyond this expected impacts, there is the potential that a small number of animals could develop any of a range of adverse effects as a result of the procedures that have been performed. These could (they are not routinely expected) include; loss of blood during surgery or from a dislodged cannula, sudden death due to abnormal cardiac rhythm disturbances or adverse reactions to administration of investigational compounds. Animals are carefully monitored by experienced care staff and investigators such that should any of these unexpected adverse effects be experienced by the animal then it is for the shortest duration possible.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Where animals undergo a surgical intervention with recovery from anaesthesia we expect all of those animals to be within the moderate severity category. Conversely, for many animals the only intervention they will experience will be a single injection of heparin to prevent blood clotting a few minutes before they are humanely killed for subsequent in vitro experiments on the harvested tissues. In these animals there will be no more than

minor transient discomfort and the overall severity limit will be mild.

Overall we anticipate approximately 70% of animals will therefore undergo mild severity experiments and the remaining 30% moderate severity experiments.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use whole living organisms because, whilst heart failure and atrial fibrillation are conditions that originate in the heart they are also influenced by the way that other parts of the body such as the kidneys, lungs and brain behave. Critically, the response of these other parts of the body can then also modify the way the heart behaves and therefore the overall progression of the disease. This cross-talk between the heart and the other parts of the body is complicated and not easy to predict as well as also changing quite rapidly. It is not yet possible to predict the outcomes of these interactions using either computer models or cells grown in a dish.

Additionally, some forms of heart failure are also more likely to occur if you have other underlying conditions such as being elderly, having high blood pressure or being overweight. Again these complex interactions and dependencies cannot yet be faithfully reproduced using non-animal alternatives such as computer models or cells maintained in culture dish conditions.

Our first major aim is to understand the mechanisms which cause the heart to stop functioning properly in diseases such as heart failure, atrial fibrillation or after a heart attack. Our second major aim is to also understand how factors such as age, high blood pressure or being over-weight lead to the onset of heart failure. In each of these aims, we hypothesise that changes in the way that the cells of the heart regulate their calcium levels is a major factor behind disease progression. Based on the findings of these initial studies and from some of our previous work we will also investigate the effectiveness of some new treatments for heart disease in these studies. Again, understanding how these new treatments work requires us to study them using approaches that are both reliable and reproducible where all the complex relationships between the heart and other tissues in the body are functioning.

Given these considerations, we need to undertake our experiments in appropriate animal models that allow us to address our key aims, advance our understanding of heart disease and to identify and test new treatments.

Which non-animal alternatives did you consider for use in this project?

There are several possible non-animal alternatives that we have considered. These include:

- human tissues obtained from either deceased people or those undergoing heart transplants
- cells grown in the laboratory
- computer models

Although there are significant limitations with each of these that prevent us from using them to fully replace the use of animal models, it should be noted that we will use some of these approaches to address some very specific questions where it is not necessary to use an animal and thus we strive to replace the use of animals with these methods as much as is practicably possible.

Why were they not suitable?

In each case there are major limitations to using these non-animal alternatives and these are considered below:

Human tissues

These would mainly be available from hearts removed from patients undergoing heart transplant operations or donor hearts that were not considered suitable for use in the transplant programme. The main issues with using human tissues are:

- Lack of availability - There is a major need for more donor hearts to match the number of patients on the transplant list. This means that, particularly healthy human hearts, are very rare and secondly there is a limited number of diseased hearts for use. If we had to rely on these then we would be very unlikely to be able to complete more than a small fraction of our proposed studies.
- Variability - A major concern in using human hearts is that they are being taken from a very diverse population. For example, important factors such as age, obesity, blood pressure and medical treatments they are taking are highly varied and thus difficult to control for in our experiments. This is a significant concern which both limits our ability to draw firm conclusions and our ability to perform reproducible and reliable experiments that others can follow and work from.

Cells grown in the laboratory - There are several types of cells that could be used including those that were originally obtained from animal hearts or stem cells that have been treated to behave like heart cells. In each case there are number of major limitations to using these cells to answer our questions and prevent us from achieving our aims. The major limitations are:

- Cells grown in a dish are normally of a single type, for example HL-1 cells. This does not even remotely reflect the situation in the heart where lots of different cell types co-exist and interact with one another.

- Cells grown in a dish, even stem cells that have been treated to behave like heart cells, lack the structure of a normal heart cell. This is important because many key processes in the cells of the heart occur precisely because of the structure of the cell. If this structure is not reflected by the cells in a dish then it is unlikely that the response of the cells to a treatment will be the same as would occur in the heart.

Computer models - Whilst these are improving all the time:

- They still lack the ability to accurately reproduce what is happening in the heart.

- Computer models cannot reproduce the complex interactions that occur in disease between the heart and other organs

- Given these interactions between the different cells in the heart and the heart and other tissues, computer models lack the ability to accurately predict how new drugs may work in the intact animal (or human)

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

At each stage of the programme of work we will estimate the number of animals that are required to complete the set of experiments before the series of experiments are started.

To calculate these numbers we use information from our own earlier experiments or those that have been published in the scientific literature or a combination of both of these to determine how variable this information tends to be. From this variability we can use statistical tests to determine how many samples are needed to detect differences between groups of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have, and our intention is to continue to, consulted with an external statistical advisor who is independent of this programme of work in order to minimise the numbers of animals that are required to address our experimental aims. We also utilise this advice in parallel with information that we have obtained as part of our consideration of key aspects of reproducibility in research as part of our regular laboratory meetings between the various groups that make use of animals in this programme of work.
Tools such as the NC3Rs experimental design assistant are a useful adjunct to these processes and help guide considerations around the allocation of animals to groups.

All of the principal investigators leading their own groups which utilise the animal models in this programme of work are also members of different journal editorial boards and regular reviewers for major UK and international scientific funding agencies. As part of these roles, we are always asked to consider experimental design which reinforces our own thinking when planning our experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For the work involving sheep there is no need to consider efficient in house breeding as animals are purchased from external suppliers as and when they are needed to complete our experimental protocols. Where mice are used, we will aim to purchase animals rather

than breed them specifically. However, where we need to breed animals we will maintain colonies as efficiently as possible and, where possible, use littermates as controls rather than separately bred animals.

In the present programme of work, we do not envisage that we will routinely be performing pilot studies. However, if at any point we do use pilot studies, these will also be considered with a view as to the most appropriate way in which they can also be used to contribute to the final experimental data in order to both inform the number of animals required and reduce animal usage.

The programme of work supports a number of principal investigators and their research groups. Importantly, we share a combined laboratory meeting programme and plan our experiments collectively. This enables us to ensure that when experimental animals are available, they are used by the full range of groups and we do not need to repeat a particular experiment twice for different laboratories.

Where relevant we will also use cell culture experiments or computer models to complement or even replace animal-based research. These are important considerations when we plan our experiments and will be used to, for example, validate test substances or test potential pathways prior to investigating their effect in the intact animal or disease model

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The principal animal model is the sheep which has been chosen because its cardiac function and response to interventions very closely resembles that in man.

We will use a number of models which closely resemble common cardiac diseases of man (heart failure, atrial fibrillation, myocardial infarction). All of our approaches are designed to be as minimally invasive as is possible (which would generally not be achievable in smaller species) and accurately reflect the same procedures that would be performed in patients requiring only a small skin incision to enable pacemakers to be implanted.

All personnel involved in conducting animal experiments are fully trained in the theory and technical aspects of procedures and only take responsibility for completing these procedures as lead operator once they have worked closely with and been observed by experienced operators.

We also work closely with the named personnel and animal care staff to ensure that effective post- operative monitoring is in place and any remedial actions are effectively applied with minimal delays.

Why can’t you use animals that are less sentient?

To deliver the most translationally relevant data from our studies and elucidate potential new treatments that are most likely to be applicable to man requires that we use appropriate animal models. To achieve this a key consideration is that potential confounding factors such as growth are removed from our experimental procedures. Another important consideration with immature animals is that their hearts are not fully developed and are structurally different to that in adults. As such, key signalling pathways which are heavily influenced by cellular architecture do not function the same way in immature animals as in adults. Thus, the translational relevance of using immature forms is a significant limitation in most of our experiments. Given these considerations, for the vast majority of our experiments, we therefore use adult animals that are fully grown. Similarly, one of our experimental objectives is to understand how certain risk factors for heart failure interact; this requires that we use a model where these key factors such as ageing can be studied reliably. These considerations apply to the vast majority of our experiments; however, in some cases the lack of (e.g.) cellular ultrastructural development in immature animals is a useful tool with which we can address some very specific experimental aims.

Given these important considerations, and our aim to use minimally invasive surgical procedures requiring only a small skin incision, our preferred animal model is the sheep. Rodent models, immature life stages or (e.g.) zebrafish models are unable to address these key considerations and are in many respects fundamentally different to the human heart such that they are not appropriate to address our aims and objectives.

In many of our experiments we are using a disease model. In each case and in humans, the diseases that we are replicating takes a considerable time to develop following the initiating event. This therefore precludes us from completing all aspects of our experiments in terminally anaesthetised animals.
However, we do strive to use terminal procedures where these are appropriate in order to minimise potential discomfort. Similarly, when investigating the potential value of a new treatment for disease, it is often necessary to apply this treatment over a prolonged period of many weeks to determine its effectiveness. This is therefore not achievable in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedures have been refined considerably through a number of years of experience. We already seek to employ as minimally invasive procedures as possible to achieve our scientific objectives.
However, we also strive to incorporate new methodologies and refinements if they become available and improve outcomes for the animals.

All surgical procedures require our team to ensure animals receive appropriate post operative care and pain management and we discuss these routinely with the named officers within our animal facility.

In some protocols we do expect animals to eventually develop some clinical signs of disease. In these animals we have an enhanced monitoring programme in place to ensure welfare harm to the animal is minimised as much as is practicably possible.

Our experimental animals become habituated to the investigators presence and in some experiments this allows us to train them to come to the side of the pen for food and completion of some aspects of our studies where remote monitoring is a feature. This means that we do not always need to restrain animals to achieve the experimental data that is being sought.

Animals are housed in social groups apart from the immediate post-operative recovery period (24 - 48 hours) when they are individually housed but in pens adjacent to and in sight of their original cohort so as to minimise any potential for separation effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are no specific guidelines covering the animal models that we will employ. However, there are general guidelines covering aspects of our experiments such as blood sampling volumes; these are used to inform our standard operating procedures.

In addition, we regularly receive updates and guidelines through our local Animal Welfare and Ethical Review Board and we monitor websites and ensuing publications that promote best practice and refinements in methodologies including nc3rs.org.uk, felasa.eu, lasa.co.uk.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our animal care facility, NC3Rs manager and ethical review board is responsible for delivering regular updates on 3Rs developments to users. We also monitor outputs published in the scientific literature and appropriate learned society websites.

When a 3Rs advancement becomes available we will consider if these can be adopted into our standard procedures as appropriate; for example, tube handling of mice, and employ them in our course of work as a matter of routine.

The project licence holder and associated investigators also attend a number of committee and scientific meetings each year where animal welfare and experimental practices are a key discussion topic. The members of the research team also attend a number of scientific conferences where animal welfare and refinements are frequent subject matter.

85. Molecular factors affecting sperm production

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

spermatogenesis, genetics, sex ratio, fertility, infertility

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how sperm cells differ from each other, what influences their fertilising capacity and survivability, and how this influences their ability to transmit their genetic information to the next generation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

When sperm function is perturbed, in particular how they handle and repair DNA damage, it can lead to male sterility and/or increase the chance of birth defects in the next generation. Studying this will help us develop new fertility treatments, and, conversely, novel methods of contraception. Rarely, alterations in sperm function affect the mathematics of genetic inheritance, meaning that genes may be inherited more than expected by random chance - a concrete example of this being a mouse strain that

produces 60% female offspring and only 40% males. Understanding this "transmission ratio skewing" may allow us to develop ways of regulating the offspring sex ratio in farm animals without needing to cull unwanted animals of either sex (as is the current practice).

What outputs do you think you will see at the end of this project?

The key outputs will be adding to the knowledge of reproductive function in males, and how reproductive function impacts genome evolution. This is expected to lead to journal publications, public engagement and external scientific meetings. As part of this work, we will develop two new mouse lines that will be shared with the scientific community and will permit more powerful and less wasteful studies of male fertility and of DNA damage repair mechanisms.

Who or what will benefit from these outputs, and how?

The basic scientific questions addressed by our work cover fundamental areas of reproduction, and the processes that control sperm production and quality control. This will be valuable to the scientific community in multiple areas of research into fertility. In the longer term we hope this research will contribute towards development of novel methods of sex selection in the livestock industry. An estimated 100,000 male dairy calves and 30-40 million male layer chicks are culled per year in the UK alone. Male pigs are routinely either slaughtered before puberty (leading to economic wastage) or castrated (an animal welfare issue) due to “boar taint”. All of this would be unnecessary if alternative more humane methods of offspring sex selection can be developed as a result of our work.

We will also develop two novel mouse lines that will be of use to scientists studying fertility and DNA damage responses, and share these with the scientific community.

How will you look to maximise the outputs of this work?

We will aim to publish all data that is generated by this work, positive or negative. In addition, we will form collaborations, when natural, to support and increase the probability of generating outputs for publication and public engagement. Novel mouse lines will be deposited in appropriate repositories and shared with the scientific community.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice because the genes we are looking at, and the cellular processes involved, are better understood in mice than in other experimental species. The project does not require any harmful procedures other than breeding. The mice are unlikely to suffer any pain or distress as part of these experiments, as the only predicted effect of the genetic alterations we are studying is an effect on the shape and fertilising ability of sperm. It is necessary to use adult animals as juvenile animals do not produce sperm.

Typically, what will be done to an animal used in your project?

The vast majority of animals used (up to 2500 in total) will not be subject to any procedures other than breeding and post mortem study of tissues following humane euthanasia. The breeding is a regulated procedure because the animals in question are genetically modified, however the genetic modifications we are studying are not expected to produce any effect other than painless alterations defects in sperm shape and function.

If egg collection is required to study the process of fertilisation, this will involve hormone treatment of the females (up to 500) to increase egg production prior to collection of the egg cells post mortem. This requires two intraperitoneal injections spaced a few days apart.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no expected adverse effects other than transient pain following injection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity is expected to be sub-threshold for the majority of animals (~80%) and mild severity for any that have had injections.

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?
Studies in vitro alone are insufficient to show a candidate cellular abnormality is relevant to a given disease. This requires interpretation of molecular and cellular mechanisms within physiological situations that can only be observed in intact whole organs and indeed whole organisms. In particular, there is no way to make sperm or eggs in cell culture and so live animal work is required to investigate sperm function. Moreover, a key aspect of this project is analysis of transmission ratio distortion - i.e. the rate at which specific genetic changes are passed from one generation to the next. This necessarily involves use and breeding of live animals.

Which non-animal alternatives did you consider for use in this project?

None - there is no alternative to the use of animals. A substantial amount of related work is being done in parallel including analysis of genomic sequence data and previously-published datasets, and cell line work to look at DNA damage in cell types other than germ

cells (which cannot be cultured).
Wherever possible we will use cells derived from our mice rather than the mice themselves to study processes including fertilisation and DNA damage repair, thus sparing mice any unnecessary discomfort.

Why were they not suitable?

Many of the experiments to be done are technically in vitro cell culture experiments using eggs and sperm - however there is no way to produce either eggs or sperm in cell culture, and thus the use of live animals is unavoidable.

For the work focusing on the DNA damage response, while many cell types can indeed be investigated in a cell culture system, other cell types such as maturing sperm cells cannot be cultured and thus once again the use of live animals is unavoidable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of our mice will be used for breeding and collection of tissues post mortem. Broadly speaking there are three types of experiment we will carry out.

The first involves studying tissues from GM animals (transgenic or natural mutant) with a known phenotype, along with normal control males, in order to study aspects of sperm development. For this, our estimates of the required number are based on the breeding characteristics of these lines and the number of animals required in order to provide an appropriate level of replication of our results. Typical experiments will use 6-10 individual animals for each genotype tested. Where possible we will archive tissue samples and use these for followup experiments rather than breeding more animals.
The second involves studying tissues from newly-developed GM animals, along with normal control animals, in order to confirm that the modifications have produced the desired effect. Estimates of animal numbers here are derived similarly to the studies on pre-existing GM lines, but will require a more staged approach, with pilot studies on small numbers of animals followed by larger studies to confirm and refine our observations.

The third involves studying sperm, eggs and embryos from GM animals, along with normal control animals, in order to study fertilisation mechanisms and outcomes. In general these will be performed by using hormonal stimulation to induce females to ovulate, followed by post mortem collection of eggs and sperm from animals of interest and in vitro fertilisation experiments. Here, the number of animals used is largely determined by the number of females required to produce enough eggs for the experiments. Our calculations are based on the average number of eggs produced per female, and where possible we will select the strain of mice used to produce the largest number of eggs from the smallest number of females. Typically, in order to detect a ~10% alteration in transmission ratio, 500 eggs are required in each of the experimental and control groups, while a female produces around 50 eggs following stimulation.

Overall, we anticipate using up to 2,000 animals over 5 years in the first two types of experiment, and up to 500 females over 5 years to produce eggs for the third type of experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Variability will be regulated by using littermate controls where appropriate and using stable well- characterised mouse lines such as C57BL/6 where possible. We used the NC3Rs Experimental Design Assistant in designing the planned experiments, and will continue to do so for future grant applications to support this work.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To determine the number of animals required for single-cell analysis of testis function, we will carry out pilot analyses of published datasets in order to determine the minimum required number of biological replicated.

We will maintain all our lines on the same genetic background where possible, to enable sharing of tissues from control animals between experiments. For example, for most of our studies only the male mice are useful (because we are studying testes). Where possible we will make use of the females also, for example as "sentinel" animals to monitory colony health, or as a source of oocytes for experiments involving other mouse lines.

For the line used to study DNA damage, once this has been generated, we will be able to use it to make stable cell lines covering a wide range of different tissues, which we will share with the scientific community.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the premier experimental model for examining gene function in mammals, being permissive for transgenic manipulation, rapidly developing, and extremely well genetically characterised. Hence, we propose the use of mice as data collected from our studies can be readily compared with that already published and, in parts, serve as control data when comparing with transgenic models.

Why can’t you use animals that are less sentient?

Alternative laboratory species that are less sentient include fruit fly, zebra fish and nematode worm (c elegans). However, in all of these the organisation of the testis differs

very substantially from the mammalian testis, and so they are not appropriate biological systems to investigate mammalian sperm production and fertilisation. Juvenile animals cannot be used as they are reproductively immature and do not produce sperm/eggs. Since we hope to ultimately develop sex selection protocols for farm animals, it is important to work in a mammalian system to ensure our data is likely to translate well into these species in due course.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At our establishment we have already moved to tube handling for all animals, which reduces fear and distress. The only procedure liable to cause any welfare impact on the animals is injection, which will be performed by appropriately trained and supervised personnel. Animals will be closely monitored during all procedures and where possible we will consider refining existing techniques or incorporating new methods to minimise any suffering to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Ullman-Cullere et al 1999 'A Rapid and Accurate Method for Assessing Health Status in Mice' Lab Animal Science; 49(3):319-323.

'The Design of Animal Experiments: Reducing the use of animals in research through better experimental design' (Festing et al 2nd Ed).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The NC3Rs website provides an outstanding resource of information. We will review this website on a regular basis for relevant information. In addition, our local AWERB provides us with an excellent platform to discuss the 3R's, where this is a long standing item on every agenda. I will attend appropriate seminars and conferences covering breeding and transgenesis technology.

Home Office

86. Identifying novel biologic drugs for the treatment of liver disease

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The identification of new therapeutic drugs for the treatment of Non-Alcoholic Steatohepatitis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Non-Alcoholic Steatohepatitis (NASH) is a progressive form of non-alcoholic fatty liver disease (NAFLD), which is the most common chronic liver condition in Western populations. NASH is characterised by chronic inflammation and an extensive accumulation of fat in the liver and, although it can affect people of any age, most patients are between the ages of 40 and 60 years. It is a silent chronic disease with few or no symptoms (tiredness, unwellness and discomfort in the upper right side of the abdomen). However, over time, it can develop into more serious conditions, such as liver cirrhosis or liver cancer, where liver transplant is the only option. In addition to liver-related morbidity

and mortality, patients with NASH are at an increased risk of cardiac morbidity and mortality This disease affects 35 M people globally and with patient numbers growing rapidly, the market is expected to rise towards £18 B by 2026. Critically, to date, there is no medication approved by Food and Drug Administration (FDA) and therefore, this innovative work emerges as an opportunity to develop first-in- class (i.e. drugs that use a new and unique mechanism of action) therapeutic candidates for the treatment of this devastating disease.

What outputs do you think you will see at the end of this project?

We are striving to identify new therapeutic drugs for NASH but due to the nature of drug discovery this is a long-term aim. In the shorter term, this would certainly lead to new intellectual property, peer- reviewed publications and conference presentations.

Who or what will benefit from these outputs, and how?

Longer term would be the clinical benefit from these new modalities by NASH patients, resulting in a huge humane and financial benefit. Given the novel approach of combining different targeting moieties there would be invaluable learning regarding the engineering behind this approach such as the stability of the linker, the impact on PK/PD of a bi-functional molecule, the stoichiometry of interaction and criticality that affinity plays in such a product.

How will you look to maximise the outputs of this work?

Primarily to gain more support to progress the work into later stage development as well as new IP, conference communications and scientific publications.

Species and numbers of animals expected to be used

- Mice: Objective 1: 1,000 mice; Objective 2: 1,000 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To date, there is no medication approved for the treatment of NASH, the most aggressive form of NAFLD. In this regard, preclinical models are needed to fully understand the pathophysiology of this disease and identify novel therapeutic opportunities. Over the last decades, several animal models of NASH have been described. Among them, induction of fibrosis by intoxication with carbon tetrachloride constitutes one of the most characterised models and a robust tool to study the ability of effective compounds to reverse fibrosis. Application of this hepatotoxin induces acute and chronic liver injury in animals, leading to fibrosis where spontaneous reversion is minimal. Therefore, this model constitutes an excellent tool to study and identify antifibrotic therapies.

We use rodent models because their genetic and biological characteristics closely resemble those of humans, and many symptoms of human conditions can be replicated in

mice and rats. The CCl_4 model can be applied to both rats and mice. However, mice are preferred, because of a higher metabolic rate of CCl_4 compared to rats. Young adult C57BL/6 mice (8-10 weeks old) will be used to perform these experiments. Although BALB/c mice shows more susceptibility to CCl_4 than C57BL/6, higher level of severity and a more specific Th2-type response are obtained by using this strain. C57BL/6 shows intermediate susceptibility to CCl_4 and is the strain most frequently used to study fibrosis in vivo by other groups. Likewise, previous studies from our group were performed with male C57BL/6 mice, and so, this strain will be used to be able to compare our results with those obtained before by our group and others.

Typically, what will be done to an animal used in your project?

For protocol 1:

Liver fibrosis will be induced by bi-weekly intraperitoneally application of CCl_4 for up to 8 weeks (0.8-
1.2 ml/Kg). Control mice will be established by injecting with olive oil vehicle. An SOP will be strictly followed covering CCl_4 preparation, vehicle (olive oil), dose, treatment duration and post-injection monitoring.

24-72 hours after the last dose of CCl_4 or olive oil of the last week of treatment, animals will receive either fluoro-labelled test article or control article. Then, mice will be humanely killed by Schedule 1 method at different time points (0 - 24 hours) and tissue and blood samples will be removed for analysis.

For protocol 2:

Liver fibrosis will be induced by bi-weekly intraperitoneally application of CCl_4 for up to 8 weeks (0.8-
1.2 ml/Kg). An SOP will be strictly followed covering CCl_4 preparation, vehicle, dose, treatment duration and post-injection monitoring.

Between the two doses of CCl_4 of the last week of treatment, animals will receive either DMSO (vehicle for toxin), free toxin, PBS (vehicle for test artcicle), control article, control article conjugated to toxin, test article conjugated to toxin or test article. This test article will be the same used in protocol 1 but, instead of being labelled with fluorescence, it will be conjugated to a toxin. 24-48 hours later, animals will receive another dose of CCl_4. Finally, mice will be humanely killed by Schedule 1 method 24 – 48 hours after the last dose of CCl_4 and tissue and blood samples will be removed for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects post-injection: animals will experience acute abdominal pain after CCl_4 administration (up to 100%). In less than 1% of the animals, the injection could breach the gut provoking peritonitis, which will be identified by rapid appearance of clinical signs of sepsis, such as swollen abdomen, lethargy, starry coat, hunched posture and reduced normal activities. If this happens, the animal will be immediately sacrificed by a Schedule 1 method. Furthermore, male mice could exhibit aggressive behaviour due to injections.

Adverse effects as a result of repeating doses: mice injected with CCl_4 do not usually lose weight, but they might not gain weight with growth like control mice (olive oil vehicle). Body weight will be closely monitored over the course of the experiment (at least twice a week). Those animals that actively loss more than 20% of their starting body weight or show any critical alterations in their behaviour will be humanely sacrificed by a schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate, only in those animals treated with CCl_4 (50% mice in protocol 1 and 100% mice in protocol 2). Mice injected with vehicle in protocol 1 (50%) will be mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

At present there is no alternative in vitro or ex vivo models for liver fibrosis. Although cell lines are available, they do not represent a true substitute for the real tissue. Given the driver is to develop a clinical drug candidate, understanding the effect of the test article within the complexity of a living animal is by far the most translatable for late stage drug development.

The team are always actively looking (via NC3Rs, CrackIT, FRAME, Norecopa, Understanding Animal Research, etc) at alternative systems for this and other programs of work, such as 3D tissue culture, spheroid and organoid models and liver chips. However, the whole living body is necessary to address the potential of our biologics in terms of specificity and effectiveness.

In vitro cell-based work will be performed in activated hepatic cells to assess these new domains and select the best one for further in vivo studies. This represents one of the go/no decision points in our protocols and only if significant in vitro cell-based work has been completed, the next step involving animal models will be performed.

Which non-animal alternatives did you consider for use in this project?

All in vivo work will only be conducted after significant in vitro cell based work has been completed to select and fully characterise the final lead product. Thus, binding and functionality of our compound will be previously analysed in vitro by using activated stellate cell cultures.

This represents one of the go/no decision points in our protocols and only if the results show good binding affinity and functionality, the next step involving animal models will be

performed.

Organoids and liver chips will be considered future projects to analyse dose-response toxicity of our compound in humans.

Why were they not suitable?

Although using activated cell lines is a good early step to analyse the functionality of the bispecific compound, they do not represent a true substitute for the real tissue. Given the driver is to develop a clinical drug candidate, understanding the effect of the test article within the complexity of a living animal is by far the most translatable for late stage drug development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on previous work conducted and significant statistical data analysed, sample size calculations have been carried out to determine group sizes for both objectives. Furthermore, an extra number of animals has been considered to include some margins in case animals become ill and to perform pilot studies. For Objective 1, 5-6 animals will be used for each group. Objective 1 involves 4 different experimental groups with 5 different endpoints each and therefore, a total number of 100-120 animals are needed for each test article. For Objective 2, an effective sample size of 8-9 is required for each group. Objective 2 includes 7 different groups, and therefore, a total number of 56-63 animals are needed for each toxin-conjugated test article.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Sample size calculations using different tools, such as the one suggested by the national statistical advisory group, G*Power 3.1.9.7, have been performed to determine group sizes for both objectives.

Since female animals show less consistent response to CCl_4 treatment, only male C57BL/6 mice will be used to reduce the number of animals per experiment.

Finally, intraperitoneally injection demonstrates less mortality than inhalational CCl_4 or gavage application and so, a smaller number of animals is needed per experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be used to select the right dose and length of CCl_4 treatment and test articles in order to and avoid mortality, which would increase the number of animals

needed. In addition to that, pilot studies will be carried out for fluoro-labelled and toxin-conjugated test articles to identify dosage with no adverse effects.

Blood and multiple tissues from each individual mouse will be collected at the end of the study. Multiple analysis will be performed from each animal, thereby obtaining maximum data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Experimental liver fibrosis can be induced in mice by genetic manipulation, change of diet, surgical intervention (e.g. bile duct ligation, BDL) and application of hepatotoxins.

Genetic manipulations rarely develop liver fibrosis as such and need a second stimulus for disease induction. Moreover, using genetically modified models would require a high number of animals, and therefore, it is not considered for this project licence (application of the principle of 3Rs, Reduction). Diet-based models are excluded because they do not reproduce human NAFLD progression into NASH (Yanguas et at, 2016. Arch Toxicol. 90(5): 1025–1048).

Our single domains have been selected against proteins that are expressed on activated hepatic stellate cells (aHSCs). In this regard, there is a study that demonstrates how hepatotoxic (CCl_4 models in particular) and cholestatic (BDL) liver injuries activate different subsets of fibrogenic myofibroblasts: CCl_4 administration activates preferentially stellate cells, whereas BDL originates activated portal fibroblasts (Iwaisakoa et al., 2014. PNAS. 111(32), E3297–E3305). Additionally, CCl_4 is the toxic model of liver fibrosis most commonly used worldwide and has been applied in more than 50,000 studies so far. It is the best characterized in terms of histological, biochemical, cell and molecular changes associated with the development of fibrosis and has been established as a standard method for the assessment of anti-fibrotic therapeutic agents. Compared to the other models, CCl_4-induced liver fibrosis is easy to set up, highly reproducible and reflects the mechanisms involved in human liver fibrosis (Janakat and Al-Merie, 2002. J Pharmacol and Tox Methods.48, 41-44; Scholten et al, 2015.
Laboratory Animals. 49, 4-11; Yanguas et at, 2016. Arch Toxicol. 90(5): 1025–1048, Hansen et al, 2017. Drug Discov Today. 2017; 22(11):1707-1718). As we study non-alcoholic steatohepatitis, ethanol will not be considered for this project licence.

Intraperitoneally injection shows less development of ascites than prolonged inhalative CCl_4 treatment, which promotes severe cirrhotic changes in the liver (Scholten, D et al. 2015. Laboratory Animals 49 (S1) 4-11; Domenicali, M et al. 2009. J Hepatol. Dec;51(6):991-9). Application of CCl_4 by gavage will not be used as it leads to significant distress and high rates of early mortality (Scholten, D et al. 2015.

Laboratory Animals 49 (S1) 4-11), which would require higher sample numbers (application of the 3R's principle: Reduction and Refinement). Also, intraperitoneally administration of CCl_4 was the route used in our original research and has been widely described as the most chosen application in the literature for C57BL/6 mice because it causes less pain, suffering, distress or lasting harm to animals than inhalational CCl_4 or gavage. A 27G short needle will be used, changing needles between different animals. Pilot studies will be carried out to address the correct dose and length of CCl_4 treatment, and all the procedures will be performed following strictly both Laboratory Animal Science Associaton (Lasa) good practice guidelines and a SOP. Animals will be closely monitored in terms of body weight loss or abnormal behaviour and humane end points will be applied all along the protocol.

Why can't you use animals that are less sentient?

Although CCl_4 accelerates and exacerbates liver fibrosis in mice compared to other methods, such as genetic or dietary models, a minimum of 4 weeks is needed to develop liver fibrosis, and therefore, young adult mice (8-10 weeks old) are required to perform this procedure.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be handled for at least a week prior to any experiment, which will result in animals being relaxed and calm at the time of injection, and therefore, anaesthesia will not be needed. A previously drawn-up chart of weight/dosages could be used to inject the animal with little or no delay after it is weighed, thus minimising stress and unnecessary handling. The person injecting the mice will be very experienced in the intraperitoneal administration technique. In addition, pilot studies to determine minimal dosage and length of treatment required for scientific outcome will be performed and will help to minimise occasional mortality. Half of the dose will be used in the first injection to allow animals to get used to the treatment. Likewise, if a slight weight loss (0.5 g) is observed during the treatment 3 times in a row (i.e. 1.5 g of weight loss between 3 injection times), only half of the dose will be applied in the following injection.

To minimise pain or distress to animals, analgesia (e.g. buprenorphine) will be administered into mice 30-45 minutes before intraperitoneal injection. Animals will be closely monitored to identify any pain associated behaviour, such as abnormal posture (hunched), piloerection, social isolation or abdominal distention. In addition to the pain relief, other measures might be considered if necessary. These would be discussed with the NACWO and NVS. If any of these signs is critical, animals will be humanely sacrificed by a Schedule 1 method. In addition, body weight will be measured at least twice a week and any mouse showing weight loss greater than 20% will be humanely sacrificed by a Schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on the Operation of the Animals (Scientific Procedures) Act 1986

(https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/662 364/Guidance_on_the_Operation_of_ASPA.pdf)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

National Centre for the Replacement Refinement & Reduction of Animals in Research website (https://www.nc3rs.org.uk/) will be periodically reviewed to be informed about any advances in the 3Rs (Replacement, Reduction and Refinement) and implement them effectively during the project.

87. Oncology Models

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Cell therapy, T cells, Adoptive cell transfer, Immunotherapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to support the research and development of new medicines to treat cancers

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is the second leading cause of death globally with estimated death rates of around 10 million per year (World Health Organisation 2021), along with estimates suggesting a 1 in 2 chance of the population getting cancer in their lifetime. It is clear there remains a high unmet medical need for successful treatments of cancer. Environmental and genetic factors also play a part in the ever-evolving battle against cancer and, despite continuous efforts worldwide over the years, new and more effective medicines are still very much in demand.

What outputs do you think you will see at the end of this project?

Validation of new therapies, and existing therapies where effectiveness has already been confirmed, with potential successful advancement into clinical trials.

Modification and enhancements of therapies currently in clinical trials. Successful modified therapies may be advanced to clinical trials to demonstrate improved long-term effectiveness.

Generation of new information on the mechanisms of therapy effectiveness, with identification and evaluation of potential safety concerns.

Who or what will benefit from these outputs, and how?

People benefiting from the new therapies would include severely and terminally ill cancer patients who may have exhausted other treatment options. These new therapies would aim to give a complete anti- tumour response or an increase in the patient's survival. There is potential that within the 5 years of this Project Licence we can achieve our key outputs.

Shorter term benefits from the work carried out on this Project Licence will include a gain of scientific knowledge as the therapies progress through the drug discovery process, including the design of clinical trials. This will allow critical decision making and prioritisation of medicines.

How will you look to maximise the outputs of this work?

Study data and knowledge gained will be shared within the company and with collaborators and applied to benefit future work. Data and knowledge will also be shared outside the company in the form of posters at scientific conferences and publications in scientific journals.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice, usually with a compromised immune system, will be routinely used on this licence. These mouse strains are often lacking in many aspects of a normal immune system, such as T, B and Natural Killer (NK) cells. This results in the mice accepting tumour cell engraftment and therapies, where immune competent animals would reject the cells and therapies as foreign bodies.

Typically, what will be done to an animal used in your project?

It is expected that most animals will have tumour cells administered to them. As these tumours grow, they will be closely monitored by either manual volumetric measurements (e.g. using callipers), imaging systems such as MRI, or a combination of both. Animals that

have imaging procedures will be under general anaesthesia and may be injected with substances, such as contrast agents, to show tumour formation and characteristics, such as blood flow. Animals may be treated with test substances, cells and therapies, usually by injection, to ascertain their effectiveness and persistence at aiding the reduction and elimination of the tumours. Conscious animals may have periodic blood samples taken from the tail veins. Larger blood samples may be taken at the end of the studies whilst under general anaesthesia from major blood vessels or the heart. These animals will never regain consciousness.

Studies will generally be 30-40 days in length but will be dictated by factors such as the rate of tumour growth and the therapies effectiveness.

What are the expected impacts and/or adverse effects for the animals during your project?

The primary expected impact on the mice is tumour formation, which could last the duration of any study. Depending on the location of the tumour, the impacts on the normal behaviour, pain and wellbeing of the mice are likely to be minimal. For instance, it is unlikely that tumours implanted subcutaneously (under the skin) would have a significant adverse effect on the mouse, unless ulceration of the skin at the tumour site is seen. The effects on mice implanted with tumour cells intravenously may be greater due to the multiple locations where tumours may form. Weight loss of the mice is not usually seen, though tumour burden can impact this. For tumours that form within multiple organs, close monitoring of these animals along with imaging techniques will allow us to humanely euthanase animal before significant impacts on the animal's welfare are seen.

Immune mediated diseases such as Graft vs Host Disease (GvHD) may be seen in animals, usually occurring 25 or more days after receiving a cell therapy. This can cause several adverse effects, including weight loss, lethargy and limb swelling, but careful monitoring of this will ensure animals showing these signs are humanely euthanased before impacting the animal's normal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately, 70% of the mice used on this licence are likely to experience moderate severity. The remaining 30% would be expected to experience mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are required to be used on this project to mimic the complex environment and interactions within the human body and the interactions that occur with cancers. These interactions play key roles in developing new therapies (medicines). Features, such as the structure of the tumour and blood flow cannot be achieved outside of an animal.

Assessment of compounds can be carried out in vitro (without using animals), however, it is primarily the interactions of the potential therapeutics with the complex in vivo environment which allow us to determine a more accurate profile of effectiveness. Assessments without the use of animals will be used prior to using animals. These in vitro experiments may look to triage therapeutics by combining tumour cells and potential therapies. The therapies most likely to benefit patients will be chosen from these experiments and may then progress for further testing in mice, where additional aspects that cannot be created in vitro, such as the effect of the therapy on the rest of the body, can be assessed.

Which non-animal alternatives did you consider for use in this project?

Many in vitro experiments already incorporated into the study designs are suitable at determining tumour cell characteristics, therapy profile and the effect of combining these to show the killing effect of the therapy on the cancer cells.

As well as these in vitro experiments, there are a number of other alternatives that have been considered, such as 'tumour-on-chip' technology. These devices aim to recreate relevant features of the tumour physiology without the use of animals.

Organoid technologies have also been researched and some evaluated in house and in collaborations. These innovative approaches aim to recapitulate the tumour microenvironment and to demonstrate interactions between the tumour cells and therapies.

Other complex in vitro models evaluated in house include ‘air liquid interface’ and ‘epi-intestinal models’, which look to model the in vivo gut environment amongst other things.

Trujillo-de Santiago G, Flores-Garza BG, Tavares-Negrete JA, et al. The Tumour-on-Chip: Recent Advances in the Development of Microfluidic Systems to Recapitulate the Physiology of Solid Tumors. Materials (Basel). 2019;12(18):2945. Published 2019 Sep 11. doi:10.3390/ma12182945

Why were they not suitable?

The in vitro experiments already performed by the company as well as other non-animal alternatives researched, such as organoid research and ‘tumour on a chip’, do not fully replicate the complex interactions between the body and tumour, but also do not demonstrate the time course and patterns of tumour growth, metastasis and establishment of a blood supply and interactions with the immune system. Cell therapies also have complex relationships within the body as they migrate and replicate. These interactions cannot be replicated or fully understood without the use of animals.

Other in vitro models researched in-house and in external collaborations, such as ‘air liquid interface’ and ‘epi-intestinal models’, produced unreliable data and tissue quality deterioration over time.

Organoid and ‘Tumour on a chip’ technology has potential and continues to be developed, but at present creates complex technical difficulties for the scientist and longer experiments can cause issues with maintaining healthy samples. As these technologies continue to be developed, further consideration to use them will be made, but at present there are no suitable alternative to completely replace using animals to achieve the objectives on this licence.

Sontheimer-Phelps, A., Hassell, B.A. & Ingber, D.E. Modelling cancer in microfluidic human organs-on- chips. Nat Rev Cancer 19, 65–81 (2019). https://doi.org/10.1038/s41568-018-0104-6

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimated animal numbers have been calculated from the experience gained from previous Oncology based Project Licences and projections of future work over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The company has a ‘Robust Study Design’ initiative in place to ensure the appropriate number of animals are used on each study and that data collected is done so in a scientifically justified way. As part of this initiative, a statistician will be consulted to advise on all aspects of experimental designs to ensure the most suitable number of animals are used on each experiment. The aim would always be to reduce the number of animals used where possible, whilst not compromising on the objectives and quality of the results obtained. An example of this would be ensuring there are enough animals in each dose group to show statistical differences, though having no more than actually required to demonstrate this.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All studies will be scientifically reviewed by an internal expert panel prior to commencing, which ensures a broad range of experienced individuals will comment on the overall study design and recommend any improvements. This includes the overall aims of the experiment and optimal sharing data to reduce replication and overall animal usage.

On occasion, small pilot studies may be undertaken to confirm readouts, such as successful tumour growth, if no suitable previous work or publications can demonstrate this. This may then lead to further optimisations, such as cell concentrations, in larger growth kinetic studies.

To reduce variation in biological readouts we will ensure that our facilities provide a constant optimal environment suitable for the strain and species, and we will control the

number of personnel involved in making any subjective experimental measures e.g. tumour measurements by callipers. By minimising variables, we aim to ensure that animal group sizes are the smallest possible to achieve the scientific objectives of the study.

Due to the complexity of the projects on this licence, it is routine that many organs and tissues are investigated by different groups within the company, including histopathology, therapy levels within the target site and imaging. Careful planning of this prior to studies starting allows for the animals to be used in the most efficient ways possible and reducing overall numbers used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species used on this licence will be mice, most of which will have deficient immune systems to allow human cancers to grow. The most appropriate strains will be selected for each animal study, which exhibit the desired traits that allow for successful tumour growth. This gives a greater chance of the treatment working in a clinical setting. These mice will be maintained and handled in such ways to maintain a barriered environment so not to compromise the health of the animals, including sterile caging and bedding. They will be handled by cupping or tube handling whenever possible. Some of the mice used may have some phenotypic traits that require careful monitoring, therefore detailed scoring sheets will allow for these observations to be captured in a clear and consistent manner.

The volumes of injections and the number of blood samples taken will be kept to a minimum to complete the scientific study objectives, whilst aiming to ensure the welfare of the animals is not compromised and that the level of discomfort is kept to a minimum. Animals will be warmed prior to blood sampling to allow for successful blood collection. This will be kept to the shortest time possible with an aim to give the smallest impact to the animal.

Tumour cells will be implanted into the mice and subsequent tumour growth routinely monitored throughout the course of the study, either by volumetric measurements (e.g. manual callipers), imaging techniques under anaesthesia, or a combination of both. There may also be occasions where technological advances allow for automated tumour measurements to be carried out on conscious animals. Bodyweight will be recorded at regular intervals which can give an indication of the effects of tumour burden on the animals. Maximum tumour volume thresholds for individual studies will be set to the minimum size to complete the study objectives instead of aiming for the maximum allowed on this licence. This aims to minimise the overall burden on the animal where possible.

Animals will be routinely group housed with appropriate caging substrate, nesting material and environmental enrichment. As animal numbers decrease during the study (e.g. as tumour volumes reach the set points and animals are euthanased), then there may be

occasion when the remaining animals within that cage are singly housed.

Why can't you use animals that are less sentient?

Animals with complex bodily interactions along with interactions with cancers are required to mimic cancers in human patients. Routinely, the adult mice used on this licence have compromised immune systems that have been specially developed for this type of research, allowing for human cancers to grow within their body. The therapies being developed also have complex interactions within the body and these need to be researched prior to progressing into patients. Studies of cancer in mice are extremely useful for understanding the cancer biology and provide insights into the tumour growth, progression and metastasis.

Although research into cancer models in less sentient animals, such as zebra fish, is taking place within the oncology community, there is no less sentient animals available that can provide as complete package of scientific data that mice can provide.

Due to the length of studies on this licence, it is not possible to use terminally anaesthetised animals for the duration of the experiment, however animals will be placed under general anaesthesia for procedures, such as tumour implantation, imaging techniques and terminal sampling, to reduce the stress to the animal.

Zhang W, Moore L, Ji P. Mouse models for cancer research. Chin J Cancer. 2011;30(3):149-152. doi:10.5732/cjc.011.10047

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals on studies will be monitored once daily as a minimum, and any adverse clinical signs that could be treatment related will be recorded and, where beneficial, scored by reference to a specific scoring system for each type of experiment, therefore allowing monitoring of potential trends and modification of treatments if necessary.

Animals will be tube and cup handled when possible to reduce stress, though scruffing of the mice will be required to manually measure tumours. Modified and newly developed restrainers will be used when possible for blood sampling and dosing inside barriered cabinets, allowing easier operation for the staff and with an aim to decrease the stress caused to the mice. These restrainers aim to confine the mice less during the procedure, allowing for greater airflow and allowing uninhibited visual monitoring of the animals throughout.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Aspects of the published principles and philosophies behind the PREPARE (2018) and original ARRIVE (2010) guidelines have been and continue to be incorporated into the sponsoring company's internal project planning, standards of care and standard operating procedures. All work carried out under authority of this licence will undergo assessment of the study design during planning stages as part of a peer review process that is based on those guidelines and will include statistical consultation. Facilities and processes are audited by independent bodies such as AAALAC International.

The company uses the following as a guide for setting maximum blood sampling and

dosing limits:

A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes Diehl et al, (2001), Journal of Applied Toxicology, 21, 15-23.

The following publications will also be used as guidance:

Workman, P., Aboagye, E., Balkwill, F. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010). https://doi.org/10.1038/sj.bjc.6605642

Ullman-Culleré MH, Foltz CJ. Body condition scoring: a rapid and accurate method for assessing health status in mice. Lab Anim Sci. 1999 Jun;49(3):319-23. PMID: 10403450

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The role of the sponsoring company named information officer (NIO) includes the sharing of animal welfare, best practice and 3Rs related information. The NIO also liaises directly with the company project licence holder network through their own regular meetings and raises this type of information and discussion points at the institutional Animal Welfare and Ethical Review Body (AWERB). The licence holder for this work attends both these groups and is also separately aware of the 3R's related work of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). Experience to date has shown that 3Rs issues and advances are highlighted, discussed and actions are implemented within the company centrally and effectively via these forums.

88. Neural Mechanisms of Social Behaviour

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cognition, neural circuits, neurons, development, social behavior

Animal types	Life stages
Rats	embryo, neonate, juvenile, adult, pregnant
Mice	embryo, neonate, juvenile, adult, pregnant
Gerbils	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the brain mechanisms involved in social perception, how these mechanisms are altered in development and eventually in disease. We also aim to explore evolutionary comparative aspects of the examined processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodevelopmental and mental health disorders are associated with alterations in social sensory processing, development and cognition. The primary aim of our research is to understand how the neural circuits of a healthy brain support social behavior, cognition, development and sensory processing. The result of these findings will support a basis on which to build an understanding of how the brain is altered in disease states and how to remedy these dysfunctions with treatment. Further unique aims of this work are to examine

neural activity and the underlying mechanisms which are most naturally relevant to the animal as well as evolutionary comparative aspects of the examined processes.

What outputs do you think you will see at the end of this project?

The result of this work will lead to a greater fundamental understanding of how the brain supports social behaviour, attachment, cognition, development and sensory processing. These fundamental discoveries of how neurons function in these processes will provide a basis for understanding how dysfunction occurs in disease and mental health disorders.

Who or what will benefit from these outputs, and how?

Our work will build a foundation of knowledge regarding the basis of neural function and how these processes may have evolved. We expect the impact of our work to have a significant impact on basic research. Once we build a fundamental understanding of brain function in social cognition, further studies will pursue an understanding of how these neural processes are affected in disease. A further, more long-term effect, will be the development of treatments to reverse the dysfunctions in disease and mental health disorders.

How will you look to maximise the outputs of this work?

We will aim to publish datasets of all of our studies regardless of outcomes. We will also maximize outcomes of our research through collaborations as well as presentations in international conferences.

Species and numbers of animals expected to be used

- Rats: 3000
- Mice: 30
- Gerbils: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use rodents for this research, which show robust social behaviours and are ideally suited for studying the neural circuits underlying these behaviours. We plan to assess how regions of the brain and genetically defined pathways support social behaviour. We will ask questions related to the structure and function underlying development of social attachments, social bonding and recognition in the context of naturally relevant social behaviours. We will assess rodents at all developmental stages including prenatal stages of development until adulthood.

Typically, what will be done to an animal used in your project?

Animals used in this project will undergo surgery, injections of substances, cranial implants, culling under anaesthesia and behavioural assessments. As social behaviours are highly dependent on identity, animals will also be identified with tattooing as well as

radio-frequency identification microchipping to ensure that identification can be reliably performed without fail. Experimental durations will range from acute (1 day) to several weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Potential adverse effects include possible death under anesthesia in survival surgeries, pain following surgical procedures which will be significantly reduced with analgesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severities are considered to be moderate and mild for all procedures. For survival surgical procedures in juvenile animals, death from anaesthesia in and following surgery may occur more frequently. Death rates occurring under anaesthesia in juvenile animals will be monitored and reported.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand neural circuit function in complex behaviour, an approach using multiple technically advanced methods are required. These advanced methods include imaging, electrophysiological, transgenic and pharmacological manipulations of the mammalian brain. Experimental systems that allow this are limited and must involve the use of vertebrate animals. We will utilize in vitro preparations where possible to assess reduced aspects of cellular function, however these approaches are limited and do not faithfully reflect the properties of an intact circuit.

Which non-animal alternatives did you consider for use in this project?

Human and ex vivo tissue investigations.

Why were they not suitable?

Investigations of the neural circuits underlying social behaviour in a non-intact animal is not possible as these behaviours can only be performed in interacting animals. Observations of social behaviour in humans is limited in scope as there are not possibilities to manipulate elements of the neural circuits in a highly resolved manner as we are able to in the rodent.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate the given numbers of experimental animals based on usage statistics of previous publications as well as information provided from other license holders at our establishment. The numbers required for upkeep and desired out-breeding of lines are derived from estimates provided by the animal facility. To stay updated on optimized experimental design, we will regularly seek guidance from biostatistical experts employed by our establishments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the experimental design stage of the project, we have made plans to perform pilot studies where possible before planning for large cohorts. All experiments will be conducted according to the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will implement efficient breeding procedures and will additionally perform well-designed pilot studies whenever possible to assess the potential for publishable results. We will additionally perform computational modelling and analysis of datasets to maximize the information extracted from our datasets.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodents as an animal model and will aim to assess neural activity and the outcomes of circuit and pharmacological effects on behaviour. We aim to understand neural function and circuits in the healthy brain which will provide a foundation for understand brain dysfunction in disease. Thus, this approach will reduce the number of animals subject to adverse states in severe disease models.

We will utilize wild-type and transgenic rodents without harmful phenotypes as animal models meaning that rodents in the unperturbed state will experience no harmful effects.

We have identified species- specific behaviours in terms of kinship and mate choice. For this reason, we aim to use an evolutionarily comparative approach to uncover differences in neural circuit structure and function which contribute to these species-specific social behaviours. We will utilise rats, gerbils and mice for their species specific social behaviours. In contrast to rats and mice, gerbils display characteristic pair bonding, parental and inbreeding avoidant behaviours which are significant to our research goals.

Why can’t you use animals that are less sentient?

As the goal of our research is to understand complex cognitive processes involved in social behavior, it is not possible to examine this in less sentient species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any of studies involving surgical or invasive intervention will adopt appropriate pain management and post-operative care.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will stay up to date on best practice guidelines set forth and regularly updated from the NC3Rs website (Guidance on the Operations of ASPA - https://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the advances in the 3Rs by attending informational events provided locally and provided by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

89. The hematopoietic system in normal development, ageing and cancer.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Blood cell production, Hematopoietic stem cells, Leukemia, Breast cancer, Ageing

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand how blood cells are normally produced, and how this process is perturbed in ageing and haematological disorders and cancers. The ultimate goal is to identify molecular targets critical to disease developmentand use these therapeutically.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood cells are critical for oxygen transport, vascular integrity and immunity, and deterioration of blood cell production with age contributes to frailty and loss of adaptive

immunity. In addition, the blood system can both give rise to cancers and contribute to tumour progression in other tissues.
Understanding how normal blood cell production is regulated, and identifying the mechanism by which the production and function of blood cells is altered in pathological conditions, is therefore important for the development of regenerative and therapeutic strategies that can maintain population health and treat malignant disease.

What outputs do you think you will see at the end of this project?

The blood system is important for the body to function and for its ability to fight off infections. The normal production of blood cells is disrupted during ageing, contributing to frailty and susceptibility to infections, and in blood cancers, ultimately leading to loss of normal blood production and death. In order to better understand how to counteract the detrimental changes to blood cell production during ageing and in blood cancer we will here perform genetic experiments to improve our knowledge of normal blood cell production, and use this knowledge to better understand how to counteract the changes that occur to the blood system in aged individuals and pathological states.

Specific outputs will be:

An improved understanding of the nature and function of blood forming stem- and progenitor cells that will allow us to understand how blood cell production normally works and to better diagnose and understand disorders of the blood system.

An improved understanding of the response of the blood system to stress, including inflammation and bleeding.

Genetic tools for the identification and genetic manipulation of blood forming stem- and progenitor cells.

Generation of accurate pre-clinical models for the study of hematological disorders that can be used for drug development and testing.

Therapeutic strategies to counteract the loss of red cell and lymphocyte production during normal physiological ageing

Therapeutic strategies to treat blood cancer, particular those affecting the myeloid cell-producing stem- and progenitor cell compartment

Who or what will benefit from these outputs, and how?

The fundamental knowledge generated about the blood system will be of use to the scientific community, as will the improved tools for the study of blood cell production that will be generated. These outputs will provide benefits within the time frame of the project.

In the longer term (5-10 years) clinicians, patients and the general public will benefit from improved therapeutic strategies against age-related anaemia and declining immune function, as well as better diagnosis and/or treatment of blood cancers.
How will you look to maximise the outputs of this work?

We will disseminate our results at scientific conferences and in publications, as well as through public engagement and engagement with patient groups.

We will make any new genetic tools and disease models available to the scientific community through collaboration and through deposition in appropriate public repositories for mouse strains.

We will engage with clinical scientists and industry to translate therapeutic strategies towards clinical use.

Species and numbers of animals expected to be used

- Mice: 42500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of the mouse as species: In this project we will use genetic mouse models to study the normal function of the hematopoietic system, how ageing affects its function, and how blood cancers develop. We use mice because they represent the species with a hematopoietic system that most closely resembles the human hematopoietic system where genetic modification is accurate and accessible, and where inbred strains exist that can be used for transplantation while avoiding immune rejection issues. Therefore, studying normal and perturbed hematopoiesis in the mouse provides information that is highly relevant to human disease and ageing. In addition, the mouse is sufficiently similar to humans to allow human cells to be propagated in vivo using xenografting of immune-deficient animals.

The choice of life stages: The hematopoietic system reaches its adult state only after birth, around week 3-4. As we wish to study the baseline and stress hematopoiesis and how hematopoiesis changes with age we will use juvenile or adult mice in non-breeding protocols, as well as aged mice in those protocols where ageing is studied. We will primarily study myeloid-lineage hematological malignancies, which are common in adults, but not children, and are closely associated with ageing

Typically, what will be done to an animal used in your project?

The majority of mice (60-70%) will be involved in breeding and maintenance only and will not experience any procedures.

Experimental mice will undergo the following typical experiences:

Induction of gene expression by substance administration (tamoxifen, 3 times by oral gavage), followed by blood sampling (8 times over 4 weeks) and exanguination under terminal anaesthesia.

Induction of gene expression by substance administration (tamoxifen, 3 times by oral gavage), leading to the development of a hematological malignancy over 12 months. A single bone marrow sample will be taken. Mice will then receive daily substance administration for 2 weeks by oral gavage or intraperitoneal injection. Blood samples will

be taken 12 times over a 4-week period. Mice will be killed by schedule 1 method.

Lethal irradiation and bone marrow transplant, followed by 4 weeks recovery. 3 times oral gavage with tamoxifen at 2-day intervals. Blood samples will be taken 8 times over a 4-month period. Mice will be killed by a schedule 1 method.

Minor surgery under general anaesthesia, substance administration (daily for 4 weeks), sublethal irradiation and bone marrow transplant, followed by 4 weeks recovery. Blood samples will be taken 8 times over a 4-month period. Mice will be killed by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts include transient discomfort or pain when substances are administered, when cells are injected, blood or bone marrow samples taken, and after surgery. Development of hematological malignancy can be associated with fatigue due to anaemia, and the experiment will be terminated if more than moderate anaemia develops. Irradiation prior to bone marrow transient plantation can cause transient mild anaemia, expected to last a few days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse:

Mild severity: 65%

Moderate severity: 35%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The physiological processes that we will study (hematopoiesis, ageing, blood cancer development) are highly complex, as they involve the dynamic interaction of multiple cell types, including systemic, metabolic and environmental changes over time and the stepwise acquisition of genomic and epigenomic changes. There is currently no adequate methodology for modelling these processes in vitro, in particular since the molecular and environmental changes involved are only partially characterised.

Which non-animal alternatives did you consider for use in this project?

Some aspects of blood cell differentiation and both normal and malignant stem cell maintenance can be mimicked in vitro, and we are pursuing these as methodologies where possible. In particular we have considered the use of in vitro cultures for the maintenance and differentiation of hematopoietic stem cells, and for maintenance and screening of malignancy-propagating cells.

Why were they not suitable?

Some aspects of blood cell differentiation and both normal and malignant stem cell maintenance can be mimicked in vitro, and we are pursuing these as methodologies where possible.

So far, we have not been able to replicate HSC fate-restriction ex vivo, using in vitro differentiation assays

While in vitro colony forming assays can reveal progenitor lineage potentials they do not read out fate.

We have been able to propagate some malignancy-propagating cells ex vivo; however, they rapidly lose their malignant properties, emphasising the need for a better understanding of the environment that sustains them. While we will continue to explore the methodologies mentioned above they currently do not adequately replace in vivo experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experiments planned for this license are similar in nature to experiments currently performed in my laboratory, and animal numbers have been calculated based on the number of projects currently ongoing and planned, and our long-standing experience with this type of research, assuming that the number of PILs working on the new license will be similar.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power calculations (using the NC3R EDA and other relevant tools such as GPower) and have been used to ensure that experiments are powered adequately, and reduce the risk of significant overpowering.

Breeding strategies have been designed to minimise the number of non-experimental mice generated (e.g. by generating homozygous lines where possible without generating adverse phenotypes)

We have planned to source mice from central colonies where possible (e.g. C57Bl6/J mice for use as recipients) to avoid redundant breeding within this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding strategies will be optimised to generate the lowest possible number of mice that cannot be used, by setting up crosses that simultaneously generate experimental and control mice where possible.

For mouse lines that are not in constant use we will preserve strains by sperm freezing or embryo cryopreservation, as appropriate.

For mouse lines that are commonly used we will interact with local colleagues to minimise the number of independent colonies of these strains that are maintained.

We will plan experiments within the lab, and where relevant across labs, to share tissues and cells from mice.

We will optimize our molecular and functional readouts to minimise the number of mice needed to generate input materials.

For pharmacological studies we will use pilot studies to determine effect sizes, and experimental block design to avoid overpowering the analysis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models used in this project are:

Mice containing constitutive and inducible fluorescent reporters: these will be used to identify specific hematopoietic cell populations and measure their output of blood cells. The genetic modifications themselves are not harmful to the animal. Administration of the drugs used to induce gene expression (such as tamoxifen, poly(I-C)) cause transient discomfort. However, these are the most efficient and inducers available, and no suitable alternative currently exists.

Mice that undergo ageing: in the study of ageing there is currently no suitable alternative to the use of intact organisms, as the processes involved are highly complex, involve both systemic and cell-intrinsic factors, and accurate replication of in vivo metabolic states. We here age mice up two years of age, as this represents the physiological age equivalent to the human age (65-70 years) where immune function declines and blood cell production is

significantly altered, where development of blood cancers accelerates, and their treatment becomes more difficult. Ageing mice to this point is therefore necessary (and sufficient) to study the effects relevant to human health. As in humans, ageing leads to physiological decline, which can cause minor discomfort; however, this is necessary in order to understand the underlying processes and devise strategies to counteract the negative effects of the ageing process.

Mice that develop hematological malignancies: The mouse currently represents the most accurate model for the experimental study of human hematological malignancies, as the disease-causing mutations can be accurately replicated and the resulting phenotypes are good representatives of the human conditions. For disease phenotypes it is necessary to allow the disease processes to proceed to a clinically relevant stage, which may cause moderate suffering for a limited time. However, this is required to obtain information relevant to human health, and will be minimised by frequent monitoring and ending the experiment as soon as an adverse clinical phenotype develops.

Mice that undergo bone marrow transplantation: The use of bone marrow transplantation represents the most refined methodology for the identification and characterization of hematopoietic stem cells and hematological disease-propagating cells, and for studying the differentiation of hematopoietic progenitor cells under physiological conditions. It is associated with transient discomfort due to irradiation where used; however, this is required for ablation of the endogenous hematopoietic cells which in many cases is a prerequisite for the transplanted cells to engraft.

Mice that are treated with pharmacological agents: To develop pharmacological strategies to counteract age-related phenotypes or to treat hematological malignancies the use of drugs is required. As ageing is a chronic condition anti-ageing compounds may have to be administered over long periods of time; however, this is necessary to determine their ability to counteract the ageing process. In addition, some drugs that are used to treat hematological malignancies are cytotoxic, and will cause transient suffering, but no lasting harm. However, their use is necessary to determine if treatments are able to improve on the current standard of care, and the least toxic alternative will be used.

Mice that are subjected to fasting: Intermittent fasting of mice is necessary to investigate the ability of metabolic reprogramming to counteract ageing-associated phenotypes and to improve therapy against hematological malignancies. This may cause transient mild discomfort, but no lasting harm (it may actually improve animal welfare, especially of aged mice).

Mice that are engrafted with human hematopoietic cells: Xenografting is the currently most refined model for studying normal human and malignant cells in a physiological setting. It does not cause any significant lasting harm, except those associated with disease progression in case of engraftment of malignant cells, as we generally use NSGW41 mice where irradiation is not required for transplantation.

Why can’t you use animals that are less sentient?

The mouse is the least sentient model with a hematopoietic system that sufficiently resembles the human hematopoietic system for the study of ageing and malignancy to be relevant to human health.

The hematopoietic system only reaches its mature state 5 weeks after birth. To obtain

results relevant to adult hematopoiesis and ageing we therefore need to use adult and aged mice. In addition, the vast majority of hematological cancers occur in adults, and their development occurs over an extended period of time, precluding the use of immature life stages and anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use the least harmful methodology for transplantations, using sublethal or no irradiation where possible, based on pilot experiments testing the feasibility of doing so.

We will use the most accurate genetic modelling available for the study of hematopoiesis, and in particular use conditional genetics where possible to avoid adverse effects due to genetic alterations in non-hematopoietic tissues.

For experiments that involve treatment of hematological malignancies to model the clinical standard-of- care we will consult with clinical haematologists to define the least harmful treatment type that achieves clinically relevant results.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgery will be performed following LASA aseptic surgery guidelines.

We will use the NC3Rs Experimental Design Assistant (EDA) online tool or similar software to design experiments.

We will conduct and report our experiments for publication according to ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All PILs attached to this PPL, as well as myself, will attend all of our local animal welfare meeting. I subscribe to the NC3Rs newsletter, and discuss relevant points in our weekly lab meetings
All PILs attached to this licence will be encouraged to attend the annual institutional 3Rs day, which I will also attend.

90. Genetic and environmental effects on mouse embryonic and placental development

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

developmental biology, mouse embryology, birth defects, gene-environment interaction

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how genetic and environmental factors affect mammalian embryonic and placental development, concentrating on, but not limited to, the formation of the cardiovascular system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
3% of people are born with some kind of birth defect. Of these, congenital heart disease (CHD) is the most common type of birth defect, representing about one third of the total number. CHD is defined as a structural abnormality in the heart that is present at birth, and it is a major cause of infant mortality and morbidity, requiring ongoing medical treatment

throughout life. Currently only ~30% of CHD can be attributed to known causes such as genetic syndromes. This is partly because our understanding of the genetics of embryonic development is incomplete, and partly because non-genetic factors can perturb this process. Examples of non-genetic factors include maternal diabetes; exposure to reduced oxygen levels (hypoxia) due to smoking or altitude; elevated maternal body temperature (hyperthermia) due to viral infection or extreme heatwave conditions; deficiencies of dietary micronutrients such as folate or iron; and exposure to toxic substances during pregnancy. My results will provide further insights into the genetic and environmental causes of CHD, as well as other types of birth defects. This will improve diagnosis, management and genetic counselling for families with inherited birth defects. It will also help identification of the extent of the risks of environmental factors through improved epidemiological studies, assist in reducing the risks posed by these factors through improved public health policy, and perhaps even guide the development of therapies to reduce the incidence of birth defects.

What outputs do you think you will see at the end of this project?

At the end of this project we will have generated new knowledge of how both genetic and environmental factors cause birth defects. These results will be disseminated by making conference presentations and publishing papers in high impact journals. After publication, we will raise awareness of our results through the general media as well as through charities such as the British Heart Foundation and Diabetes UK. We will have also generated new resources, such as RNASeq data, that will be useful for future studies in this scientific field.

Who or what will benefit from these outputs, and how?

Our results will be of use to a broad range of academic and non-academic users:

other researchers in the fields of developmental biology and diabetes research. Our outputs will assist in a greater understanding of embryonic and placental development in both normal and pathological conditions.

clinicians and patients. Our genetic outputs will enable new genes to be added to genetic screening programs to identify if there is a genetic cause of individual cases of birth defects.

the general public and policy makers. Dissemination of our results through the news media and charities such as Diabetes UK and the British Heart Foundation, will raise awareness of environmental risks factors during pregnancy.

the pharmaceutical industry. Our work may provide a rationale for the development of therapeutic interventions to reduce the prevalence birth defects.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work we will actively collaborating with other specialist groups to extend the use of our genetic and environmental models to study their effects on aspects of embryonic and/or placental development for which we lack sufficient expertise, or time, to study ourselves. Additionally, we will to freely share these models with other groups for their own research, without any conditions.

We constantly endeavour to increase the awareness of the scientific and clinical community of our work, and the availability and utility of our animal models. This includes writing reviews (e.g. we wrote a review on the different types of environmental factors affecting embryonic heart development), giving presentations at conferences and seminars at a wide range of locations and topics, and engaging with the public through giving media interviews, writing blog posts, and participating in events (e.g. Pint of Science).

Species and numbers of animals expected to be used

- Mice: 26,000 juvenile to adult; 30,000 embryos E14.5 to birth.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are investigating how both genetic and environmental factors can perturb embryonic and placental development to cause birth defects. We are using mice because they are easily genetically manipulated , and because mouse embryos develop in a very similar manner to human embryos, and insights derived from mouse embryological studies translate well to the clinic. In addition, the genes, proteins, signalling pathways and cells involved are almost identical between mouse and human. We require analysis of developing embryos in vivo, as this process is four-dimensional (i.e. varies in space and time) and in vitro systems cannot mimic the complexity of a functioning organ such as the heart, let alone an embryo. Computer simulations can extend theoretical approaches to embryonic development, but cannot tell us about the real biological processes occurring. This work will use both wildtype and genetically altered mice. Genetic modifications will include transgenic mice with reporter genes to help detect where specific genes are normally turned on or off during the formation of the embryo; transgenic mice enabling the activation, deletion or mutation of one or more specific genes, either throughout the embryo or within particular tissues or structures in the developing embryo; and combinations of these two.

Typically, what will be done to an animal used in your project?

For two-thirds of mice, the only procedures will be breeding and maintenance (protocol 1), in which we will produce genetically-altered mice for use in protocols 2-7. The other third may be subject to additional procedures. These male and female mice will always be timed mating to produce embryos. In most cases, the resultant embryos will be analysed after death, but in less than 5% of cases these embryos will be analysed in utero by non-invasive means. In addition, female mice may be: exposed to a single environmental challenge (e.g. hypoxia, to mimic smoking or altitude; hyperthermia, to mimic viral infection or extreme heatwave conditions; or dietary modification, to mimic nutrient deficiencies) or have substances administered (e.g to activate or repress gene expression, to induce or prevent birth defects, or to allow in utero embryo imaging).

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of mice (over 80%) will not experience adverse effects because they will only be used for breeding and maintenance or timed matings.

No adult mice will have structural birth defects. All embryos and pups with birth defects will be culled humanely before 5 days old.

A small percentage of adult mice exposed to altered environmental conditions may suffer some adverse effects:

Alterations of oxygen levels may include transient distress similar to a human at high altitude, including lethargy and increased breathing rate at the beginning of the procedure (for approximately 30 minutes). The mice will never be exposed to hypoxia for longer than 8 hours but are not expected to show adverse effects for longer than 15 minutes. If distress persists for more than 30 minutes at the start of the exposure, the animal will be killed by schedule 1 method.

Hyperthermia may cause distress and dehydration, similar to a human sitting outside in the shade during a heatwave. The mice will never be exposed to hyperthermia for longer than 120 minutes. If distress persists after exposure, the animal will be killed by schedule 1 method.

Dietary modification may occasionally lead to weight loss over a period of weeks. If weight loss is more than 15%, the animal will be killed by schedule 1 method if humane endpoints are met.

Hyperglycaemia, similar to that of untreated type I diabetes in humans, will result in more frequent urination, and may result in weight loss. The animal’s weight (or body condition score for pregnant mice) and blood glucose will be monitored regularly throughout the protocol. In addition, cages will have extra absorbent bedding and/or will be changed more frequently, and water bottles will be changed more frequently to ensure ad libitum access.

Mice will be frequently observed for meeting defined humane end-points, but most are not expected to experience these adverse effects.

Impacts and adverse effects from the administration of substances to activate or repress gene expression, to induce or prevent birth defects, or to allow in utero embryo imaging are expected to be rare, but may include damage from administration route (e.g. gavage causing oesophageal rupture, injections into pregnant mice inducing miscarriage, wound breakdown after implantation of slow- release pellet or osmotic minipump), adverse phenotypes in response to alterations of gene expression (e.g. smaller size), or adverse effects in response to substances (e.g. weight loss). Mice will be frequently observed for meeting defined humane end-points, but most are not expected to experience these adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols and males for timed matings (which make up 80% of our mouse usage), we expect all mice to experience sub-threshold severity.

For adult mice experiencing hyperglycaemia, hypoxia or hyperthermia to investigate their effects on embryonic and placental development (protocols 2, 4 and 5, maximum of 1000 mice for each protocol), we expect the majority to experience moderate severity (approximately 70%) as a result of hyperglycaemia/hypoxia/hyperthermia and/or additional steps (such as blood sampling, substance administration and/or in utero imaging).

For mice experiencing dietary modification or teratogen administration to investigate their effects on embryonic and placental development (protocols 3 and 6, maximum of 1000 mice and 5000 embryos for each protocol), we expect the majority to experience mild severity (approximately 80%) and 20% to suffer moderate severity as a result of additional steps (such as blood sampling, substance administration and/or in utero imaging) combined in one animal such that cumulative suffering could be considered moderate.

For genetically altered mice to investigate the effects of gene mutation on embryonic and placental development (protocol 7, maximum of 1000 mice and 5000 embryos), we expect the majority to experience mild severity (approximately 80%) and 20% to suffer moderate severity as a result of additional steps (such as blood sampling, substance administration and/or in utero imaging) combined in one animal such that cumulative suffering could be considered moderate.

Approximately 60% of the experimental embryos (5000 for each protocol) will be collected before two- thirds gestation (not regulated), and the remainder between two-thirds gestation and 5 days after birth (maximum severity mild).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are investigating how the specific shape and function of the heart, placenta and other organs form in the embryo. Mouse embryos develop in a very similar manner to that of humans, and the genes, proteins, signalling pathways and cells involved are almost identical. Mice are the only mammalian model to which can be applied forward and reverse genetics to assess the effects of individual loss or gain of gene function on cardiac formation. Over the past 30 years, very powerful techniques have been developed to turn on and off individual genes in the developing embryo, both throughout the embryo or just within a single organ or tissue. These have been shown through our studies and others to faithfully recapitulate many birth defects. Furthermore, gene-environment interaction studies in mouse are well documented in the literature. Embryonic development is a four-dimensional process (i.e. varying in space and time), and therefore requires the analysis of whole developing embryos. Direct genetic studies of foetal (embryonic) humans are difficult practically, and only descriptive analyses are possible, as experiments are ruled out on ethical grounds.

Which non-animal alternatives did you consider for use in this project?

Tissue culture systems and computer simulations.
Why were they not suitable?

Tissue culture systems, although they can provide useful information on certain molecular or cellular phenomena, cannot mimic the complexity of a functioning organ such as the heart or placenta, let alone the developing embryo. Computer simulations can be valuable in extending theoretical approaches to embryonic development, but cannot tell us about the real biological processes occurring in the embryo. Finally, gene-environment interactions can only be studied in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Projected animal usage is based entirely on the experiments to meet the objectives of the PPL, with the relevant genetically altered strains either currently in house or to be imported into the colony. Most animals will be used for colony breeding and maintenance, where excess mice will be culled by a Schedule 1 method. The numbers requested are sufficient to maintain working colonies for each genetically altered mouse strain and for expansion to generate the required number of embryos for phenotyping. For example, to maintain a particular reporter or Cre strain, we will house 6-18 mice at one time, and replenished every 4-8 months. However, breeding numbers may vary depending on the specific genotypes and numbers of embryos required for a specific project. For example, to produce the mice for protocol 2, we require female mice of a certain genotype. On average, half the mice in each litter will be female; and half the females with be the required genotype. Thus, on average only one quarter of the mice from each litter will be used for procedures. The remaining mice will be culled by a Schedule 1 method after genotyping. This will necessitate maintaining a higher number of breeding pairs to get sufficient females of the correct genotype than if all females in a litter had the correct genotype.

Experiments are designed to generate statistically significant results using the minimum number of animals. For all experiments we will consult regularly with statisticians in the neighbouring Statistics Department and also with colleagues doing similar experiments to ensure we are employing the minimum number of animals to power the analyses for statistical significance. For example, in Objective 1 in order to determine the penetrance of a particular cardiac phenotype, or of embryonic lethality, a sufficient number of litters will need to be analysed, at various developmental stages, in order to correlate phenotype with genotype and to calculate Mendelian ratios. For each new strain, we will perform a pilot study initially in a small number of litters (n=5), at one or more appropriate developmental stages, for histological analysis. We will scale up for a comprehensive analysis once a phenotype has been confirmed and the most informative developmental stages have been determined.

Two types of experiment are proposed: qualitative studies without a specific numerical end-point, such as importation of new transgenic mice where a few founders will be sufficient, and quantitative analysis which addresses questions such as the role of a particular gene in normal embryonic heart development or the mechanism of perturbation of heart development by environmental factors. In the quantitative studies, two or more groups will be compared over two or more time periods with respect to continuous variables. Regression analysis will be used to quantify differences between groups. For

example, to assess the impact of a particular environmental stress on heart development, power calculations suggest that experimental groups with ~30 embryos are required to obtain 80% confidence of detecting a 10% difference in heart defect incidence.

Finally, we commit to validate experimental design using the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) “Experimental Design Assistant”.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, genetically altered mice will be bred as homozygotes to minimize excess waste.

Animal numbers will also be minimised for Objective 1 by the fact that we will predominantly be using knockout lines from the DMDD programme for which we already know there is a heart defect.

Procedures on live animals will be used to create embryos, the final phenotyping of the morphological, cellular and molecular effects of genetic and environmental factors on embryonic development will mostly be done using fixed tissues from culled embryos and only in the case of live imaging will we require procedures to be performed on live embryos.

We have used the NC3R's Experimental Design Assistant to help design analysis of both qualitative studies of embryo morphology and quantitative analysis of changes in gene/protein expression. We have also used statisticians to advise on POWER calculations, and the relevant statistical analysis required to provide meaningful results.

Where possible we will use in vitro cell culture system to confirm the molecular findings of our studies. For example, where an environmental stressor causes perturbation of the action of a particular intracellular signal transduction pathway, we will attempt to model this in vitro to verify our conclusions.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have put advice on efficient breeding into practice. In general, breeding cages are separated after 4-5 litters and retired at six litters.

For wild type strains shared with other labs/outside suppliers, we buy/import animals rather than generate them in-house

Where possible, mouse lines are frozen down. In cases where we do not anticipate usage in the next 6 months, lines are not maintained.

We perform breeding calculations before we plan our experiments and only produce the numbers of animals that we need.

Animal numbers are recorded on a database in real time, and are monitored regularly.

We ensure any welfare or husbandry requirements of the strain have been identified. The cage card alerts people to any special welfare or husbandry requirements.

Tissue samples are analysed for multiple different assays (e.g. by staining consecutive sections with different probes or by multiplexing immunohistochemistry on individual slides). In addition, excess tissue samples are shared with other researchers, where possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The main source of potential discomfort within this project is through the possibility of adverse effects via the use of genetically altered mice. These animals may experience adverse effects depending upon the nature of the introduced genetic material, site of insertion and level of altered gene expression.

Heterozygous breeding animals supplied from commercial sources are well characterised and documented for any potential adverse effects. The vast majority of these strains do not cause pain, suffering, distress, or lasting harm to the animals. However, in many genetically-altered mouse lines where key genes involved in embryonic development are perturbed, homozygous animals may die in utero (embryonic lethal). Homozygous animals are produced from heterozygous intercrosses.

Therefore, to minimise adverse effects, our breeding colonies will be maintained as backcrosses (heterozygous GA x wildtype), and we will only use heterozygous intercrosses to generate our experimental animals. In maintaining colonies, procedures such as tail-tipping for genotyping will only be used very rarely. In addition, the use of partially characterised mouse lines arising from the Deciphering the Mechanisms of Developmental Disorders (DMDD) programme for phenotyping embryonic lethal mice will reduce the numbers of animals used for Objective 1 of this study. In studies of gene

function using transgenic mouse models there is the element of risk that the gene selected for knockout will not have the phenotype expected. For example, knocking out a gene with very strong evidence for a critical role in heart development might still result in a mouse line without any embryonic heart defect at all. This could result in the use of significant numbers of mice for little benefit. However, in general I will use mouse lines arising from the DMDD programme that are already known to have a specific type of heart defect at the single embryonic stage analysed (E14.5), but still require further analysis to understand why they develop these defects as this has not been undertaken. This will ensure that the number of mouse lines to be imported for analysis will be the fewest possible to successfully complete the study, thus making the most efficient use of mouse numbers.

For studying the effects of maternal diabetes on embryonic development, we will use the ßV59M mouse strain. This is a recently developed model that is the least invasive diabetes model available. In this model, mice are phenotypically normal until 2 days after tamoxifen injection, whereafter they become hyperglycaemic. This minimises the time that these mice experience the adverse effects of hyperglycaemia. If required, this hyperglycaemia can be reversed by administration of sulphonylurea drugs such as glibenclamide. This is in sharp contrast with other commonly-used diabetes models such as streptozotocin-induced pancreatic ablation. This latter technique is much more invasive because mice must be made diabetic, then kept euglycaemic with implanted insulin pellets prior to mating, followed by removal of the pellets once pregnant.

For studying the effects of maternal hyperthermia on embryonic development, previous studies by other research groups have immersed pregnant mice in water warmed to 43 degrees. This is the quickest way of increasing core temperature, but mice do not like getting wet, so this causes extra distress over that caused by the increased temperature. We will use exposure to increased air temperature to increase core temperature. Although this takes longer than immersion in hot water, it is a less stressful method that also allows careful monitoring of the animal’s reactions to elevated temperature. In addition, it can take place in its home cage, with free access to water and food to maintain hydration, and so that the animal does not experience the extra distress of being removed from its normal physical environment.

Primarily, our experiments are investigating the effects of genetic and environmental factors on embryonic development. As such, in a majority of experiments, embryos will be killed by a Schedule 1 method, or other suitable means, prior to phenotyping. This will minimise potential suffering of these embryos. Mothers will also be culled by a Schedule 1 method prior to embryo collection, and will not be re-used for subsequent experiments.

Why can’t you use animals that are less sentient?

We have chosen to study a mammalian species, the mouse, so that the principles emerging from our research have the greatest chance of applying to the human situation. Mice have been used throughout scientific history and are today considered one of the best models of mammalian embryonic development. Thus, it is the most refined choice for

our studies. Less sentient animal models commonly used in developmental biology are the zebrafish (Danio rerio), the fruitfly (Drosophila melanogaster) and the nematode worm (Caenorhabditis elegans). Although all of these have a similar range of genetic tools available to mouse, their embryos all develop independently of their mother and none has a four- chambered heart. The chicken (Gallus domesticus) does have a four-chambered heart, but lacks the genetic tools available to mouse, and its embryos also develop independently of the mother. Thus, none of these less sentient animals accurately reflect human embryonic or placental development, and using these less sentient animals would reduce the clinical applicability of our results.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will not be kept beyond 15 months of age to avoid unnecessary adverse effects associated with ageing.

For subcutaneous injections we have introduced the use of a sterile ScruffGuard (https://researchdevices.com/product/scruffguard-reusable). This provides an enclosed, dark environment for the mouse which reduces its stress levels, rather than scruffing using conventional methods. In addition, more back skin is available, meaning greater accuracy for subcutaneous injections.

The cage environment is enhanced by the addition of objects that allow the animals to exhibit their natural behaviours and improve general welfare.

For subcutaneous implantation of slow-release pellets we have refined the procedure by:

cutting the superficial incision to create a subcutaneous pocket rostral-caudally as opposed to medio-laterally. This minimises the number of sutures required, makes it harder for the mouse to open their sutures as the incision site is right at the midline. In addition, there is a reduced chance of the skin stretching as the mouse moves around, meaning a reduced chance of suture opening.

The mouse is given additional cage items to aid its recovery. We provide mashed food to ensure that diabetic mice experiencing polydipsia are well-hydrated during recover and to provide a distraction to the mouse and therefore helps ensure they do not scratch their incision site. In addition, we provide additional environment enrichment, such as a gnaw stick to act as a distraction from their incision site, and a nestlet to provide extra comfort.

Where funds allow, cryopreservation of new lines will occur early in the breeding programme.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow advances publicised in the NC3R newsletter. This provides information on the most refined techniques, including new guidelines on non-aversive methods of picking up mice, single-use of needles and blood sampling. We will also adhere to updated ARRIVE guidelines on reporting work with animals as now required by many journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend all of our local Gold Standard meetings, and will transmit relevant information to all PILs working on this PPL.

We subscribe to the NC3Rs newsletter, and discuss relevant points in our lab meetings.

All PILs working on this PPL will be encouraged to attend the local annual 3Rs symposium.

91. Mechanism and Application of FLASH Radiation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cancer, Therapy, Radiation, Mice

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The long-term goal of our research is to better understand the biology behind a new radiotherapy technique known as FLASH, in order to take full advantage of this promising technique for treating cancer, with higher treatment efficiency and reduced side effects. FLASH involves delivering an intense radiation treatment in a fraction of a second, which has so far only been used for one clinical treatment globally. The overall aim of this project is to 1) identifying mechanisms and optimal radiation delivery parameters responsible for an increase in the therapeutic index with FLASH and 2) expand the therapeutic application of FLASH radiation in combination with other therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
One in two people in the UK born after 1960 will be diagnosed with some form of cancer

during their lifetime (www.cancerresearchuk.org). 30-50% of these are expected to receive radiotherapy as part of their treatment. The current level of long term (> 10 years) cancer survivors is 50% but this number is expected to increase if cancer diagnosis and treatment can continue to improve. The success of a radiotherapy treatment depends on the ability to deliver a high enough radiation dose to the tumour to eradicate it, while keeping the dose to adjacent normal healthy tissue low enough so that severe adverse effects do not occur as a result of the treatment. The quality of life following treatment is as important as the prolongation of life due to treatment. Hence, there is a need to improve the level of success of radiotherapy treatment. The most promising new radiotherapy technique is FLASH radiotherapy. In this project, we aim to better understand the biological mechanism that underpins the observed and highly beneficial FLASH sparing effect in normal tissues, to find optimal FLASH delivery parameters which maximizes the effect. Such information will be essential in our efforts to construct the next generation pre-clinical FLASH photon treatment device and to design a clinical FLASH photon treatment device, which would enable FLASH treatment of deep-seated tumours. If successful in meeting our aims, the knowledge learned will have brought us closer to a clinical implementation of FLASH radiotherapy, potentially benefiting all future patients receiving radiotherapy as part of their cancer treatment.

What outputs do you think you will see at the end of this project?

We will identify some of the potential mechanisms contributing to the FLASH effect and have a greater understanding of how it is different from conventional radiotherapy. We will also establish FLASH delivery parameters to enable the future design of clinical FLASH irradiators. We will also establish whether additional therapies have exerted an enhanced anti-cancer effect, without further damaging the surrounding normal tissue, when combined with FLASH radiotherapy. We will be able to readily translate these findings into the clinical studies currently underway (for vet practice) and in future clinical studies of human patients (treating superficial tumours with high energy electrons and treating deep-seated tumours with proton beams, e.g. brain and lung tumours).

The results of the proposed in vivo pre-clinical studies will be made available to the scientific community through presentations at National and International Conferences, and publications in peer- reviewed journals. Where applicable, the results will also be made available through publicly accessible databases, and the outcomes of this project will be highlighted through the relevant funding bodies and the 3R subcommittee as a refinement for in vivo radiation research.

Who or what will benefit from these outputs, and how?

Researchers in the international cancer and radiotherapy communities will benefit from our work, as we will present our findings through publications in peer-reviewed journals and presentations at national and international scientific conferences and meetings. Our findings will be essential when designing clinical trials with FLASH radiotherapy, with potential benefits for all future cancer patients receiving radiotherapy as part of their treatment.

In addition to the immediate professional circle carrying out similar research, we anticipate that our project will provide a cornerstone for this technical innovation in clinical radiotherapy and benefit the following groups:

The clinical research community will benefit from our results and findings, which will be

used to assess FLASH radiotherapy in clinical trials in the next 3-5 years. This will enhance the UK radiotherapy clinical trials portfolio and establish international, multi-centre clinical research collaborations.

Companies interested in commercialising relevant technologies , will also benefit from this project. The research will provide a scientific ground for new relevant technology development from the private sectors. The involvement of these commercial groups will facilitate the dissemination of FLASH technology to the wider patient population in the next 5-7 years.

Cancer patients, will benefit from the project in the longer term if the technology is successful in clinical trials and becomes a standard of care within national/international cancer management guidelines in the next 5-10 years. The quality of life of the cancer patients can be improved by the FLASH technology as less normal tissue toxicity/side effects are expected from FLASH radiotherapy.

NHS radiotherapy health care providers and the NHS will benefit from this technology in the longer term 10-15 years, as the radiation delivery will be much quicker requiring fewer medical resources. Fewer medical resources will also be required to manage the lesser side effects of FLASH radiotherapy and more emphasis can be placed on improving tumour control. The overall improvement in healthcare economics will allow the re-distribution of the medical resources to more pressing healthcare issues, benefiting everyone.

The general public will benefit from our public engagement events during this project (0-5 years). All the PIs are already heavily involved in public engagement activities organised by the Department/University. These activities will allow the general public to gain a better understanding of this state-of-art radiotherapy modality in cancer management.

How will you look to maximise the outputs of this work?

We are collaborating with other research institutes, looking at different types of FLASH irradiation (e.g. photon and proton), as well as the industrial partners with the aim of maximising the likelihood that some of the FLASH methodologies are applied in a clinical setting.

The results of this work will initially be presented to the scientific community through national/international meetings (such as annual meeting from Radiation Research Society, American Association for Cancer Research, and International Congress for Radiation Research) and appropriate funds have been requested to enable this. The meetings will be carefully selected and will include both smaller specialised conferences, as well as larger international meetings in order to reach both basic research and clinical research audiences. The data will subsequently be published in high-impact journals with relevant open access provision (such as International Journal of Radiation Oncology • Biology • Physics and Clinical Cancer Research). We will also distribute our advances in orthotopic model establishment and 3Rs to the wider research community within the UK.

We will highlight our findings on the departmental websites and where appropriate, our research will be communicated in the form of a press release linked to publication of a journal article. We will utilise social media such as twitter to publicise our findings widely and encourage post-peer review comment on our work.

Species and numbers of animals expected to be used

- Mice: We expect to use up to 2,600 mice over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice will be used in this project as their genetic background comprise of well-defined models and plenty of literatures are readily available with known reagents and treatment regimens to use.

With this project, we aim to gain understanding on the tumour response to different therapeutic strategies, specifically FLASH radiotherapy alone or FLASH radiotherapy in combination with chemotherapy (established substances), immunotherapy and/or novel compounds that will be tested under this licence. The overall goal of the licence is to identify the mechanisms responsible for the FLASH sparing effect seen for normal tissue and to find the FLASH parameters and combination treatments that will further improve the therapeutic index of radiotherapy.

It is therefore, necessary to perform this work in a living organism, given the interplay of the different components that might be responsible for the tumour response, whether within the tumour or belonging to the tumour microenvironment.

Furthermore, we are also interested in examining the response of the normal (non-tumoural) tissue to the given therapies, as this would be necessary to validate the suitability of the therapeutic strategy.

The mouse represents a feasible model to test our hypotheses, since multiple reagents, such as antibodies, are readily available, and since the current knowledge on cancer models and responses to therapies is broadly available.

Typically, what will be done to an animal used in your project?

In brief, we will induce tumours in our experimental animals and apply radiotherapy at different dose rates (FLASH and conventional) with or without a combinatory treatment, e.g. chemotherapy or immunotherapy, to analyse the tumour response to the treatment. We will also analyse the impact of these therapies in healthy tissue, to understand the effect of the treatment regimens on normal tissues.

Known agents will be administered based on literature. If novel agents are to be used in combination with radiation, we will ensure the agents have been tested safe with known treatment regimens from other PPLs.

For subcutaneous models, tumour cells will be subcutaneously implanted in the experimental animal, usually on the flank or the back, under brief recovery anaesthesia. For orthotopic models, tumour cells will be implanted locally to the intended area typically through percutaneously injection or under ultrasound guidance. Tumours will be grown for the minimum time and volume that is needed to deliver the scientific outcome. Tumours

will be measured regularly with callipers or more advanced imaging modalities.

Once the tumour reaches a certain size, radiation will then be applied to the tumours, locally, with or without a combinatory therapy, to assess the tumour response. Different substances may be given to the experimental animals before or during radiation. The preferred route would be intravenous injection to mimic the clinical condition but other route such as inhalation may be used depending on the substance.

One focus of attention in this licence is the role of the immune system in the tumour response to FLASH radiotherapy. Some experiments designed to investigate this include implantation of two subcutaneous tumours in the experimental animals. In some occasions, only one tumour will be treated, with the second tumour being used to test the systemic effect of the treatment given, in particular effects on T cell responses. This is named the abscopal effect. In other set of experiments to test the role of the immune system in the tumour response, we will aim to test that a successful therapy, manifested by tumour regression, is durable or specific to a cell line, for example. For this, we will implant a second tumour (once the first tumour has fully regressed) and observe if the tumour growth is impaired. These are the experiments of tumour re-challenge.

Experiments focused on tumour response to the different treatments, are expected to last a couple of months, generally. In some cases, experiments of tumour re-challenge upon tumour regression will be performed, and these will typically be completed within six months. Experiments of normal tissue response are completed within 3-5 days (abdomen) or within 4 months (non-whole abdominal treatment).

What are the expected impacts and/or adverse effects for the animals during your project?

The main adverse effects that the experimental animals would experience under this licence are due to:

Tumour bearing (ulcerations, intramuscular growth, difficulty to eat, pain, body weight loss).

Administration of substances, some of which might not have been previously tested in vivo in combination with FLASH radiation (toxicity, whether acute or chronic: diarrhoea, dehydration, pain, body weight loss, behavioural or neurological changes, choking or cyanosis due to technical error in gavage).

Radiation: whether applied locally to superficial tumours (skin irritation, ulceration) or to orthotopic implanted tumours or to the normal tissue (gastrointestinal and pulmonary toxicities): body weight loss, behavioural changes, pain.

Blood sampling from a superficial vein could cause bruising and damage to the tail.

Some interventions will be performed under anaesthesia, with the consequent risk of failure to recover. Best practice for anaesthesia in small rodents will be applied, and with this we expect all animals to make a rapid and unremarkable recovery from the anaesthetic.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

See Table below:

Protocol number	Title	Estimated number per protocol	Proportion of animals experience moderate severity	Proportion of animals experience mild severity
1	Normal tissue response	1000	<40%	>60%
2	Subcutaneous tumours	1000	<40%	>60%
3	Orthotopic tumours	600	<60%	>40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our overall aim of this project is to understand the mechanism of FLASH irradiation on normal tissue sparing and tumour control. Unfortunately, so far the normal tissue sparing effect has mainly been demonstrated on in vivo models as little information has been known about the contribution of local tissue microenvironment on the effect. Therefore, it is essential to use animal models in the project to elucidate the mechanism. The information from animals in this project will promote the development of non-animal alternatives for future FLASH radiotherapy.

Which non-animal alternatives did you consider for use in this project?

Once we had record enough local tissue information from our project, we aim to develop relevant 2D and 3D models with relevant microenvironmental cue (e.g. oxygen level, immune infiltration etc).

Why were they not suitable?

The normal tissue sparing effect from FLASH cannot yet be demonstrated in 2D or 3D models due to the lack of local tissue microenvironment. As we are still not sure which environmental factors actually contribute to the effect, we cannot rely on the use of 2D or 3D models in our research to further develop FLASH therapy for clinical use. However, in our aim to develop relevant 2D and 3D models, we foresee that these will be able to replace animal models in future work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimations are based on the literature on the variability of the outcomes of interest (e.g. tumour growth and outputs from functional assays). Different organ sites, tumour types, and combination of therapies will be used in our studies. These variables in our studies add to the number of animals used but is important for the completeness of our results exploring the potential of FLASH as a radiotherapy technique.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use The Experimental Design Assistant (EDA) and information from literature to aid in the design of our experiment. We have implemented additional steps to ensure randomization and blinding to avoid bias and increase reproducibility, using pilot or pre-existed data for power analysis and statistics-based guidance for future experiments.

For example, we determined the effect size from our previous experiments and the literature using the mean time to reach a specified tumour size as endpoint. This effect size was then used to calculate the sample size required in our proposed experiment to allow robust comparison between groups. This gave us the overall number of animals included in this project licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will design our experiments and narrow down the study variables (e.g. radiation dose and fractionation) primarily based on the previous literatures on conventional irradiation. This will reduce our animal number in finding the dose regiment for tumour control. If transgenic mice are to be used, wild type or heterogeneous littermates with no intended phenotypes will be used as a control to minimise the breeding waste.

During the experiments, various non-invasive imaging and functional assays will be conducted on the same animal to maximise the outputs and at the end of the procedure, various tissues and blood will be collected for further investigation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used as they are the best characterised species for the types of experiments we propose in this project licence. Immunodeficient mouse strains will typically be used, with naturally occurring or genetically engineered mutations. In addition, immunocompetent mouse strains with pre-existing mice cancer cell line will be used in this project.

For subcutaneous models, tumour cells will be subcutaneously implanted in the experimental animal, usually on the flank or the back, under brief recovery anaesthesia. For orthotopic models, we will implant tumour cells percutaneously to the intended area by less invasive methods without suture or bone incision. Ultrasound guidance will be used to precisely position the needle for the organ not externally visible. Tumours will be grown for the minimum time and volume that is needed to deliver the scientific outcome. Tumours will be measured regularly with callipers or by more advanced imaging modalities. In some cases, where there is more than one tumour inoculated, the total tumour volume limit for a single tumour will be applied for the combination of both tumours to minimise suffering due to tumour burden on both sides. These will be carried out under anaesthesia with appropriate contrast agent when necessary.

Known agents will be administered based on literature. If novel agents are to be used in combination with radiation, we will ensure the agents have been tested safe with known treatment regimens from other PPLs. Based on our 3 years of experience with dietary modulation, during which no adverse effect on the animals have been observed, we do not expect this to have a negative impact on the animals.

Why can’t you use animals that are less sentient?

We will use adult mice as most radiation studies have been conducted on this model, which will help us with methodology and interpretation of our results. Mice are considered as the lowest order species in which we can study tumour growth and normal tissue repair in a way that is still relevant to human cancer treatment. Zebra fish is an example of a less sentient species that could potentially be used instaed of mice in some of our future studies, once we have acquire more expertise in the area. We will use terminal anaesthetised mice in some experiments to minimize animal suffering but due to the time needed for cell regeneration and tumour response, we cannot use it exclusively.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For each step in the protocols we have introduced monitoring and controlling measures to minimise the harms for each animal used in this licence. Some of the most significant ones

are specified below:

Orthotopic tumour implantation: Only methods without suture or incision will be used to generate the models.

Tumour growth and physiology: Tumour induction will be done under brief recovery anaesthesia, which will help with precise positioning of the tumour to avoid the tumour invading the underlying muscle.
Tumours will be grown for the minimum volume scientifically needed. If tumour develop wet ulcer, mice will be killed. Some tumours may develop into an ulcer, which will be monitored for signs of healing for 48h and killed if there is no improvement.

Administration of substances: Known agents will be administered based on literature. If novel agents are to be used in combination with radiation, we will ensure the agents have been tested safe with known treatment regimens from other PPLs. Only substances, administration routes and formulation that are shown not to cause adverse effects will be used for tumour response experiments. Mice will be regularly monitored and killed at humane endpoints to ensure keep the suffering to minimum.

During application of ultrasound for drug delivery, mild heating of tissue (1-4 degrees Celsius) may occur. To ensure minimal heating to the tissues, the acoustic characterisation of ultrasound will be carefully studied in vitro for the heating capacity and other PIs with relevant in vivo experiences will be consulted.

Radiation: Radiation will be applied, under anaesthesia, locally or regionally, with shielding of the rest of the body. This will minimise the parts of the mice exposed to radiation and, therefore, will avoid unnecessary harm to normal tissues.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will be based on the “Guidelines for the welfare and use of animals in cancer research” (British Journal of Cancer, 102, 1555-1577, 2010). Additional literature includes “Preclinical formulations for discovery and toxicology: physicochemical challenges” (Expert Opin. Drug Metab.
Toxicol. 2, 715-731, 2006) for administration of substances; “The Design of Animal Experiments: Reducing the use of animals in research through better experimental design” (2nd edition, 2016) for experimental design; “Handbook of Laboratory Animal Management and Welfare” (2003), the termly newsletters from the university’s 3R subcommittee and other guidance from NC3Rs. Imaging of cardiac physiology will be conducted based on “Guidelines for measuring cardiac physiology in mice [34].”

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a general measure, we will continuously revise our methodology and adapt it according to new policies, technologies and approaches aimed at minimising welfare costs. To achieve this, we will attend the seminars provided by NC3Rs, keep up to date with NC3Rs recommendations via its website and seek for advice to improve the 3Rs in our experiments, and together with the university’s 3Rs subcommittee of the Committee on Animal Welfare Ethical Review Body (AWERB), to help diffuse our particular advances on the 3Rs.

92. Developing gene therapies to treat neurodegenerative diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neurodegeneration, Motor Neuron Disease, Dementia, Gene Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will assess the viability of potential new therapies that may alter the activity of selected genes to stop or slow the progression of neurodegenerative diseases such as motor neurone disease, frontotemporal dementia, Parkinson’s Disease, Huntington’s Disease and Alzheimer's disease. It will help us test the feasibility, efficacy and safety of these therapies and how they may be translated to develop gene therapies in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are currently no effective treatments that significantly alter disease progression for the neurodegenerative disorders listed above. As our population ages the impact of caring

for people affect will increase dramatically and this presents one of the greatest social and financial challenges to our society.

One major barrier to the successful development of new treatments is our ability to target the brain, which is challenging to access. This project focuses on gene therapy, which offers us a new and powerful tool to directly target genes that may be involved in the disease process. Doing this, a single acute intervention will have long-term effects on the disease.

What outputs do you think you will see at the end of this project?

We hope that one major output from this project will be new gene therapies for neurodegenerative diseases that can be progressed to clinical trials. In addition, we anticipate generating new knowledge regarding the contribution of various genes/proteins to the neurodegenerative disease process, and their potential to provide future targets for gene therapy.

Who or what will benefit from these outputs, and how?

In the short to mid-term, over the course of the project, the development of gene therapies that can be moved into clinical trials will deliver new hope to patients and families dealing with the relevant neurodegenerative disorder, as well as medical staff involved in the treatment of these patients. Longer term, beyond the end of this project, a successful outcome in clinical trials, which will be well predicted by these robustly run preclinical assessments, will deliver huge social and economic benefits both country and world-wide.

Additional short-term benefits throughout the course of this project will be seen by other researchers in the field of neurodegenerative diseases, as we will provide information to improve our understanding of what goes wrong in these diseases and identify new targets and approaches to try to slow or stop disease progression. Longer term, again over the course of this project and beyond, data obtained in this project may help us to identify additional targets for new therapies that can be developed to treat various neurodegenerative diseases.

How will you look to maximise the outputs of this work?

The development and validation of gene therapy vectors in this project is to be done in collaboration with a gene therapy start up company co-founded by this PPL applicant, who’s primary goal is to deliver viable and targeted gene therapies to the clinic. A structured process is in place to facilitate this, and to maximise the potential benefits of any viable new therapies developed.

While successful new viral approaches will be patented, all basic discovery data obtained in this work will be widely shared throughout the academic community, with the goal of publishing all findings, positive or negative, in relevant scientific journals. As new findings are obtained, collaborations with both local colleagues and those further afield will be sought out to further develop our research. In addition, efforts will be made to engage with the local lay community to share any findings of interest, and in cases of specific interest to patient groups, we will liaise with the appropriate support group to try to disseminate the relevant information widely and accurately.

Species and numbers of animals expected to be used

- Mice: 10,000
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project is designed to evaluate potential new treatments for neurodegenerative diseases such as motor neurone disease and dementia. These diseases affect the brain and spinal cord as we age, so in order to test out whether new therapies might be effective in human patients, we need to be able to show that they have an impact on the progression of the disease. In order to fully assess the benefit of our therapies, we will need to study them out into old age, hence some mice will be aged. The mouse has been selected as they possess a brain region called the cerebral cortex, which is only found in mammals, and this region is preferentially affected in many neurodegenerative diseases. Most animals in this project will have genetic alterations that are known to cause neurodegenerative diseases in humans, these animals will develop aspects of the disease as they age, and are needed so that we can see if our treatments are effective at reducing or preventing the development of these disease features.

Typically, what will be done to an animal used in your project?

The work planned in this project falls into three main categories:

Normal mice will receive a brain injection of viral particles that have been engineered to deliver a possible disease treatment. This will allow us to develop the most effective delivery system possible. Following this injection, most mice will be kept for 4-8 weeks, with approximately 10% being kept out to a maximum of 2 years old, then they will be culled for tissue collection.

Normal mice will either be genetically modified, or they will receive a brain injection of a virus that contains a gene that is know to cause a neurodegenerative disease. They will then be aged out to a maximum of 2 years old, and during their life 30-40% of these mice will undergo behavioural tests to look at how well their brain works. These tests will include tests of memory, and tests for mobility. In most cases, memory tests will be done every 2-3 months, while mobility tests will be conducted monthly. A small number of animals (10%) may also receive brain scans to look at their brain function. At the end of the testing period, mice will be culled and tissue collected.

Mice that model a neurodegenerative disease will receive a potential therapy or a placebo either via brain injection (80% of animals) or via a drug given orally or as a peripheral injection. They will then be aged out to a maximum of 2 years old, and during their life 30-40% of these mice will undergo behavioural tests to look at whether the treatment is working. These tests will include tests of memory, and tests for mobility, and as above, in most cases, memory tests will be conducted every 2-3 months, and tests of mobility will be conducted every month. A small number of animals (10%) may also receive brain scans to see if the therapy has improved their brain function. At the end of the testing period, mice will be culled and tissue collected.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that undergo brain injections may experience some discomfort in the first 2-3 days following the injection, but this is not expected to have any long-term consequences.

Animals that model a neurodegenerative disease are expected to develop either mobility or memory problems as they age.

Memory problems are not expected to have major impact on mouse welfare, although a small number of animals may display reduced self-care as the disease progresses. If this results in significant discomfort or distress to the animal that cannot be rectified by providing food and water that is easy to access, the mouse will be culled.

Mice that develop mobility problems are expected to experience mild to moderate difficulties in moving around their home cage. These difficulties are not associated with any pain. Mild impairments are not expected to cause any significant distress or suffering to the animal, and these mice may be kept for several months. If the motor impairment worsens, animals will be given moistened food at floor level, to ensure they can successfully feed. If they show any evidence of a decline in general health, they will be culled.

Animals on this project that are maintained out to old age may develop various age-related issues that are common to mice, such as benign tumours or hair loss, and in some cases sore patches on the skin. If these effects are only mild, and cause minimal distress, the animal may be maintained for several months, however, if any of these issues are thought to cause significant pain, discomfort or distress, the animal will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 75-80% of mice on this project are anticipated to undergo brain injections, which will cause short-term moderate discomfort, without any long-term welfare issues. Disease model mice will form a major component of this project, and are expected to make up 60-70% of total animals used.
Approximately half of these are only expected to develop mild memory problems, while the other half are expected to develop mobility issues that will cause mild to moderate discomfort as the animals age. Since most of these animals will undergo a brain injection to try to treat their disease, most mice on this project (75-80%) are expected to fall into the moderate severity category. All other animals are not anticipated to exceed a mild severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you

have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to test new therapies that may be effective in treating neurodegenerative diseases, and in order to fully establish whether these treatments will be effective in humans, we need to see whether they can slow or stop the progression of the clinical features of the disease, which can only be done by using live animal models.

Which non-animal alternatives did you consider for use in this project?

Various cells, including stem cells (grown in a dish).

Brain slice cultures (thin slices of brain that are grown in a dish).

Why were they not suitable?

A major aim of this project is to see whether our potential new treatments improve the memory and movement problems patients suffer with in neurodegenerative disorders like motor neurone disease and dementia, which can only be assessed in living animals. We also want to see how the treatments may alter the progression of the disease in the brain as it ages, and at present, none of our non-animal models can fully mimic the impact of interactions between the millions of cells within the brain, and also how communication with, and the function of other parts of the body can impact on the brain, and how these diseases progress.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers to be used on each protocol of this project have been estimated as follows:

For the assessment of new genetically modified mouse lines, or other disease models, numbers have been selected based on our experience with pre-existing mouse lines that are expected to behave similarly, along with an estimation of the number of new genes or gene variants we are likely to want to investigate over the course of the project.

For the validation and testing of new viral delivery systems, numbers have been estimated based on total numbers required for the validation of each system, together with an estimation of the number of different variants we expect to be testing over the course of the project.

For therapy assessment, numbers have been estimated based on total numbers required for the validation of a single therapy or therapeutic target, together with the total different number of disease models and therapies we are hoping to test over the course of the project.

In addition to this, we have accounted for the number of animals required to maintain our different lines of genetically modified mice throughout the course of this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the design phase of each experiment, appropriate searches were done to identify what mouse lines may be available for us to use, and to ensure we had access to all relevant information regarding expected outcomes in these animals. Wherever possible, lines to be used were chosen based on how easily we would be able to measure the impact of our therapies on the disease. Only if no suitable lines were identified, were plans made to generate additional models of disease.

Consideration was also given to how much variation there is between control animals for each of the factors being measured, based on our own experience as well as reports in the literature. Extra consideration was made for a number of variables we control, including sex, age and background strain. The statistical approaches to be used at the end of the study formed a major part of the experimental design process, ensuring that all experimental approaches are robust.

The experimental design was also discussed with other researchers familiar with these kinds of studies, to further validate the design, and to ensure that we had included adequate control groups to each experiment, such that all data obtained will be valid.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As far as possible, all experiments will be conducted longitudinally, where we will monitor the same animals throughout their life, to allow us to maximise the data obtained from each animal. For tissue harvest, all organs of interest will be harvested from each animal, and experiments will be designed to allow multiple follow ups in the tissue from each animal, thus minimising the total number of animals required.

Where relevant, and in most case of therapeutic testing, small scale pilot studies will be conducted prior to each full scale study, with follow up analyses to ensure that the treatment appears to be working as predicted, without any unexpected adverse effects, and also to allow subsequent experimental design to be optimised to use the minimal number of required animals. This will ensure that unnecessary large scale experiments do not take place.

As far as possible, breeding strategies will be designed so that all animals from a mating are used for an experiment, and for general maintenance of a line, animal breeding will be monitored and controlled to ensure that we obtain sufficient mice to maintain the line, while minimizing the birth of mice that are not required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime

of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Almost all the work planned in this project will use mice. These include healthy control mice, and mice that contain genes that give them aspects of various neurodegenerative diseases such as motor neurone disease and dementia. Since these are all diseases of ageing, all animals are healthy when they are young, and develop memory or movement problems as they age. None of these models result in any pain for the animals, but some animals will develop mobility problems. These problems are progressive, and so animals can be monitored for any decline, and additional care measures can be implemented to minimise distress if required. Experiments will be designed to ensure that these animals do not experience any significant long term discomfort as a result of these movement problems, and in most cases, disease models that only develop mild mobility issues will be used.

Injection into the brain under anaesthesia is a procedure that is required for many of our therapy treatments to ensure the treatments reach our target sites. This procedure is minimally invasive, and animals are usually completely recovered from this within a week.

A small number of healthy control mouse and rat pups will be killed to provide brains for cells and brain slice experiments in place of live animals wherever this is possible. The use of this model will ensure that animals do not experience any distress or suffering as a result of the experimental aims.

Why can’t you use animals that are less sentient?

This project is designed to assess how well new therapies will work to treat neurodegenerative diseases like motor neurone disease and dementia. These are diseases of ageing, which result in impairments in memory or mobility. We therefore need to be able to assess whether our proposed treatments can improve these clinical symptoms. In order to do this we need to be able to work with models which allow us to measure these behaviours as the animals age, to see if disease mice receiving the treatment do better than those that do not.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals undergoing brain injections will be given a long acting pain killer and local anaesthesia to minimise surgery associated pain. They will be monitored for at least one week following the surgery to check for any evidence of pain, and if required, will be given additional pain killers.

Disease model animals that develop movement problems that may impair their ability to access food and water will be given moistened food at floor level, and will weighed at least weekly (daily as required) to ensure they are remaining healthy.

Any animals undergoing frequent handling as a part of the experiment will be handled regularly prior to the start of the experiment, to ensure that this process does not induce unnecessary anxiety or stress to the mouse. In addition, all mice will receive appropriate training for all behavioural tasks prior to the onset of experiments, both to minimise anxiety

and stress, and also to improve outcomes, which should ensure consistent data from all mice, and hence allow the use of the smallest number of tests and animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work will be conducted following the general principals of the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will regularly check the NC3Rs website for updates, as well as liaising with both our NTCOs and our local NC3Rs regional programme manager. Any relevant changes will be implemented immediately for all new experiments, and consideration will also be given to implementing changes to ongoing experiments, provided any such change is not expected to have an impact on the animals such that it may alter research outcomes.

Home Office

93. Transgenic Mouse model for poliomyelitis

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Transgenic mouse, Poliomyelitis, Polio vaccines, Safety, Efficacy

Animal types	Life stages
Mice	embryo, neonate, adult, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine the safety and efficacy of poliomyelitis vaccines as well as antiviral treatments against poliovirus infection

To evaluate the effect of different genomic mutations on the attenuation phenotype of poliovirus strains and variants

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The Transgenic mouse neurovirulence test is an important vaccine safety test for Oral Polio Vaccine (OPV). The test in transgenic mice carrying the human receptor for

poliovirus has largely replaced the test in non-human primates that were previously the only adequate models for testing vaccine safety. This transgenic mouse assay has been established by the World Health Organization (WHO) through collaborative studies and is detailed in WHO and European Pharmacopoeia regulatory documents, which specify the procedure, numbers of animals and the particular line of mice to be used. They have been designed to minimise animal usage and suffering while producing statistically reliable results.

The production of OPV has decreased but is still an important tool for outbreak control, so OPV production will still continue for several years until polio is eradicated globally. It is possible to produce batches of vaccine that fail the test, and in rare instances the vaccine can cause poliomyelitis itself.
Thus testing of every batch is necessary and currently there is no alternative to the use of animals although the developmental aspects of the work to be undertaken aim to explore alternatives based on molecular biology which will be validated against the mouse test.

The test will also be used to qualify new attenuated strains to be used for vaccine production as part of the global polio eradication final stages.

Finally, there is rising interest in the use of inactivated polio vaccine (IPV) and other non-infectious vaccines including the use of new strains and antiviral compounds whose effectiveness needs to be evaluated. The mouse model provides a way of assessing protective efficacy and will be increasingly important for this purpose.

What outputs do you think you will see at the end of this project?

We will generate scientific information that will allow us to further improve quality assure methods which supply vaccines of high quality and safety and hopefully lead to a significant reduction of the use of non-human primates for testing vaccines globally. We will further investigate the effect of different poliovirus mutations on its attenuation phenotype to validate molecular methods against tests in mice to further reduce the need of animals for vaccine testing. Importantly, we will use results from tests in mice to support the clinical evaluation of new poliovirus vaccines which will be essential to complete global polio eradication. We aim at publishing our findings in peer-reviewed scientific journals.

Who or what will benefit from these outputs, and how?

Continuing to be able to perform the test in the medium to long term (3-10 years) is essential to maintain the ability to effectively control the release of OPVs and facilitate vaccine development globally.
Vaccines being assessed by these quality assured methods are essential to the continued success of the polio eradication programme which depends on the supply of vaccines of high quality and safety. New strains being developed and tested in clinical trials also provide more benefits to the polio eradication programme.

The reduction in the use of non-human primates supports 3Rs initiatives. Results obtained with this test can be compared to those from other possible assays, particularly laboratory tests not requiring the use of animals, giving greater confidence in their reliability, applicability and validity for the batch release of vaccines. Therefore, the benefits of this work will have ramifications at the national, European and global level.

How will you look to maximise the outputs of this work?

Continued collaboration is essential as part of this work, international workshops with all institutions involved in the testing, including WHO, are held annually which means discussions on improvements and refinements to the testing can take place. There are also grant-funded projects which provide opportunities for collaboration and discussion with all parties involved in the development of novel strains of OPV. Projects looking at replacement of animal test with next generation sequencing are also in process which will provide valuable data for 3Rs initiatives.

Species and numbers of animals expected to be used

- Mice: Up to 30,000 mice are expected to be used in 5 years (25,000 bred at our Establishment).

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The test in transgenic mice carrying the human receptor for poliovirus has largely replaced the test in non-human primates that was previously the only adequate model for testing vaccine safety. This transgenic mouse assay has been established by WHO through collaborative studies and is detailed in WHO and European Pharmacopoeia regulatory documents, which specify the procedure, numbers and life stages of animals and the particular line of mice to be used. They have been designed to minimise animal usage and suffering while producing statistically reliable results.

Typically, what will be done to an animal used in your project?

Genetically modified mice are bred under one protocol in this licence under strict conditions laid out in the project.

Suitable animals will be selected and randomised to meet the scientific requirements. This will be done at an early age and maintaining original weaning groups where possible to minimise aggression between males. Husbandry measures will be adopted to minimise any aggression. The animals will be monitored closely for signs of aggression and animals separated if needed.

Animals will be inoculated with different biological preparations using different inoculation routes. In case of intraspinal inoculation, a surgical procedure is performed to expose the tissues around the specific area of the mouse’s spine to ensure accurate inoculation. This is done under anaesthesia and analgesia is routinely provided to all animals before the procedure. The surgical wound is closed after inoculation.

Animals might be immunised with polio vaccine or treated with an anti-viral compound before poliovirus infection. Blood may be sampled at different steps to measure anti-poliovirus antibodies. Animals may be kept for up to 12 months to investigate the persistence of antibody response and/or possible non- acute effects of the procedure and then challenged with paralysing doses of poliovirus using different routes. Infected animals will be monitored for clinical signs of polio, typically for up to 21 days after inoculation.

What are the expected impacts and/or adverse effects for the animals during your project?

Experience has shown that the genetically modified lines to be produced under this licence have no adverse effects on the mice and that the genetically modified traits have no adverse effects.

A small number of animals (less than 1%) may display trauma arising from the inoculation procedure. Affected animals will show varying degrees of limb paralysis but will otherwise appear and behave normally. There is a small risk of infection developing at the closed incision site and/or animals showing injection trauma after inoculation. Regular monitoring ensures affected animals are treated quickly and/or euthanized should their condition not improve.

After infection with poliovirus, typical clinical signs of polio start with weakness of the hind limbs, which may develop into partial or full paralysis of one or both hind limbs. There is no evidence of pain associated with the progression of polio symptoms which are rather characterised by loss of neural sensation. The degree and duration of any clinical signs arising from the virus inoculation to allow the animals to be conclusively assigned to a treatment group are not expected to exceed the moderate category due to the controls and humane endpoints in place. The endpoint will be full paralysis of one hind limb, however for some studies this will be refined to two consecutive days of partial paralysis of one hind limb. Animals reaching the required endpoint will be killed immediately. However, a small number of animals, approximately 1%, may experience a rapid onset and/or progression of paralysis that cannot be predicted, which may, in extreme cases, result in quadriplegia. Any animal showing clinical signs affecting one or both front limbs will be killed immediately regardless of whether the hind limbs are affected. There may also be cases of complications relating to the virus infection including urine retention. Animals with any clinical signs of polio will be monitored more frequently, which may include additional timepoints during the working day and outside of normal hours, to ensure the endpoints can be applied effectively.

Animals that are unable to readily feed or drink as a result of their condition will be killed immediately. Veterinary advice will be sought in all other cases of variation from normality.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected level of severity of transgenic mouse test ranges from mild to moderate depending on the protocol. Based on 2020's figures, the proportion of mice reaching sub-threshold, mild and moderate severity was 30%, 12% and 58%, respectively.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The transgenic mouse neurovirulence test is well defined in regulatory documents. It is intended to replace the test in non-human primates and has been validated for this purpose which has helped significantly reducing the need for non-human primates for OPV testing.

Which non-animal alternatives did you consider for use in this project?

Molecular tests have been developed to measure the proportion of a mutation associated with a virulent phenotype at certain positions in the viral genome. The test is included in regulatory requirements but has still not been shown to provide the same level of information as animal tests. The advent of deep sequencing technology makes it theoretically possible to scan the entire genome and establish variability at certain positions with effect in virulence, or to demonstrate their value as markers of manufacturing consistency and differences between producers. This approach will be pursued in parallel with the in vivo based tests; if validated appropriately, in part against them, it could ultimately lead to the disappearance of the need for animals for testing vaccine safety as “safe” whole-genome genetic profiles could be established.

Why were they not suitable?
Molecular tests described above could replace some aspects of the work, particularly testing vaccine safety. However, the inherent complexity of the vertebrate immune system precludes the use of non- animal models for the assessment of vaccine-induced immunity. Similarly, there are not non-animal alternatives to study how mutations affect virulence as this requires assessment of specific clinical signs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The design of the regulatory test was based on intensive statistical discussion and input to define the minimum number of animals required to give valid results. They are detailed in official regulatory documents. With respect to the developmental work, statistical input is sought as part of the process of experimental design to ensure that the minimum numbers of animals are used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There is full control over the training process for this technique, which means that operators can be selected based on genuine experience of proficiency in Regulated

Procedures, and can be monitored closely and constantly by experienced operators to determine genuine competence. This will help reducing the number of invalid tests and the unnecessary repetition of procedures. We will make efforts to reduce waste, promote animal alternatives (all the three Rs), and increase the reproducibility of research and testing by following PREPARE guidelines when designing experiments (https://norecopa.no/prepare). We will also follow ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments), recommendations to improve the reporting of research involving animals – maximising the quality and reliability of published research, and enabling others to better scrutinise, evaluate and reproduce it.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of animals used under the breeding protocol will be minimised through effective breeding colony management. Experiments will use an equal number of both sexes to minimise the numbers used under the breeding protocol.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The only animal alternative to the mouse is the non-human primate: work to develop the mouse model has allowed the replacement of primate testing. The particular strain of mouse most commonly used is required as all validation work was conducted using this strain. This programme will also demonstrate the utility of mouse strains other than the strain used in the regulatory test.

Why can’t you use animals that are less sentient?

Our experience and that from other organizations that have implemented this test, strongly indicates that it is not possible to use less sentient animals, this testing has been validated thoroughly and no alternatives have been deemed suitable.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During husbandry and the frequent clinical scoring, the animals will be handled using refined techniques e.g. use of tunnels or cupping in the palms to minimise stress.

Improvements in technique have reduced the likelihood of complications arising from wound closure. There is a remote possibility of bacterial infection, but this has not been observed previously. Good aseptic technique will be used during the procedure. Good post-operative care will be provided including analgesia. Supportive measures will be provided during the recovery phase including the provision of additional warmth. Animals

will be examined following recovery from anaesthesia and the site monitored for any deterioration on a daily basis. Veterinarians will advise on surgical techniques and best practice.

Following infection, the animals will be provided with longer bottle spouts and diet on the floor of the cage for ease of access. Post infection, animals are examined daily in the course of the studies and clear humane endpoints have been defined. For some studies it will be possible to refine the endpoint further depending upon the scientific information that is required. The period of monitoring clinical signs will be extended beyond normal working hours as required to make sure any harms to the animals are minimised, through effective application of the defined endpoint.

Additional supportive husbandry measures will be used to ensure the animals have easy access to food and water.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The general LASA guidance is followed: Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Training protocols were optimised under WHO supervision through experience in different laboratories and discussions in training workshops.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Staff attend conferences on these subjects and are continually researching new methods. Having access to a local Animal Welfare and Ethical Review Body (AWERB) also helps in conducting regular reviews of procedures and control of best practices. Annual meetings are organised for this forum where presentations are given on 3Rs initiatives and how these have been implemented.

94. B cells in tumour immunity

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

B cell, cancer, vaccine, autoimmunity

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Characterising the function of B lymphocytes in immunity to tumours. Developing a new tumour-specific vaccination approach that activates B lymphocytes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a main cause of death of the aged, but also of younger patients. New and cost-efficient therapies are clearly needed. Recent major advances in cancer immunotherapy have shown that the immune system is able to attack and destroy cancerous tumour growth. Still, harnessing the immune system to specifically attack structures on tumour tissues is a major challenge. Tumour tissue is made of the patient’s own tissue, i.e. it consists of immunological self-structures (or autoantigens). The problem with inducing immune responses to self-structures is that our immune system is very good at avoiding attacking immunological self in order to avoid autoimmunity. This phenomenon is called immunological tolerance to self.

A now established therapy against cancer is that monoclonal antibody drugs are injected

that target human self-antigens expressed by tumours. These antibodies are originally generated in animals. In animals these human antigens are foreign, so self-tolerance is not an issue and antibodies are produced after vaccination. Generating monoclonal antibody drugs, and the production, storage and administration of monoclonal antibody drugs are expensive and laborious, and antibody drugs last in the patients only for a limited time.

We plan to harness vaccination in order to let patients generate their own antibodies against self- structures on the tumour. Advantage of vaccination is that it is a well-established method against pathogens. Vaccines can be generated and administered cheaply and therefore have been used widely for therapy and prophylaxis in underdeveloped parts of the world. While vaccination against self- antigens should be difficult, as immunological tolerance prevents responses against self, we have developed a new vaccine conjugate that should be able to overcome self-tolerance and efficiently induce self-specific and tumour specific responses.

In the current project we plan to develop and test variations of this vaccine. At the same time, we plan to study interactions of B cells – the cells that produce antibodies to tumour structures – with tumour tissues, and the role of immunological self-tolerance in the interactions of B cells with tumour tissue.

What outputs do you think you will see at the end of this project?

The project will generate better understanding on how B cells interact with the environment in tumours (tumour cells and immune cells). Outputs will be presentations at scientific conferences, publications in scientific journals, and/or patents.

The second aim of this project is to optimise our vaccine design that is able to induce antibody responses to self-structures expressed on tumour tissues. We plan to generate variants of this vaccine and test their efficiency in pre-clinical animal models. Outputs during this project will be presentations at scientific conferences, publications in scientific journals, and/or patents. In the long term the project shall lead to the development of new vaccines that will allow preventative or therapeutic vaccination to cancer.

Who or what will benefit from these outputs, and how?

In the short term, this project will have broad local benefit, provide new information on how antibody responses are triggered to self-antigens after vaccination, and new methods how of inducing self-antigen-specific antibody responses. Mouse models of tumour development will provide information of B cells in primary tumours and tumours after vaccination, which will increase our fundamental understanding of B cell activation in different tissue environments, and in response to the tumour or to vaccination.

Further, it will let us test new versions of our cancer vaccine and its prophylactic and therapeutic efficiency against tumour growth in mouse tumour models.

In the medium to long term this project will impact on clinicians and patients: If translated into clinical use, this vaccine has potential benefits for the prevention or treatment of cancer by vaccination. Cancer vaccines have the potential to bring major benefits in treating antigen-expressing tumours, either alone, or as adjuvant or in combination therapies, to improve cancer treatment. This approach also has potential benefit for other disease types where self-antigens might be targeted.

Commercialisation would benefit UK biotech industry in the long term (>10 yr).

How will you look to maximise the outputs of this work?

This interdisciplinary project links groups working in immunology, cancer immunology, tumour biology, and clinical cancer medicine. We will present findings locally through shared meetings, and in our animal facility. This large base of scientists and clinicians interested in immunotherapy of cancer will provide opportunity for interdisciplinary discussion and project support from the local community, maximising the opportunities for new collaborations.

Results of the work will be published in high quality open access journals according to the ARRIVE guidelines and presented at both national and international scientific meetings, and the local institute websites regularly updated. We plan to publish unsuccessful approaches as well.

New approaches may be patented, which will maximise the potential to translate this into successful biotech products that become quickly available at large scale.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used in this project as preclinical models, studying the complex interplay of the local immune environment in tumours and lymphocytes, that are activated in lymphoid tissues distant from the tumour. At present, there are no models that replicate the complex interplay of different immune cells and stromal elements in tumours and lymphoid tissues in vitro.

The adult stage will be used as the antibody immune response is only fully developed in the adult. Further, immune tolerance to self-antigens will be studied, and this is only fully developed in the adult organism.

Mice are the most appropriate animal, because as mammals their immune system has a huge degree of homology with the human immune system, their immune system is best studied, and there is the largest number of experimental tools available to manipulate and analyse their immune response (e.g. gene manipulated animal strains, antibodies to detect specific proteins, and gene expression detection reagents).

Typically, what will be done to an animal used in your project?

Subcutaneous tumour models will be used in this project.

Tumour cells will be injected once subcutaneously on a single flank site. Tumour sizes will

be measured regularly.

Vaccines will be injected prior to or after the tumour implantation via subcutaneous injection.

Blood sampling may be taken during the tumour growth from peripheral blood vessels in accordance with LASA guidelines.

After not more than 6 weeks the animals will be killed by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

Implantation of tumour cells under the skin may cause adverse effects. The adverse effects are expected to be transient and mice are expected to return to normal behaviour within 2 hours of implantation.

Tumour implantation may be done under short general anaesthesia. Mice will be appropriately monitored during anaesthesia. Mice will return to normal behaviour after waking up from anaesthesia.

Growth of tumour cells under the skin in some mice may cause adverse effects such as distress or pain leading to weight loss. The animals will be closely monitored after the implantation. They will be humanely killed if any adverse effects are observed which exceed moderate severity (including weight loss (maximum of 20%), a body condition (BC) score of <2.5, reduced activity, continuous hunched posture et al). Subcutaneous tumours will be measured maximum length x maximum breadth in mm. These two measurements will be used to estimate the tumour volume. If this exceeds 1.25 cm^3 then the animal will be killed.

Treatment with vaccine (e.g. immunogens, adjuvants). These may have side effects. The type of immunogens and adjuvants proposed for use in the project generally have few side effects, however we will use previous experience and data in the scientific literature, plus pilot studies to inform our use.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity level in all animals is moderate. The majority of animals will have a tumour implanted, and the majority of these will be vaccinated. A minority may encounter vaccination only in order to study the immune response to self-antigens.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Aims of this project are to test the role of B cells in tumour immunity, and developing a therapeutical vaccine targeting tumour blood vessel development, inhibition of tumour growth and spread. This is going to develop data to support clinical trial. At present, there are no models that can mimic the complex interactions of the immune system (lymphocytes and lymphoid organs where lymphocytes are primed) with tumours, or the development of an immune response to a vaccine in vitro. Therefore we are dependent on mouse models.

Which non-animal alternatives did you consider for use in this project?

In silico analysis of interactions of the immune system with tumours and of vaccine responses

In vitro B cell activation

Analysis of immune responses in human tumour tissue

Review of the scientific literature

Why were they not suitable?

We have been developing in silico methods to analyse immune responses, however, these are only able to test hypotheses that have been developed with data derived from in vivo experiments. They are able to inform about optimal design (e.g. optimal time points or doses) of future in vivo experiments and generate new hypotheses, but these new hypotheses have to be tested again by in vivo experiments.

Wherever possible, we do in vitro experiments to study individual steps of B cell activation and differentiation in vitro. In vitro models are useful for variation of simple processes immediate after B cell stimulation, however, do not replicate the immune system and the complexities of immune cells interacting with each other and their environment, i.e. in the tumour or in lymphoid tissues.

We are collaborating with local colleagues who do analyse fixed explant tissues from tumour patients. However, this is not sufficient to analyse the complex interactions during the initiation of an immune response, interactions between the tumour and local lymphoid tissues where the response is started, or model the complete anatomical, and cellular interactions.

We do continuously review the scientific literature and will adopt our research plans accordingly.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have experience from our own studies on vaccination of tumour implanted mice about the expected data variation and group sizes necessary that will provide sufficient statistical power.
Individual experiments comparing two parameters would need 30 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experiments are based on our earlier studies. Therefore, we have extensive experience on techniques of studying tumour growth and experimental data variation. Future experiments will be planned and performed with advice from our collaborators, who have long-term experience in studying tumour growth and vaccination. This will help establishing optimal tumour implantation techniques to reduce experimental variation.

We will reference online tools NC3R's Experimental Design Assistant for experiment design, statistical analysis to predict the numbers of animals used in the study.

For each experiment, we will produce a written protocol. In this the numbers of mice used and the procedure they will undergo will be details, according to the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will apply good colony management to ensure the desired numbers and desired genotypes are generated with minimal wastage. Computer modelling may be used to predict experimental conditions that will show the largest effect sizes. At the end of the experiment we will harvest the maximal possible number of tissues. Tissues not immediately analysed will be archived frozen and will be made available to other researchers working on similar questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used in all experiments.

Tumour models will be used to study B lymphocyte infiltration in tumours and interaction with other cells.

Mouse tumour cells (e.g. Lewis Lung Carcinoma Cell) will be subcutaneously injected into one single flank site of wild type mice or B cell reporter mice. Comparing to tumours that develop in the organ from which they are derived, subcutaneous implantation of tumours is one of the most refined tumour models because it minimally invasive method to administer cells, and subcutaneous tumours can be more closely monitored, allowing for better humane endpoints, and less likely to impact on animal welfare than those growing in organs and potentially impacting upon organ function. This will be the model of choice to determine how vascular targeting by vaccination and immune responses affect primary tumour growth.

Vaccination will be used to induce anti-tumour immune responses and test interactions of the immune response with the tumour. Mild adjuvants have been selected for immunisation that avoid significant pain or distress to the animals.

Why can’t you use animals that are less sentient?

Mice are the most appropriate species, because they have a huge degree of homology with the human immune system, and have been used extensively in previous studies meaning there is a wealth of information and established techniques available to us (e.g. gene manipulated strains, antibody and gene expression detection reagents). Adult mice have to be used because only the adult immune system efficiently reacts to the self-antigens we are planning to target with our vaccination strategy. The experiments run over several days and weeks and therefore cannot be done under anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures that may cause acuter pain, e.g. implantation of tumour cells by subcutaneous injection, will be done under short term anaesthesia.

Treatment with vaccine (e.g. immunogens, adjuvant) or modulators. These may have various side effects. Immunogens used in this project generally have little adverse effects, however we will use previous experience and data in the scientific literature to inform our use. Mice will be monitored appropriately after injection.

Implantation of tumour cells under the skin could cause adverse effects such as significant weight loss, distress or pain. Appropriate analgesia will be provided after injection and otherwise when necessary to reduce pain. The animals will be closely monitored after tumour implantation and humanely killed if any adverse effects are observed which exceed moderate severity. The subcutaneous tumour models is well established at our facility, and staff are expert at monitoring animals during the procedure and minimising adverse effect.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experimental design, execution and publication will be done in line with the PREPARE and ARRIVE guidelines and in accordance with published best practice for use of animals in cancer research (British Journal of Cancer (2010) 102, 1555 – 1577).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will reference online tools NC3R's Experiment Design Assistant for experiment design, statistical analysis to predict the numbers of animals used in the study.

For each experiment, we will produce a written protocol. In this the numbers of mice used and the procedure they will undergo will be details, all study report written according to the ARRIVE guidelines.

We will keep up to date following NC3Rs news and courses, attending NC3Rs and other 3R focussed events regularly offered at our institution. We have also signed up for the NC3Rs newsletter.

95. Studies of brain development in the mouse

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain, development, neural circuits, neuro-developmental disorders, visual system

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We would like to identify and understand molecules and mechanisms that ensure that neurons form the correct connections and neural circuits during development of the brain.

Our focus will be on neural circuits in the visual system and those controlling social behaviour.

Using similar techniques, we would like to identify those molecules and mechanisms which - if mutated or disrupted - are involved in the establishment of neural connectivity between the eye and the brain or/and in the aetiology of neurodevelopmental disorders such as autism spectrum disorders (ASD).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

For an understanding of the function of the brain, it is important to understand how different groups of neurons are connected to each other and how this is controlled during neural development. The precise connections between different groups of neurons are the basis of the function of the brain. However, there are thousands of different connections between thousands of different groups of neurons. To understand general principles of the set-up of these connections, researchers have to investigate a number of different connections and try to find common building blocks.

We would like to study a few of them. We are investigating first the connection between the eye and the brain which is already quite good understood. Here some molecules and mechanisms contributing to development of this neuronal connections have been already identified. We would like to understand these connections in further detail. We think this will help to better understand other connections and with this the overall function of the brain.

In contrast to this, an understanding of neural connectivity involved in neuro-developmental illnesses is still at its infancy. However, a few molecules and some neural connections involved in these illnesses have been identified and serve as a starting point for further investigations. The study of mice with genetic alterations in candidate genes for neurodevelopmental illnesses will provide important insights for a better understanding of these disorders.

What outputs do you think you will see at the end of this project?

We hope to contribute to a better understanding of the etiology of neuro-developmental disorders with particular emphasis on autism spectrum disorders. Our focus for the next few years will be an understanding of the role of microglia and astrocytes in this disorder, but we will be very open to further developments, either due to our own research, or through the publication by other labs.

Our output will be primarily publications in, if possible, general and high ranking journals. We will also communicate our findings via our webpages, and by attending scientific conferences, where we will present our data in form of presentations and posters, while also extensively networking with our colleagues.

Who or what will benefit from these outputs, and how?

Some considerable knowledge has been accumulated on the role of non-neuronal cell types in the brain, in particular microglia and astrocytes. Most of the functions of these glia are in supporting the function of neurons, however, there is also an extensive communication between these three cell types indicating that an understanding of the function of the brain requires an understanding of each of these cell types and their communication.

However, their role during the development of the nervous system, and in particular their role during the development of disorders of the nervous including autism spectrum disorders is much less understood. We would like to better understand the role of these glial cell types and their communication with neurons during normal development of neural connectivity and in situations where these functions are disturbed.

An understanding of the precise involvement of microglia and astrocytes in normal development is at the core of the research activities of numerous labs all over the world.

Some research findings indicate that if the function of these glia is disturbed, it leads to neurodevelopmental disorders. Therefore, an understanding of the processes which go wrong during neural development leading, for example, to autism, might be very helpful to find cures for bettering the conditions of those individuals affected by these disorders. Generally, it appears that in some cases of autism, more fundamental processes are disrupted leading to more severe cases, while in other cases the deficiencies are smaller and the individuals are less affected in their normal life. Therefore, autism is also described as a spectrum disorder.

Our projects will be of interest for these labs, since we aim to understand on a deep mechanistic level the role of microglia and astrocytes during development of neural circuits. New principles, concepts and molecules linked to these important cell types might be discovered in our projects. We think that the outcomes from our proposal might give new views of these cell types in the adult nervous system and might further an understanding of autism spectrum disorders during development, maintenance, stabilisation, homeostasis and repair of existing, adult neural circuits.

Furthermore, our research will be of intriguing interest for research labs working on the normal development of neural circuits, providing new starting points to understand these complex processes. One process we are in particular interested in is the control of the local connection points between neurons, the synapses, and we would like to understand here the pruning or removal of synapses in a process called autophagy or self-eating. Our pilot data might open-up a new area of research towards defining the importance of autophagy for the normal, undisturbed development of the brain.

How will you look to maximise the outputs of this work?

Naturally, we aim to publish our data in more general journals to reach a wide audience of neuroscientists, and aim to publish our research on web pages of the Institute, as well as communicate via social media including twitter.

We will communicate our results on meetings and congresses which have a wider spread of covered topics including neuro-developmental disorders. We aim to attend meetings which have a focus on autism.

Species and numbers of animals expected to be used

- Mice: 2000 wild type mice; 2000 transgenic mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice since for this organism relevant, well-established models are established to study on a genetic level neuro-developmental disorders such as autism spectrum disorders (ASD). These models comprise (conditional) knock-outs and knock-ins of candidate autism genes. We will be working in particular with genes, for which it has been shown that in humans mutations in these genes are associated with neuro-developmental disorders.

Since ASD is a disorder affecting early neural development, we would like to analyse in particular early, postnatal, states of neural development in these model systems.

Additionally, we would like to extend our studies on the development of topographic projections, in particular the retino-collicular projection (I.e., the connection between the eye and the brain).
Topographic projections describe the axonal connections between groups of neurons in which neurons which are neighbouring in one area are connected to neurons which are neighbouring in the other area. In this way positionally organized information can be communicated between different groups of neurons. We will use the mouse system since only here particular mouse lines are available, in which select key molecules can be removed or inactivated very locally and in a very time dependent manner.

We will study early postnatal stages.

Typically, what will be done to an animal used in your project?

One major strand of research in my lab will be the investigation of neural circuits in the cortex, which are affected in neuro-developmental disorders (for example the medial prefrontal cortex). We will be analysing here typically the morphology, function and connectivity of neurons, microglia and astrocytes in mouse lines with genetic alterations in candidate autism genes and compare them to the wild type situation.

Another major strand will be a functional approach, in which we will alter the function of microglia and of astrocytes during early postnatal development, and study the consequences of these interventions on the morphology of neural circuits in the cortex of wild-type and mutant mice. We also will study consequences of these interventions on the behaviour of these mice in typical ASD behavioural assays.

For analysis of topographic projections, we will fluorescently label local areas in the retina using fine needles and analyse a few days later the connections of these retinal cells within the brain.

What are the expected impacts and/or adverse effects for the animals during your project?

In structural investigations of neural circuits in the cortex we will use a variety of mouse mutant lines. For these, we do not expect adverse effects. At the moment, it is not planned to generate new mouse lines. The existing mouse lines we would like to use are very well characterized, and their characterisation so far does not suggest increased pain, weight loss and/or tumors. Abnormal behaviour in terms of social interactions, repetitive behaviour, ultrasonications and a tendency for increases in epileptic seizures have been reported.

In our functional approaches, we will interfere with the function of cells in the CNS, with particular emphasis on microglia and astrocytes, and study their consequences. These interventions have been principally already performed by other labs, and no gross phenotypes in terms of pain etc. have been reported.

The combination of approaches we are planning in terms of mutant mouse lines, functional interferences, and behavioural studies, have not been carried out so far.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The functional characterisations will involve the administration of tiny amounts of substances to the brain and to the body of young mice (wild type and mutant). These approaches involve small operations, meaning that the expected severity of the approaches will be medium.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We would like to better understand the aetiology of autism spectrum disorders. These disorders are believed to be caused predominantly by genetic mutations in genes which control neural circuits and eventually behaviour.

For this, we need to work with intact mouse models, since the read-out of ASD will be a behavioural analysis which is controlled by the complex interaction of multiple groups of neurons. We therefore have to interfere on a molecular level with the function of neurons, microglia and astrocytes in vivo, and study the consequences of these interventions on their behaviour.

Which non-animal alternatives did you consider for use in this project?

We have considered to study, for example, the interaction between neurons, microglia and astrocytes *in vitro*. These approaches will likely generate further knowledge on molecules and mechanisms involved in these interactions.

Furthermore, brain development in mammals involves a complex choreography of events that are poorly understood. For this reason, it is currently inconceivable that we could generate computer models to advance our understanding of brain development and the disorders that affect this process.

I have checked at the frame web site (www.frame.org.uk) and there are no current alternatives to my research on brain development on animals.

Why were they not suitable?

However, these results have to be taken with great caution, since there are time- and region-specific interactions in the brain between these cell types, which only exist *in vivo*, which will be disrupted if one or the other cell type is put in culture, and where they can be

functionally and structurally investigated.

A well documented example are microglia, which when taken out of the brain context, rather dramatically change their functional characteristics in culture.

Nevertheless, we will use organotypic cultures of brain slices whenever possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have from the beginning of our experiments, a clearly outlined set of breeding based on year-long experience to achieve our experimental goals.

We do know which mouse lines we would like to analyse; we do know the number of mice for each parameter to be investigated, we do know the number of breeding to achieve this number of mice. We have a clear idea which ages we would like to investigate. We have a clear knowledge which controls to include. We have a clear knowledge to plan for back-up breeding in case some experiments go wrong.

Our own year-long experience is substantiated by our knowledge of approaches of other labs to achieve functionally and statistically relevant data, based on their publications.

We will constantly aim to improve our statistical methods. We will also seek for statistical advice in very complex experiments. Based on previous experiments, with a power of 80% and an effect size of 20%, our sample size varies from 4-5 animals (e.g., quantification of the number of cells) to 12-15 (e.g., behavioural tests).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have more than 20 years of experience using mice as a model system for brain research. My research project is designed to minimize the number of animals used to obtain statistically significant results when testing our hypotheses, including the use of factorial experimental designs.

We will review our mouse colony on a weekly basis, and will reduce the number of mice if possible.

We will investigate ways to analyse experiments in multiple ways so that with fewer mice more data become available.

Because the mouse brain is relatively large, for structural investigations we will generate hundreds of sections from one brain, allowing us to obtain material for multiple sets of experimental approaches.

In addition, we use a highly developed database that aids us in obtaining the precise number of transgenic mice required for our experiments. Furthermore, we collect the brains of all the mice that we used in our experiments (including many from mice that are only used as breeders) and we store all the relevant information in a database.

In addition, we make this material available to other researchers in our Centre, which also contributes to reducing the number of mice used in experimental procedures.

Personnel in my laboratory will take the online course designed by M. Festing (www.3rs-reduction.co.uk) to minimize the number of animals before starting their experiments.

Only a fraction of the total number of animals that will be breed will be used in experiments. This is due to the fact that the desired genotypes (e.g. a conditional mutation) are generated along with non-desired genotypes. For example, breeding might involve crossing of mice with floxed alleles and the cre -driver allele, however, in the offspring a few pups would not have the desired phenotype (homozygous floxed, cre positive). Those mice, for example pups without the cre allele, might not be of relevance to be included in the experiments and therefore killed using a Schedule 1 procedure.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Apart from good experimental design, we will review the number of mice and the ongoing breeding on a weekly basis.

We will review our results on a routine basis, and change our experimental design accordingly.

We will aim to record as much data as possible from each experiment so that experiments do not need to be repeated as often.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use the mouse as the animal model system. Methods used are structural and functional investigations of most suited (conditional) knockout mice of candidate ASD genes. The mouse model system is the only model system with such a variety of genetic tools and already available mouse lines to study ASD. For this purpose, the mouse is the best possible animal model because their genome is relatively easy to manipulate and their brain develops in a similar manner to humans. The use of conditional mouse mutants, in which only a specific population of neurons lacks the gene of interest, provides the most accurate results and hence refinement. In contrast, full knockouts in mouse – but which are available also in other species -often have disadvantages since here the protein/gene

of interest is removed from the entire animal which could have multiple effects, and which might be difficult to understand.

Why can’t you use animals that are less sentient?

To study the etiology of ASD in the context of neural circuit development linked to behaviour, we would like to use a model system as close to humans as possible. Therefore, we are interested in using the mouse model system with its huge genetic resources, while other model systems such as zebrafish and Drosophila appear much less suited.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will constantly aim to improve our statistical methods.

We will investigate ways to analyse experiments in multiple ways so that with fewer mice more data become available.

In particular, for structural investigations we will generate hundreds of sections from one brain, allowing us to obtain material for multiple sets of experimental approaches.

Finally, to improve the welfare of the animals, anaesthesia, analgesia and general protection will be provided to the mice to avoid any suffering prior to manipulation or sacrifice for the experimental procedures, using approved methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will get our information on how to conduct experiments in the most refined way from the relevant NC3R web pages. We also will be in close contact to the local Ethical Review Committee.

Personnel in my laboratory will take the online course designed by M. Festing (www.3rs-reduction.co.uk) to minimise the number of animals before starting their experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will rountinely on a monthly basis visit relevant web pages to look for updates, such as the ones from the ' UK National Centre for the replacement, refinement and reduction in animals in research NC3Rs), and the web page ' understanding animal research ' .

Recommendations will be implemented imminently.

96. Understanding cortical plasticity and learning

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Memory, Learning, Neurone, somatosensory, cerebral cortex

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, neonate, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understanding learning and memory processes in the cerebral cortex and the synaptic plasticity mechanisms that underlie them. By understanding synaptic plasticity in healthy brains, we will gain insights that will help us design treatments for psychiatric and neurological conditions in which plasticity is impaired such as schizophrenia and Alzheimer's disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work because the synaptic processes that underlie learning and memory are defective in several conditions that afflict people and so far, therapies are

lacking. Synaptic plasticity conditions can broadly be divided into two main categories, (a) neurodevelopmental conditions, where defective plasticity during development leads to miswiring of the nervous system (examples here would include schizophrenia, autism, and fragile X), and (b) neurodegenerative conditions where the neuronal circuit underlying learning and memory is initially healthy but degenerates with time and can no longer create or recall memories (for example Alzheimer's disease). By understanding how synapses are modified, which neuronal circuits control synapse modification and how these processes are affected by abnormal development we may be able to develop therapies to treat these conditions.

What outputs do you think you will see at the end of this project?

Our main outputs from this project will be publications in scientific journals. We aim to produce information on how neuronal circuits control changes in synaptic structure that lead to enduring memories. We aim to produce information on how information is transmitted from sensory parts of the cerebral cortex to the hippocampus where short term memories are stored and how the short term memories become consolidated into long term memories during sleep. We aim to produce information on how neuronal circuits can go wrong due to defective development in neuropsychiatric conditions such as schizophrenia. Finally, we aim to understand the potential benefit of nascent therapies for restoring synaptic plasticity in conditions in which it is lost such as Alzheimer's disease.

Who or what will benefit from these outputs, and how?

Short term Impact:

The short term impact of our studies will be realised within a year or so of the start of this licence and will mainly affect scientists working in the area of neuroscience who will read the papers we begin to publish. They will benefit by gaining greater understanding of how cortical plasticity works and what factors within the neuronal circuit affect synaptic changes underlying memory formation. The fields of academic research that will be affected are expected to be those of Perceptual learning, Psychiatric disorders, Cortical processing of information, Sleep research, Somatosensory processing. As the primary research articles are published, we will integrate this information with that from other labs to write review articles and hence disseminate the knowledge to a wider audience, including academics, medics and researchers in industry.

Longer-term Impact:

The longer term impact of our research will be to create a more complete understanding of how synaptic plasticity occurs from the level of the molecular mechanisms at the synapse, to the level of the neuronal circuit in the cortex, where several elements dynamically interacting to generate synaptic changes under some conditions and not others. This will create a test-bed system that can be built on to
(a) further understand the mechanisms involved and (b) to understand how these synaptic and anatomical pathway mechanisms are disrupted in psychiatric and neurological conditions and (c) to test therapies for improving synaptic plasticity and hence memory function.

How will you look to maximise the outputs of this work?

We will collaborate directly with academics at our home establishment with whom we

jointly hold grants for research in the departments of Bioscience and Psychology. These collaborations will create synergies between our work on somatosensory cortex and touch memory and the work of scientists currently studying plasticity in the visual and limbic systems. We will therefore create a more generalised and holistic understanding of learning and memory by combining understanding with our studies. Our interactions are likely to influence one another's studies within our own subfields and hence help us to disseminate knowledge further afield via non-overlapping components of each others' professional networks. We will also interact with the wider home institute's neuroscience community, including those located in medical centres aiming to understand human psychiatric conditions through genetics. Interactions will naturally occur via seminars, symposia and workshops. Our work can help them to explain the functional consequences of the mutations and molecular pathways they identify in the human population. Internationally we will interact with neuroscientists in Japan and South Korea via annual symposia sponsored by the Medical Research Council and with neuroscientists from all over the world, who meet at the annual Society for Neuroscience meeting in the USA.

In order to maximise the impact of our findings, we will publish our studies in prominent internationally read journals and publish reviews and public engagement articles for a wider audience. An integral part of our publications will be to describe what did work and what did not work in the experiments (or trial experimental therapies).

Species and numbers of animals expected to be used

- Mice: 2000
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We wish to use rodents in this study because they are the lowest sentient mammals that have a similar cortex to humans. Because they are relevant to humans, rodent studies allow us to probe the effect of genetic mutations present in the human population that lead to psychiatric and neurological disorders. Mice are a commonly studied laboratory animal and are available in many genetically mutated forms. We need to use the mouse genetic mutations available in the research community for two main reasons
(a) because they mimic human mutations that predispose people to psychiatric and neurological disorders; we can gain insight into the causes of these conditions by studying the mouse genetic models. (b) several strains of mice allow cell-specific expression of artificial ion channels that can be stimulated optically and chemically in order to probe particular anatomical pathways. In addition, because our lab has specialised in plasticity in the barrel cortex and visual cortex of the mouse, we have extensive prior experience and data that can be used to predict sample size and understand the new data as it is generated. In some circumstances, rats are a preferable model to study. This is usually because they are larger, which allows them to carry head implants more easily and occasionally because their behaviour is more accurately measured and interpreted.

Typically, what will be done to an animal used in your project?

Animals used in these studies will typically carry prior mutations that enable them to express genetic material in a cell specific manner or to mimic a particular psychiatric or neurological condition. We will need to breed animals of known genotypes to do this. Consequently, we will need to take a small ear sample biopsy to run a PCR based genotyping typically at the stage when the animals are weaned.

The following procedures will be use to understand synaptic plasticity

Animals will receive an injection of virus to transport the genetic material to the neurones under investigation so that we can see the neurones and manipulate them.

Some animals will receive a cranial window implant during the same surgery that delivers the virus. This enables us to see and manipulate the neurones under study over a period of several weeks.

The animals will then be trained on behavioural tasks where their learning is assessed under various conditions, which typically comprise optically activating or inactivating subsets of neurones .

Some animals will learn a tactile texture discrimination in a free-moving task in order to obtain a food reward. The mice will have food restriction during this period.

Some animals will learn a very similar texture discrimination while located under a microscope in a head-fixed apparatus to which they will have become acclimatised over several days. They are able to move while in the head-fixed position by walking or running on a ball or track. They will receive a water reward during this period having been on water restriction before hand.

Another group of animals will receive the viral injections but then be killed rapidly by decapitation and brain slices prepared for detailed intracellular micro-electrode recordings in vitro.

Rats will receive an electrode implant and following a recovery period of several weeks learn the same free-moving texture discrimination for a food reward. The animals will have undergone food restriction during this period.

Some animals will have received viral injections as described above but then be anaesthetised and positioned in a stereotaxic frame and the cortex exposed for electrode recording while stimulating sensory inputs. These studies will be concluded under the same anaesthesia without recovery.

Some animals may undergo sensory deprivation, which either involves suturing closed one eyelid, being placed in the dark for a few days, or having their whiskers trimmed. Following these procedures the animals will either be placed in stereotaxic frame and electrodes used to record sensory responses or be rapidly decapitated in order to prepare brain slices.

What are the expected impacts and/or adverse effects for the animals during your project?

For some animals the impact is mild or negligible as anaesthesia is rapidly induced with isoflurane before the animal receives an injectable anaesthetic from which they do not

recover. For the animals receiving head implants, viral injections and electrode implants, the adverse effects is a week or so of recovery from the surgery, which is mitigated by analgesics. For the animals undergoing behavioural studies, those undergoing food restriction will lose some weight compared to when fed ad libitum, but we will monitor this closely and ensure it is not more than 15% of their initial weight. The animals undergoing the head-fixed behavioural task will endure some anxiety until they learn that the apparatus is safe and they are used to it. These animals will also undergo water restriction and so may feel thirst, which can be sated during the experimental learning task. The implants are typically in place for 3 weeks before experimental handling and acclimatisation to the apparatus begins. Behavioural studies typically carry on for a further period of 3 weeks beyond that.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Breeding only (20%) subthreshold

Viral injections followed by non-recovery anaesthetic and stereotaxic recording or preparation of brain slices (30%) Moderate

Viral injections followed by head-fixed behavioural tasks (25%) Moderate

Viral Injections followed by free-moving behaviour with or without intermittent imaging under anaesthesia (20%) Moderate

Rats:

Viral injections and electrode implantation followed by free moving behavioural studies (5%) Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals have to be used because the subject of the study is how learning affects the plasticity of synaptic circuits in the brain. Therefore, we need a whole animal with an intact brain and all its motor and sensory apparatus available to acquire information from the animals environment.

Which non-animal alternatives did you consider for use in this project?

Cell culture Computer models

Why were they not suitable?

Cells in culture are immature and so cannot mimic the plasticity present in the adult brain. Cell cultures are not linked up to the sensory apparatus of a whole animal and are unable to learn about the environment. Finally, cell culture lack the complexity of the brain which is composed of billions of cells organised in several different functional subsystems.

At present we do not know enough about how plasticity works to model how experience affects the brain in a computer model. If we did know how to make such a computer model we would still need to check its validity using animal experimentation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have calculated the number of experiments we anticipate performing and the numbers of animals required for (a) breeding the experimental animals (b) determining whether the experimental results are valid and reproducible. We know from previous years' animal use that we are approximately correct in these calculations. We have also allowed a buffer in case some experiments fail for technical reasons or unforeseen difficulties.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used power analysis to estimate the number of animals necessary for statistical validity of our studies using an alpha value of 0.05 and power of 0.95. We used prior measures of effect size and variance for the power analysis, largely from our own previous data but occasionally using data from other labs. We multiplied the number of variables in the studies by the group size needed for statistical significance to arrive at the total number of animals that would typically be required. We took into account that animals in each comparison would be of similar age and size and balanced for gender. We took into account that in some cases we could use each animal as its own control, while in other cases we needed to compare across cohorts of animals (for example different genotypes or different treatments).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where we have not already done so, we will undertake pilot experiments to improve technical measurements and optimise animal learning procedures and apparatus.

We will use efficient breeding to keep the number of experimental animals generated to low levels. In several of the genotypes that we plan to use the heterozygotes exhibit the

phenotype. Where double heterozygotes are required we can use the single heterozygote progeny for further breeding or often as wild-type controls.

In some experiments where brain slices are produced, we may be able to share the tissue between two researchers on different recording rigs in the same lab at the same time to maximise the number of cells recorded from each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodents in these studies, mainly mice and a smaller number of rats. We will use the somatosensory cortex as a model system for how different cortical areas interact to create the conditions for plasticity during learning. We will minimise suffering in every case by the use of anaesthetics and analgesics. We will minimise the chance of animals suffering from infection by using aseptic techniques for surgery. We will minimise the chances of animals with head-plates becoming entangled in their home cages by housing them in large cages. We will minimise the chances of the head-plates becoming detached by using a combination of strong adhesives. Animals undergoing food or water restriction during their learning tasks will be carefully weighed regularly (usually every day), and their health closely monitored.

Why can’t you use animals that are less sentient?

Examples of less sentient animals might include flies, fish and worms. While these animals can learn, they do not have the same brain structure as rodents, which do have a cerebral cortex that is similar in form to human cortex. Given that we would like to understand how the human brain learns and what goes wrong in the plasticity processes underlying psychiatric and neurological conditions, we need to use a species with a similar enough brain to make the studies relevant.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are monitored almost continuously during the recovery phase from surgery to ensure they are feeding, drinking and moving well. Pain management is controlled by prophylactic analgesics before surgery and afterwards in the drinking water as needed. All surgery is conducted aseptically, topical antibiotics are used and all wound margins sealed to prevent infection routes. Animals are left to recover for several weeks before introducing them to the behavioural setting. Animals undergo several weeks of gentle handing and general acclimatisation to the apparatus before we begin training. We will explore new published methods of delivering Clozapine N-Oxide (CNO) via a micropippette as an alternative to intraperitoneal injection of the drug.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will broadly follow the methods outlined in the Animal Research Reporting in vivo Experimentation (Arrive) guidelines in order to use animals in the most efficient way. These guidelines describe high quality methods and standards for reporting the results of in vivo animal research and are recognised internationally. They cover the content required for each section of a paper from the Title and Abstract through to the Discussion. The recommendation on the Methods and Results sections are particularly important and include detail on clearly stating many aspects of the study from study design, experimental procedures, housing and husbandry and statistical measures through to outcomes and estimation of precision of measurements. An updated version has been published in PLOS in 2020 (https://doi.org/10.1371/journal.pbio.3000410).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are constantly in touch with the animal care staff at our home institute and receive regular bulletins from NC3Rs about advances. We frequently attend international meeting where best practice is discussed. We have a Regional Programme Manager from the NC3Rs working with our establishment and benefit from advice and updates.

97. Genetic modification of chickens to understand vertebrate development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

embryonic development, organogenesis, tissue fusion, organ size, developmental timing

Animal types	Life stages
Chickens (Gallus gallus)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to modify specific genes in chickens to understand their function during vertebrate embryonic development. The results from these studies will improve understanding of the genetic regulation of normal vertebrate development and the causes of human and animal developmental disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The chicken, a non-mammalian animal, is a valuable and tractable model for understanding the genetics and developmental processes important to form a healthy embryo. Understanding the genes that control development and growth of the chick embryo and how these regulate the inherent cell behaviours and molecular interactions in these processes, is important to help elucidate the causes of human developmental defects and how these can be treated or cured, but also will inform the study of developmental processes common to other vertebrates.

There are many human developmental defects, and a large proportion of these are genetic in origin. One example of these is tissue fusion disorders, such as cleft palate or spina bifida, or coloboma of the eye. The incidence of these can be as common as 1 in 500 new births. Many of these defects cause significant morbidity throughout the life course and currently have no cure. In addition, multiple birth defects do not have their causative gene (or genes) yet identified, reflecting a gap in our knowledge of the relationship between genes and the processes that they regulate. One major way we can acquire knowledge of gene function in development is through studying normal and abnormal developmental processes in vertebrate embryos, with particular emphasis on how these genes are turned on and to what levels, when and in what tissues. These are major outstanding questions in our understanding of normal embryonic development and the causes of human birth defects. Such studies can also lead to preventative measures being taken to reduce the number of birth defects, a good example for this is taking folic acid during pregnancy.

The value of the chick embryo as a model for vertebrate development continues, with added value conferred by access to transformative improvements in genetic modification capabilities; these have been pioneered and are readily available at the host Institute. The chick embryo can be easily accessed in the egg and manipulated experimentally (without affecting the mother as is the case in the mouse). In addition, many of the key developmental processes take place before the regulated stage of embryonic chick development. Indeed, for this licence, the majority of work will be performed in embryos prior to embryonic day 14. In parallel with the development of genetic modification technologies for the chicken has also been the freely accessible publication of the complete chicken genome. This widens the scope, utility and validation potential of genetic modification approaches and functional genomics in the chicken. It is important to now

utilise these advantages of chick experimentation to address the needs of developmental biologists and human geneticists and clinicians in understanding the causes of developmental birth defects, and the processes that underlie normal development.

What outputs do you think you will see at the end of this project?

The intention is to combine the generation of new genetically modified lines with complementary transient transgenic approaches where possible. It is expected that up to 10 new genetically modified lines could be generated throughout the duration of this project, and in all of these the majority of work will be performed in unhatched embryos. The work will help identify the genes that are important for the development of healthy chicken embryos that will be valuable for improved understanding of human embryonic development. We will also gain more understanding of how certain faulty genes can lead to birth defects affecting the face, eyes, and limbs, and other tissues or organs. We will be able to make progress in determining what cell behaviours these genes control during development, and how these processes are coordinated to produce specific organs or tissues from small numbers of starting cells.

This project will also develop improved methods and approaches to generate more data from each single embryo by selectively isolating the specific cells of interest for analysis of genes or proteins. This will reduce the number of animals used for this type of research. During this study we will continue to make available these novel tools to other academic researchers and to develop additional genetically modified lines that will significantly enhance the knowledge gained from studying vertebrate in the chick embryo.

Our results will be published in scientific journals and communicated to developmental biology and clinical genetics research laboratories worldwide.

Who or what will benefit from these outputs, and how?

The work will improve the knowledge base among biologists. For example, those in the fields of eye development, tissue fusion, limb development and craniofacial biology. Many findings will have broader relevance to biologists working in other developmental contexts (e.g. palate, neural tube and heart development), or in disease contexts affecting patients over the wider life-course, e.g. protein interactions and cell behaviours in cancer or neurobiology studies, or offering an improved understanding of the molecular basis of ciliopathies. These beneficiaries will benefit directly through publication of new experimental evidence of the key cells, their shape changes and behaviours, and the precise mechanisms, genes and molecular interactions involved during these developmental and disease processes. This will improve understanding of which processes are essential for development, where and when in the embryo these are required, and how they are likely to cause disease if not correctly regulated at any stage of life.

The work described in this study may have a wide impact on developmental biologists currently working in other model species such as mouse and zebrafish. The chick embryo has traditionally been lauded for its utility but has been hampered by the lack of genetic modification methodologies. Work in this study will bring the tractability of the chick in line with these other species, with the underlying benefits of chicken embryology, such as the ability to synchronise development between eggs/embryos, and the ability to keep the mother alive to continually produce genetically modified offspring (in contrast to mouse). In general, developing tissues in the chick embryo are larger and provide more cells to

perform experimental analysis, and can be cultured outside the egg and used for live microscopy.

These advantages may provide the basis for other developmental biologists to select the chicken as their future model organism of choice, making a significant 3Rs improvement to the field of developmental biology research.

Clinical geneticists with interests in a range of birth defects, such as the causes structural eye defects, limb abnormalities and craniofacial disorders will also gain new knowledge into mechanisms of disease causality and the identification of novel candidate disease genes. Any new genes revealed from these studies will be shared to be included in patient screens to identify potentially causative mutations from large gene sequencing projects, leading to improved molecular diagnostics. Examples of this are the NTN1 and SMOC1 genes in eye patients, and the TALPID3 gene in ciliopathy patients. In the longer term, these studies will inform genetic counselling for families affected by developmentally regulated birth defects.

How will you look to maximise the outputs of this work?

We collaborate internationally and communicate our scientific results at seminars, conferences, 3R conferences, and through scientific publications and a combination of broad scope and specialist open access journals. We will endeavour to publish all results, whether successful or unsuccessful, in a timely manner in high-ranking open access journals with broad scope.

We communicate with other laboratories who are also developing avian genetic modification techniques for developmental biology, and who work on the same tissues or organs in other species. We will utilise well trained bioinformaticians to analyse the gene expression data.

In particular we will maintain and expand collaborations with clinical geneticists to maximise the impact of this work. These will be strategically developed with world-leading clinicians, e.g. with specialities in both ophthalmology or limb defects, and those with interests in broad syndromes. In particular we will seek those with large patient cohorts. These collaborations will allow us to expedite clinical relevance of findings, or to determine which aspects of our research to focus on for maximum clinical benefit.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The chicken embryo is an appropriate and well established animal model to study vertebrate development and the basis of human developmental disorders. The chicken is very useful to study embryonic stages as a fertilised egg can be obtained without surgery on the mother. To develop genetically modified lines we need to use adult birds, and to

enable us to study gene function and cell behaviours in some contexts, we may need to use hatched or adult birds.

Typically, what will be done to an animal used in your project?

The animal will be blood sampled one to five times during its life. Its behaviour may be observed. It may be treated with a drug to change gene expression or to label or ablate cells in the animal. The animal will be humanely euthanised after which phenotypic and genotypic data will be obtained.

What are the expected impacts and/or adverse effects for the animals during your project?

There is a reduced hatching rate experienced for some of the lines of chicken and from manipulated eggs. Most of the chickens will lead a normal life. There is the consistent problem to breed homozygous animals for a genetic locus while avoiding the health deficits associated with inbreeding of chicken lines. We will maintain an up-to-date list of all genetically modified birds on a public website with details of linked publications and methods.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity: 95% of animals Moderate severity 5% of animals

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The biology of embryonic development in birds is of interest in terms of understanding developmental mechanisms for all vertebrate animals (including humans or farmed animals), while the developmental process that occur in the embryo are also what determines good health throughout the life of the animal. We will keep the use of animals to a minimum by focusing work in this licence on embryonic stages prior to embryonic day 14.

The use of embryos and animals is necessary to study the function of genes during a range of developmental stages throughout the whole organism, and in physiologically-relevant contexts. This is particularly the case in genetically modified models where a gene or region of DNA sequence has been perturbed. Gene expression, specific cell behaviours and molecular interactions in an embryo are a result of each cell’s ability to interpret cues

from secreted growth factors, cell-cell signalling, and the interpretation of positional information within a developing tissue, in combination with the physical stresses on each cell. The responses and cellular interactions within live embryonic tissues are also highly dynamic through developmental time and the life of the animal, which allows complex structures to develop and be healthily maintained, such as in the eye or limb. The combination of all of these parameters are what determines the phenotypic outcome, and this cannot currently be replicated in existing cell culture systems, or explant or organoid cultures. For example, the organoid culture system developed to understand early eye development does not undergo the complex process of tissue fusion or the structural development of many other ocular structures. Similarly, existing limb cultures do not readily recapitulate the early development of limbs and the complex arrangements of bones, tendons and musculature. Therefore, to determine the precise role for a gene during the complex development of an organ, it is vital that the organism is intact when such developmental studies are carried out.

The use of the chicken as a model species itself addresses “replacement” to the extent that licensed experiments carried out in mice may be replaced by the use of genetic modification chicken embryos from lines created under this licence, for studies before the regulated, late stage of development.

Which non-animal alternatives did you consider for use in this project?

In vitro organoid culture systems have been developed to generate embryonic eye tissues from stem cells and these were considered for aspects of this study.

We will use cell cultures to provide supportive data for some experiments. For example, to identify the interaction partners of some encoded genes or to explore upstream influences on the expression of specific genes.

Why were they not suitable?

The in vitro organoid culture system to generate eye tissue does not produce the complex folding and tissue fusion events seen in the developing chick eye. Organs such as the limb, which consist of populations of cells from multiple embryonic origins, have not been cultured in vitro through all developmental stages. Therefore, this approach is not suitable for the eye development work in this project.

Investigation of some aspects of development will be carried out using in vitro systems where possible, but comprehensive studies, for example the impact to a particular region of the embryo of the loss of a specific gene, the fate of cells in a developing tissue, or cell behaviours in a complex 3D tissue framework, are only possible in a whole animal. Indeed, the study of eye, face, skeleton or limb development are not possible in other non-vertebrate models such as flies and worms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the total number of genome edited and transgenic lines we will establish over 5 years, and the number of genome edited offspring that will be bred during that time period. For each genome edited line, we will need to generate surrogate host birds that will carry the genetic material and use wild type birds for experimental crosses and breeding to maintain these lines. For each genome edited line, tissue-grafts or other experimental approaches, we will use power calculations to determine the number of animals we need to breed or use in order to carry out the required experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The cell culture of reproductive chicken cells enables us to carry out some experiments without using animals. The donor reproductive cell injections are carried out at unregulated developmental stages in eggs and many of the experiments will also be performed before the chick would hatch. The use of avian species as models offers advantages over mammalian species for the study of embryonic development. In this instance, the chicken offers advantages over using a mouse models as the mother does not need to be culled to obtain the embryo and a surgical manipulation is not needed to introduce donor reproductive cells into the embryo.

The majority of experiments will also be carried out at unregulated developmental stages (before day 14 of incubation) in the egg. Most aspects of eye, limb and facial development have occurred in the chicken embryo before day 14 of incubation so early development can be studied in embryos before they would hatch.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Experimental designs will be developed with advice from our Institute statistician who is a member of our AWERB. The number of birds required to maintain breeding lines of genetically modified birds will be kept to a minimum (2-3 pens) required from our past experience of the numbers required to ensure continuity of a line. Birds of a specific genetically modified line will be bred at greater numbers where specific project requirements need greater numbers of birds for limited periods. Discussions with colleagues and wider collaborators developing and utilising genetically modified mice or other available species will also ensure we benefit from advances in emerging genetic modification processes to ensure the number of animals used are continually kept to the minimum required. Flocks are maintained in known families at a size which balances adequate material balanced with maintaining a healthy in-breeding co-efficient (approximately 16 females 2 males per family).

Where possible, we will always endeavour to utilise multiple tissues from each embryo or sample to maximise the experimental outputs from individual samples. Similarly, we will make use of Institute freezer facilities and standard tissue fixing protocols to store samples for future work. All samples will be considered precious.

We have worked to improve the efficiency of hatching surrogate chicks carrying donor genetically modified reproductive cells. We will make use of genetically modified surrogate hosts birds (male and female) that lay 100% of the offspring from the donor genetically modified cells. We have improved our genetic modification of the donor genetic material

(chicken cells in culture) to screen for the genetic modification before the genetic material is introduced into the surrogate host chick embryos. We are also developing methods to reduce breeding by directly mating the surrogate hosts to generate pure offspring in a single generation which greatly reduces the number of chickens bred in these experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The chicken is both a farmed animal of major importance to human nutrition worldwide, and a versatile model organism for the study of vertebrate development. Increasing basic knowledge of the physiology and development of the chicken that can only be investigated in the intact embryo/bird, and that involves understanding tissues and organs in the intact animal, is the focus of this PPL. Applications of genetic modification technologies in biotechnology and genetics also must relate to the function of the intact animal. The studies are designed to be as minimally invasive as possible; the vast majority of birds will only be blood sampled to confirm genetic modification or transgenesis and then used for breeding as required.

All new transgenic and genetically modified lines are planned to target genes where there are no expected adverse phenotypes in heterozygous birds, which will be used for crosses to generate embryos for experimental analyses. These heterozygous genetically modified birds will be closely monitored for any adverse phenotypes. Furthermore, within this licence the significant majority of work will be performed in chicken embryos prior to embryonic day 14 when they become recognised as protected animals under current UK legislation.

The use of cultured avian reproductive cells that can be genetically modified to disrupt gene function and used to produce genome modified birds is unique to the chicken and avian species. The access of the fertilised avian egg also means the surrogate host chicken can be hatched without killing the mother to obtain the egg. The transfer of reproductive donor cells into surrogate hosts is done in the laid chicken egg at young ages (unregulated stages) before the formation of a nervous system. The surrogate hosts chickens will grow normally but make eggs and sperm from another chicken breed or potentially another bird species.

Why can’t you use animals that are less sentient?

The majority of work in this study will be performed on chicken embryos. There are few vertebrates that are experimentally tractable as chick embryos, or that mimic the developmental processes and genetic regulation of humans as closely. In addition, chick embryos undergo many of their organogenesis and structural organ or tissue development processes prior to day 14 (2/3) of gestation. The chicken offers further advantages over

using mouse or other rodent models as the mother does not need to be culled to obtain the embryo, while a surgical manipulation is not needed to introduce donor reproductive cells into the embryo.

The study of eye, face, skeleton or limb development is not possible in other non-vertebrate models such as flies and worms as the organs and tissues of these species lack the complexity of higher vertebrates. This is also largely true for fishes as they are cartilaginous and also do not have closely comparable limbs to mammals. Although some fish eye development processes have developmental similarities with humans, the chicken is structurally more similar and has more available tissues from which a larger number of cells for experimentation can be collected and analysed.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have selected genes for modification where heterozygous animals are not predicted to be adversely affected. For all new lines, we will instigate increased monitoring for the weight and behaviour (feeding, social) of newly hatched novel genetically modified chicken lines to verify wellbeing and reduce suffering for all hatchlings. For new genetically modified chicken lines all preliminary work will be performed in embryos to assess any deleterious phenotypes. These will primarily be aimed at early embryos during the first 1/3 of development, then at ½ gestational stages, before assessing phenotypes at pre-hatch late stages in the final 1/3 of gestation. This strategy will be employed to specifically identify any potential welfare costs to subsequently hatched birds.

For any new lines that show an unexpected adverse phenotype we will immediately consult our Named Veterinary Surgeon to assess the welfare issues and to discuss pain management or therapeutic strategies. We will also aim to reduce the number of animals hatched and maintained with the adverse phenotype, and will consult with the Home Office Inspector to agree on best practice in this scenario and conduct additional harm-benefit analyses.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work is undertaken in close collaboration with our Named Veterinary Surgeons. Study protocol forms must be completed and submitted to them prior to proceeding with any experimental work and animal unit staff are closely involved in experimental work and will offer advice on improvements to experimental protocols and monitoring/raising of the animals.

The group contains all the competencies required to perform the majority of techniques and procedures outlined in this project. Where additional expertise is required, staff will undergo appropriate training until competent.

Animals will be kept in accordance with annex III of Directive 2010/63 EU and/ or Home Office Codes of Practice, as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We communicate with our NVS on current developments to enrich the environment of

housed chicken. Our poultry workers are trained in proper welfare techniques for birds and we are strictly monitored by our veterinary scientists and the Home Office on current practices. We visit the NC3R website for new information on animal use in research, and are kept up to date with associated scientific literature. As part of this we will access and complete relevant e-learning resources that are freely available for training and continuing professional development on the NC3Rs website. We will also remain in close contact with veterinary staff and attend annual conferences covering veterinary ethics and welfare.

98. Translational Cancer Therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immunotherapy, Liver

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to improve direct anti-cancer and immune-mediated therapy for various cancers, including primary liver cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are several potential benefits likely to derive from this project including:-

Development of more informative tumour models

Optimisation of single-therapy, combinations and schedules of therapy

Provide rationale for early-phase clinical trials

We anticipate that our experiments will directly provide the rationale for early phase clinical trials in patients. The above work will benefit academia in general, industrial collaborators, and ultimately, patients with cancer. In the short-term, we anticipate that the optimised cancer models will enhance our understanding of the interaction of tumour cells with immune cells in the tumour. We also anticipate short-term preliminary therapy results. These results can then be used in the mid-term to set up early phase clinical trials, which in the long-term are likely to lead to improved patient outcomes.

What outputs do you think you will see at the end of this project?

At the end of this project, we expect to have new information on: 1) the development of more informative tumour models; 2) the optimisation of both single and combination treatment strategies and their schedules of therapy; and 3) providing rationale for early-phase clinical trials. We also expect to produce peer-reviewed publications as a result of the undertaken work.

Who or what will benefit from these outputs, and how?

This work will be of benefit to academia in general, industrial collaborators and, ultimately, patients with cancer. In the short-term, we anticipate that the optimised cancer models used here will enhance current understanding of the interaction of tumour cells with the immune microenvironment.

We anticipate that the results from these experiments will provide the basis for early phase clinical trials, which in the long-term are likely to lead to improved patient outcomes.

How will you look to maximise the outputs of this work?

Results from this work will be publicised through peer-reviewed publications, as well as through oral and poster presentations at national and international conferences.

Species and numbers of animals expected to be used

- Mice: 3900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We plan to use mouse tumour models for our experiments, which constitute the lowest form of mammal recognised as being relevant to human cancers. To achieve the aims of the project, we will use mice at the adult stage of life to ensure we can study a fully-functioning immune system to provide meaningful data towards clinical trial applications in humans.

Typically, what will be done to an animal used in your project?

The vast majority of animals will be injected with tumour cells which will be allowed to grow and form established tumours. Animals will receive treatment with various drugs, including

immune-stimulating drugs, or radiotherapy. Tumours will be measured and examined in order to assess the effects of therapy.

What are the expected impacts and/or adverse effects for the animals during your project?

Injections of tumour cells and the resulting growth of cancer masses may cause some transient discomfort. Similarly, procedures involving treatment with various drugs or radiotherapy may cause transient discomfort to the mice, the majority of which will be from the administration of the treatment
e.g. needlestick.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The animals are not expected to suffer more than a moderate degree of adverse effects during the entirety of our experiments.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As far as possible, my group utilises patient-derived samples including blood and tumours for laboratory studies. These studies can yield some information regarding the effects of cancer therapies on tumour and immune cells. However, immune responses in patients involve complex interactions of multiple cell types in different sites within the body and these interactions cannot be fully replicated in a laboratory setting without the use of animals. A fully-functioning competent immune system is essential to evaluate new strategies for use in patients and hence there is an absolute requirement for animal studies.

Which non-animal alternatives did you consider for use in this project? Laboratory studies using patient-derived samples including blood and tumours. Why were they not suitable?

Immune responses in patients involve complex interactions of multiple cell types in different sites within the body and these interactions cannot be fully replicated in a laboratory setting without the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical analysis will be used to determine the minimum numbers of mice used, while ensuring sufficient data are generated to produce meaningful results. The use of pilot studies will help to assess animal numbers and how best to design the main study in order to gain maximum information.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing experiments, statistical analysis, including power calculations, will be performed to ensure that we use the minimum number of animals per group to be informative and to provide robust results.

Our experiments will be conducted using genetically identical animals that are free of obvious disease; this avoids the variability of treatment response associated with non-identical animals and thus reduces the required sample size.

Initially, preliminary non-animal laboratory work will be used to guide therapeutic dosing and treatment schedules, which will be evaluated in pilot studies involving small groups of animals. These short-term studies will guide the most appropriate doses, schedules and combinations of therapies to be undertaken in longer-term experiments in both protocols 1 and 2. Group sizes for individual experiments will be based on efficacy seen in these preliminary experiments. For new models, study design will be discussed with statisticians prior to planning large experiments

We have utilised the NC3R's Experimental Design Assistant to plan experiments and sample size has been determined using Power calculations as determined using G*power 3.0.10.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To maximise the information from a single animal, we will aim to collect tissue samples from multiple body sites and provide other affected tissues to appropriate scientists, so that they do not have to breed mice specifically for their experiments.

Non-invasive imaging techniques in live animals and analysis of tissue samples collected after sacrifice of the animal will allow us to maximise data collection during and after experiments and reduce the total number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All of our experiments will be conducted in mice. Most of the experiments planned will utilise a superficial tumour model, which is a short-term model that does not require the added stress of anaesthesia for tumour measurements. The severity of the procedures used will be kept to a minimum, whilst providing meaningful data for progression of these approaches to patient care. None of the studies detailed in this project exceed a 'moderate' degree of animal suffering as useful data can be obtained from animals bearing low tumour burden, with the animals being killed after only short periods of tumour growth.

Why can't you use animals that are less sentient?

The use of less sentient animals or those terminally anaesthetised is not possible here due to the need for the whole animal physiologically to enable tumour growth.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All of our experiments will be conducted in mice. Mice constitute the lowest mammal recognised to be relevant for human cancers. Most of the experiments planned will utilise a superficial model, which is less intrusive than implantation of tumour into the liver and does not necessitate anaesthesia for tumour measurement, as is required for liver tumour models.

Animals will be monitored daily for any signs of distress that might affect their well-being. Such signs of distress include loss of appetite, huddling, shivering or any abnormal behavioural problem. Any mice that show persisting signs of distress will be humanely killed.

Superficial tumours may develop signs of ulceration, irritation or reddening. Animals developing such symptoms will be closely monitored and where needed pain controlled through use of analgesia.
Tumours will be monitored using a tumour scoring system and humane end-points will be based on a both tumour size as well as tumour ulceration in combination with general well-being of the animal.

In the majority of experiments, this subcutaneous model will be more than sufficient to determine the effectiveness of the treatments being used with minimal harm/discomfort to the animals. However, the most promising approaches (those that show the greater impact on tumour burden) will then be tested in the liver model to further confirm the relevance of these therapies before moving forward to clinical trials in patients.

The severity of the procedures used will be kept to a minimum, whilst providing meaningful data for translation of these approaches to patient care. Discomfort and distress experienced by the animals will be limited to unavoidable procedures required for the conduct of sound research. All methods will be based closely on UKCCCR Guidelines for the welfare and use of animals in cancer research British Journal of Cancer (2010) 102,

1555 –1577. For delivery of therapeutic agents, daily maximum volume and number of injections will not exceed the limits recommended in the guidelines above.

None of the studies detailed in this project exceed a ‘moderate’ degree of animal suffering as useful data can be obtained from animals bearing low tumour burden, animals being killed after only short periods of tumour growth.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All methods will be based closely on UKCCCR Guidelines for the welfare and use of animals in cancer research British Journal of Cancer (2010) 102, 1555 – 1577.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date with advances in the 3Rs by keeping up to date with correspondence regarding this and ensuring attendance of the PPL holder and any PIL holders working on this licence at the relevant meetings.

99. Elucidating the development and function of the chicken immune system

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Chicken, Immunity, Transgenic, Gene editing, Immune response

Animal types	Life stages
Chicken	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to answer the question: As the basic structure of the birds' immune systems is quite different to mammals, how do chicken immune cells develop and perform the same basic functions of immune surveillance and antigen presentation as their mammalian counterparts?

To achieve this aim, this project will genome engineering technologies to study the development and function of the avian immune system

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Poultry, especially chickens, form the most important sector of livestock keeping worldwide, with the production of meat and eggs being a major contributor to human nutrition. Management of diseases is a major challenge to poultry production in terms of economic cost, animal welfare and, for avian influenza for example, the zoonotic challenges to human health. Increasingly, the improvement in protection against pathogens in poultry production must be achieved in the context of overall reduction of antibiotic use. Knowledge gains in avian immunology that lead to better and more efficient vaccination strategies or breeding of more healthy robust chickens will have significant academic, social, economic, environmental, and industrial impacts.

Unlike mammals, birds do not have specialised lymph nodes and have other very different lymphoid tissues. Despite this the majority of our knowledge on how vertebrate immune systems develop and function is based on mammalian model systems. To understand how the chicken system develops and functions and use this knowledge to improve animal health, we must first produce avian specific biological models. This project will enable the production and maintenance of gene edited and transgenic chickens which will be a very powerful way of generating robust biological models, and will lead to rapid knowledge gains in chicken immunity.

What outputs do you think you will see at the end of this project?

Output derived from this project will include: Knowledge gains in avian immunology

Publications on avian immunology

Novel gene edited chicken lines

Novel avian specific immune assays Improved vaccine design

Who or what will benefit from these outputs, and how?

Stakeholders have been identified as beneficiaries of this work:

The poultry breeding industry:

The consequences of improved vaccine responses and disease resistance may provide a panel of phenotypic biomarkers which could be developed as affordable tools to inform breeding strategy. We have established collaborations with major poultry breeding companies.

The animal health industry:

The data generated during this programme will allow us to improve vaccine targeting and will develop tools to modulate immune responses at mucosal surfaces.

Animal welfare:

The reduction of disease as a result of improved vaccine strategies supports the Five Freedoms implicit to animal welfare as set out by the Farm Animal Welfare Council.

General public and the environment:

The consequences of improved vaccine responses and disease resistance will lead to a reduction in the prophylactic use of antimicrobials and the risk of contamination of the food chain and the environment.

Academia and Training:

The multidisciplinary nature of this programme will provide opportunities for broad training to all staff including other members and students of the institution ('strengthen the research community in the areas of disease and pest resistance of farmed animals through interdisciplinary research and the provision of training'). Results with respect to the identification of cell subsets associated with antigen uptake, processing and presentation will be of interest to a wide scientific community and will be published in peer-reviewed journals and presented at national and international scientific meetings.

How will you look to maximise the outputs of this work?

Results will be shared primarily by publication. Owing to the high potential for major knowledge advancement; we will target general interest journals to reach the widest audience (e.g. Nature, Science, PNAS) and high-ranking discipline-specific journals (e.g. Journal of Immunology, Elife, Genome Biology). All papers will be open-access and made available . We will share our findings, including unsuccessful approaches, at international scientific conferences, engaging researchers working in diverse fields and informally through our laboratory website, our institutional websites and via social media.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of chickens is appropriate as the development of new immunological reagents and vaccines requires an understanding of the immune system in birds, and extrapolation from rodent models is not appropriate as there are many significant differences between the immune system of birds compared to mammals.

The avian immune first forms in the early embryo and is present during the entire life of the chicken. Studying the chicken immune system will involve study of all chicken age stages, including embryos.

While a chickens lifespan can be as long as 7-8 years, broiler chickens are mostly culled by six weeks of age. As a consequence of this immunisation of chickens occurs in the late embryo stages (day of incubation 17-19) and in neonatal chicks. For these reasons, studies of the immune system of chicks of this age are required and appropriate.

Typically, what will be done to an animal used in your project?

Chickens used in this programme to study the development of and function of the avian immune system may have the following procedures done to them:

Genetic modification. Changes will be made to the individual base pairs, or genes. This may include deletion of genetic information or the addition of genetic information (e.g. transgenic chickens). These changes will be made in primordial germ cells or the very early embryo. These changes will be for the duration of the chicken's life.

Genetic modification may have no apparent impact on chicken development and health (e.g. a transgenic reporter chicken expressing a fluorescent reporter protein) or may impact the development and immune system of chickens (e.g. knockout of a immune related gene or immune cell type). These changes will be for the duration of the chicken's life.

Genetic modification to delete a specific gene, maybe done in such a way that it is acute and transient (one to two days) or could occur for the duration of the chicken's life.

Injection of chickens (genetically modified and wild-type control birds) with antigens. These antigens may include known model antigens or novel vaccine antigens. Antigens may be injected in a neutral medium (e.g. saline) or adjuvants to drive specific immune responses. The duration of these procedures would vary with particular experiments, as would the route of injection. Routes of antigen administration via injection may include: intravenous, subcutaneous, intra-muscular. Non-injection routes of antigen administration may include: Intratracheal, intracloacal, intranasal and intra-ocular.

Injection of chickens with substances that modify immune responses. Substances may include natural or recombination proteins (e.g. cytokines, chemokines or growth factors), pathogen derived substance (e.g. LPS or microbial derived nucleic acids), specific immune agonists (e.g. specific agonists to trigger cell death in genetically modified cells), or a combination of these factors. The duration of these procedures would vary with particular experiments, as would the route of injection. Routes of antigen administration via injection may include: intravenous, subcutaneous, intra-muscular. Non-injection routes of antigen administration may include: Intratracheal, intracloacal, intranasal and intra-ocular.

Cell transfer: Immune cells from non-genetically modified and genetically modified chickens (including embryonic and post-hatch stages) may be transferred into non-genetically modified and genetically modified chickens to determine how the immune system develops and functions. The duration of these experiments will vary with individual experiments, but may be for a very short period (e.g. one day) or for the duration of the animals life. The duration of these procedures would vary with particular experiments, as would the route of injection. Routes of antigen administration via injection may include: intravenous, subcutaneous, intra-muscular. Non-injection routes of antigen administration may include: Intratracheal, intracloacal, intranasal and intra-ocular.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects will depend on the nature of the procedure. In some cases (e.g. in genetically modified chickens) this will be for the duration of the chicken's life, while in other cases it will be of an acute nature (e.g. injection of LPS).

Impacts may include:

- increased susceptibility to infections.
- Loss of specific immune cell populations, rendering birds refractory to successful immunisation.
- developmental abnormalities. Genetic modification of chickens to study the development/function of the immune system, may impact other body system development and/or function.
- Weight loss. Increased susceptibility to infection or developmental abnormalities can result in weight loss.
- Pain. Increased susceptibility to infection or developmental abnormalities can result in pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity of the procedures is expected to be moderate.

The severity limit for most gene edited chicken lines is expected to be mild.

In cases where genetic modification procedures effect immune function, the severity limit may reach moderate levels.

Injection of antigens or immune modifying substances will be a moderate severity level.

On balance, the proportion of minimum to moderate severity for these procedures is expected to be at a ratio of 70:30.

What will happen to animals at the end of this project?

- Killed Kept
- alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Poultry form the most important sector of livestock keeping worldwide, with the production of meat and eggs being a major contributor to human nutrition. Management of diseases is a major challenge to poultry production in terms of economic cost, animal welfare and, for avian influenza for example, the zoonotic challenges to human health. Increasingly, the improvement in protection against pathogens in poultry production must be achieved in the context of overall reduction of antibiotic use. Knowledge gains in avian immunology that

lead to better and more efficient vaccination strategies or breeding of more healthy robust chickens will have significant academic, social, economic, environmental, and industrial impacts.

The use of chickens is required to study the development and function of the avian immune system as there are fundamental differences between the mammalian and avian immune systems. For instance, birds do not have lymph nodes which are a highly developed feature of the mammalian immune system. This in turn means that knowledge derived from mammalian model systems cannot simply be used it infer information about the avian immune system.

Gene editing of chickens is a methodology that will enable the creation of high quality biological models that will enable the rapid knowledge gains in the developmental biology of the chicken immune system and an overall reduction in the number of chickens used, compared to conventional techniques.

Which non-animal alternatives did you consider for use in this project?

We considered trying to grow different chicken immune cells so they could then be studied in cell culture. Potentially we could change the genes in these cells to study gene function.

Why were they not suitable?

The number of chicken immune cell types that can be grown in culture is extremely limited and the ability to culture and gene edit keep immune cell types is lacking. Immortalised chicken cell lines for some key immune cell types (e.g. T-cells and dendritic cells) also do not exist. It is also not possible to address the key aim of this project ("How do chicken immune cells develop and perform the same basic functions of immune surveillance and antigen presentation as their mammalian counterparts in a radically different lymphoid tissue environment?") using cell culture as this cannot replicate the complexity and diversity of chicken lymphoid systems.

Our skill in culturing chicken macrophage cells allows us to carry out some experiments in cell culture without using animals. Our use of chicken embryos mostly involves injecting macrophages at unregulated young stages in eggs and many of the experiments will also be performed before hatching of the chick. The use of the chicken as a model species is an improvement over using mammals. In this instance, the chicken offers advantages over using a mouse models as the mother does not need to be killed to obtain the embryo and a surgical manipulation is not needed to introduce donor reproductive cells into an embryo. The majority of experiments will also be carried out at unregulated developmental stages (before day 14 of incubation).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For chicken, we have estimated the total number of genome edited and transgenic lines we will establish over 5 years, the number of genome edited offspring that will be bred during that time period. For each genome edited line, we will need to generate surrogate host birds that will carry the genetic material. For each experimental genome edited line, we use a power calculation to determine the number of animals we need to breed in order to carry out the required experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The cell culture of some immune cells types (e.g. macrophages) enables us to carry out some experiments without using animals. For the production of novel gene edited chicken lines the injection of lentivirus pseudovirus or donor reproductive cell are carried out at unregulated developmental stages in eggs and many of the experiments will also be performed before the chick would hatch. The production of novel transgenic immune cell reporter lines of chickens reduces the number of animals used overall as if offers a highly efficient model to visualise and characterise specific immune cell populations compared to conventional techniques.

The use of avian species as models offers advantages over mammalian species for the study of the early stages of the development of the immune system. In this instance, the chicken offers advantages over using a mouse models as the mother does not need to be culled to obtain the embryo and a surgical manipulation is not needed to introduce donor reproductive cells into the embryo. The majority of experiments will also be carried out at unregulated developmental stages (before day 14 of incubation) in the egg.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

With our colleagues at our Institute we have worked to improve the efficiency of hatching surrogate chicks carrying the donor genome edited reproductive cells. Colleagues have developed germ cell culture and genetic screen techniques that in combination with genome edited surrogate hosts that mean that 100% of the offspring are derived from the donor genome edited cells. This means that compared to older methods, there are no excess non-GA bird produced. We are also developing methods to reduce breeding by directly mating the surrogate hosts to generate pure offspring in a single generation which greatly reduces the number of chicken bred in these experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use the chicken as a model to study the development and function of the avian immune system. The use of lentivirus transgenesis of early embryos or cultured avian

reproductive cells that can be genetically modified to disrupt gene function and used to produce genome modified birds is unique to the chicken and avian species.

The production of transgenic immune cell reporter chickens (e.g. the expression of a fluorescent reporter protein in selected immune cell populations) is not expected to cause any pain, suffering, distress, or lasting harm to the animals.

In the case of gene edited birds in which a particular gene is knockout out to access the impact of the gene product on the development and/or function of the immune system, we are refining systems that mean that this will result in temporally or cell specific restriction of gene knockout to minimise pain, suffering, distress, or lasting harm to the animals.

The studies are designed to be as minimally invasive as possible; the vast majority of birds will only be blood sampled to confirm transgenesis and/or gene editing and then used for breeding as required. All new genetically modified lines are closely monitored for any adverse phenotypes. We work closely with our named veterinary surgeons.

Why can’t you use animals that are less sentient?

The chicken is an important agricultural animal and it is important to study the development and function of the immune system of this animal for sustaining and improving food production. The understanding of the genes involved in the major production traits of disease resistance, feeding, and production traits will lead to more efficient agriculture and the production of more healthy, robust poultry.
The biology of immunology of birds is of interest in terms of understanding evolution of the immune system and function of individual immune cell types of all vertebrate animals (including humans).

Applications of gene editing technologies in genetics and immunity also must relate to the function of the intact animal. As the chicken is used as a livestock species for meat and egg production, studies using these bird will largely be focuses regulated embryonic stages (post day 14 of incubation) or post- hatch stages. For studying the early development of the immune system in vitro culture techniques and/or embryos at unregulated developmental stages (before day 14 of incubation) in the egg will be used as appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are developing gene editing technologies which will enable the temporally and immune cell lineage specific manipulation of gene function. The aim of this refinement will be to narrow the impact of gene manipulation to produce more precise, high quality data on gene function and to reduce pain, suffering, distress, or lasting harm to the animals.

We have instigated monitoring the weight of our newly hatched genome edited chicken to verify a normal growth curve for hatchlings.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work is undertaken in close collaboration with our Named Veterinary Surgeons. Study protocol forms must be completed and submitted to them prior to proceeding with any

experimental work and animal unit staff are closely involved in experimental work and will offer advice on improvements to experimental protocols and monitoring/raising of the animals.

The group contains all the competencies required to perform the majority of techniques and procedures outlined in this project. Where additional expertise is required, staff will undergo appropriate training until competent.

Animals will be kept in accordance with annex III of Directive 2010/63 EU and/ or Home Office Codes of Practice, as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We communicate with our NVS on current developments to enrich the environment of housed chicken. Our poultry workers are trained in proper welfare techniques for birds and we are strictly monitored by our veterinary scientists and the Home Office on current practices. We visit the NC3R website for new information on animal use in research. We hold annual conferences in veterinary ethics and welfare.

100. Dissecting the response to metabolites in the inflammatory micro-environment

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

immune-mediated inflammatory diseases (IMIDs), inflammatory disease micro-environment (IDME), ectopic lymphoid structure (ELS), metabolic pathways, immune response

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to identify the metabolic type of immune cells in inflammatory diseases that are characterised by the presence of ectopic lymphoid structures (ELS), collections of immune cells in specific parts of the body that contribute to the development of diseases including Sjogrens syndrome and Rheumatoid arthritis. This information will potentially identify new ways to treat these diseases by changing the cell's metabolic type to one that is anti-inflammatory.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will open new possibilities for drug development by aiming to change the

metabolic type of immune cells to one that is anti-inflammatory. In the longer term, this will impact positively upon the clinical management of chronic inflammatory diseases such as Sjogrens syndrome, Lupus, Multiple Sclerosis and Rheumatoid arthritis, which all involve the development of ELS.

What outputs do you think you will see at the end of this project?

We will generate new information on the role that the metabolism of immune cells, and metabolic products such as lactate, play in the formation of ectopic lymphoid structures (ELSs) in inflammatory conditions such as Sjogren's syndrome, Lupus, Multiple Sclerosis and Rheumatoid arthritis. These ELS are known to help maintain the inflammation in these diseases. The successful delivery of this research programme is likely to result in high impact publications benefiting the scientific community at large.
The new information in this project on metabolism and immunity may also encourage new thinking in other diseases that are driven by uncontrolled inflammation, such as cardiovascular disease.

Who or what will benefit from these outputs, and how?

We have chosen Sjogren's syndrome as a paradigm for inflammatory conditions that involve the formation of ectopic lymphoid structures as a key part in disease pathogenesis. The murine model we have chosen, the sialoadenitis mouse model, recapitulates very well the clinical features of this disease in humans and will allow us to carry out research that will give short, medium and long term benefits as follows:

Short term gains: From the start of the project a range of communities will benefit as we will share any knowledge generated with the wider scientific, clinical and pharmaceutical industry communities through attendance at conferences where we will present the data, and through publication of the data in appropriate journals using the ARRIVE guidelines on reporting in vivo experiments. We will also ensure that refinements that we develop over the course of the in vivo work are also reported as part of our commitment to the 3Rs. Additionally, we will be engaging with established Public and Patient Involvement and Engagement (PPIE) groups to ensure our communications are suitable for a lay audience.

Medium term gains: We anticipate the main outputs from this work to be the scientific data and associated publications, and the identification of novel drug targets for chronic inflammatory diseases such as Sjorgens syndrome. We disseminate our work frequently at conferences and have been invited to speak about our work in more than 20 occasions in the last three years.

We would also envisage the submission of a patent that would cover the “use of any novel agents in the treatment of chronic inflammatory conditions” and would benefit the pharmaceutical industry by identifying a potential new therapy.
