Animals (Scientific Procedures) Act 1986

Non-technical summaries for project licences granted July - December 2022

Contents

1. The mechanisms underpinning ‘steroid’ (glucocorticoid) development of obesity and diabetes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Steroids, Glucocorticoids, Diabetes, Obesity, Brain

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Synthetic glucocorticoids, commonly called steroids, are used as medicines to treat a wide range of illnesses such as asthma, rheumatoid arthritis, and multiple sclerosis. Although well tolerated, long term, high dose use can lead to side effects including obesity and diabetes. Therefore, the aim of this study is to identify how longer term use of glucocorticoids acts in specific parts of the brain to increase food intake, and to alter processes in the body leading to high glucose and diabetes. Our long term aim is to find alternative synthetic glucocorticoids or alternative ways of administering them to reduce the associated obesity and diabetes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Glucocorticoids (steroids) are a widely used class of medicines. They are anti-inflammatory and used to treat diseases such as asthma, arthritis and autoimmune conditions such as multiple sclerosis as well as in the treatment of cancer. With long term, high dose use, patients can develop side effects similar to those seen in the metabolic syndrome, a cluster of illnesses associated with obesity and diabetes. These include weight gain, especially around the waist, type 2 diabetes, and fatty liver disease. These side effects can limit the use of an otherwise good and inexpensive medication. In this body of work, we want to understand how the glucocorticoids cause the side effects. By understanding this, it might be possible to find other glucocorticoids that don't cause the side-effects or medicines to be given with the glucocorticoids that decrease the side effects. This would mean that more patients could be treated with these medicines.

What outputs do you think you will see at the end of this project?

At the end of the project we will have gained new information about how glucocorticoid treatment causes side effects such as obesity and diabetes. Diabetes is a serious, longterm illness, that often requires daily medication. Furthermore, when not well controlled, diabetes can increase the risk of kidney disease, blindness and cardiovascular disease, including heart attacks and strokes. Obesity is a condition, which itself can lead to diabetes, but can also increase the risk of certain cancers. All of these are life limiting for the patient and the complexity of the treatment decreases their quality of life and makes it very expensive for the NHS.

The information generated from this proposal will be shared in research papers and with other scientists and doctors at conferences. If we can understand how the side effects develop then we, with doctors and the pharmaceutical industry, will be able to design new types of glucocorticoids which don't cause the problems or different treatments given with the glucocorticoids to reduce the side effects.

Who or what will benefit from these outputs, and how?

The main beneficiary of this work will be patients treated with glucocorticoids and their doctors who are able to prescribe them with reduced worries about side effects. The NHS will also benefit, as glucocorticoids are cheap medicines and will be able to be used more widely. Additionally, the costs of treating the side effects such as diabetes are also high, so these may be reduced if the side effects of glucocorticoids are reduced. The scientific community will also benefit from the outputs generated in this project, as we will be increasing the knowledge of how these steroids work.

How will you look to maximise the outputs of this work?

Previously, we have collaborated with groups at other universities, with pharmaceutical companies, and with clinical endocrinologists who see patients with these side effects. Therefore, we are well placed to contact those groups of people who can use the outputs of our studies most effectively. These collaborations have not only been for exchange of knowledge, but also to learn the most refined way of carrying out the experiments. We will present our early data at conferences, so fellow scientists and doctors can comment on the experiments while they are progressing. This will ensure that the correct studies are being carried out. We will also publish our data, whether successful or not, in open access

scientific journals as well as sharing our new publications on social media platforms to increase the visibility. All raw data will be made available upon request.

Species and numbers of animals expected to be used

- Mice: 10500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For our research we use an adult mouse model, which is treated with glucocorticoids (steroids). This model is able to mimic the side effects of the treatment that are seen in humans. Also, the pathways in the development of these side effects of obesity, diabetes and fatty liver disease are thought to be similar between humans and mice. In addition, we are looking at actions in the brain so we need to collect brain tissue and we look in mice bred with certain pathways removed, making these animals the best model for our investigations.

Typically, what will be done to an animal used in your project?

Most mice in this project will be treated with glucocorticoids to look at the side effects of diabetes and obesity. Typically, we give this treatment in their drinking water to reduce the stress of handling and the short term pain of an injection. They will be weighed frequently and depending on what we are looking at they may have a glucose tolerance test, where they will be fasted before they are injected with glucose and small blood samples taken from the tail. Alternatively, they may have their metabolic rate measured by placing them in special cages that can measure this. We also may look at how much fat they have using a type of MRI scan, but as it doesn’t give an image, they don’t need to stay as still. Before the end of the study, we take blood samples from the tail to measure things such as stress hormones and insulin. Many of our protocols look at changes in factors associated with appetite and feeding in the brain, but these measurements are made after the study finishes.

Some studies will be carried out where we need to give drugs directly into the brain. For these studies, mice will undergo a short surgery with a quick recovery anaesthetic and a device will be inserted, so these drugs can be directly administered to the brain when the mice are awake and freely running around. During and after surgery, mice will be given appropriate pain relief, kept warm and given soft food to help them recover as quickly as possible.

What are the expected impacts and/or adverse effects for the animals during your project?

With glucocorticoid treatment the mice should gain weight and become overweight or obese. The treatment period for these studies are 4 weeks at their longest, so the animals are just at the start of developing diabetes. Some will develop diabetes and therefore drink more and urinate more, but we will change their bedding more frequently to account for

this. As the measurement of food intake is important for our research, animals will often be in a cage on their own, which can disrupt their normal behaviour, but we provide them with tubes to play and hide in and additional bedding and chew sticks to reduce the impact of this. The total length of time where the animals would be housed alone is generally 7 weeks (1 week to acclimatise, 2 weeks to take normal measurement and then 4 weeks on treatment). A very few studies may want to investigate genetic changes related to glucocorticoids in mice and then mice may need to be housed alone for up to 6 months.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals will have a mild experience. They will eat more and will gain weight, but not to the point that it impacts their welfare. There could be transient pain from injections or blood sampling. There may be a mild stress effect of social isolation.

The animal having surgery will have a moderate severity experience. They will be given quick recovery anaesthetics to reduce the impact of the anaesthetic, painkillers to reduce any pain and will be kept warm until fully recovered. Mice tend to recover quickly from this surgery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We look at the effects of glucocorticoids (steroids) on the whole of the body. We mainly give these to the animals in their drinking water, which is similar to patients swallowing tablets, and we look at their effects on multiple organs in the body, such as fat, liver and muscle. It is not possible to mimic these effects in dishes of cells as you cannot look at the overall effect on the body.

Additionally, we look at how glucocorticoids acting in the brain then signal to the other organs in the body. As we are looking at how one organ in the body controls others, a whole body system is needed for this.

We have found from our previous studies that mice respond similarly to patients when given these steroids, so they are used in our studies.

Which non-animal alternatives did you consider for use in this project?

A potential alternative is to work on neurons growing in culture. However, these neurons do not survive and do not develop into cell lines. There is a technique for adapting them to

grow continuously which is complex but possible, and this offers a way of addressing specific questions about the neurons that regulate food intake. Several years ago, we obtained immortalised hypothalamic neuronal cell lines from a collaborator to determine if they produced a key neuropeptide regulating food intake. Despite a lot of effort in culturing the cells, we were unable to get these neuronal cell lines to synthesise this neuropeptide. We subsequently worked with another collaborator who uses embryonic stem (ES) cells differentiated into neurons and studied the production of these neuropeptides. As the neuropeptides are a glucocorticoid (steroid) target in the brain, we will be able to assess the effects of chronic glucocorticoid treatment on these peptides in the ES cells. This would complement the *in vivo* studies where we consider the effects of glucocorticoids on food intake.

Why were they not suitable?

As stated above, neurons which were adapted to grow continuously did not produce the neuropeptides, but we have subsequently collaborated with a research group using ES cells which could provide key information on the effects of chronic glucocorticoid treatment. However, there is growing evidence that these neurons are quite heterogeneous in the brain and they act at several different target neuronal populations which would be impossible to mimic *in vitro*.

In addition, to prove that glucocorticoids are acting via these specific neuropeptides to modify food intake, body weight and peripheral metabolism, we will still need to do these studies *in vivo*. We also need to study the effects of glucocorticoids on multiple body tissues such as liver, adipose tissue and muscle at the same time, to examine the molecular changes underpinning the side effects in patients treated with these medicines. Therefore, single cell types will not inform us of the overall effects on the body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Generally, we use the data from previous studies to help us estimate the number of animals required for an experiment. This allows us to use the minimum number of animals to give us a reliable answer to the question. Where it is a completely new experiment, we will use a small group size at the start, so we can monitor how many animals we will need.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To design the experiments we use the NC3Rs experimental design assistant to get the best study design and to use the correct number of animals. At the end of the study we take organs from the animals that we might not necessarily need at the moment, but so we wouldn't need to run another study in the future if we need to look at the effects of treatment that organ.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We breed the minimum number of animals possible for our projects that will give us the best experimental results. When we start new studies, we carry out pilot studies to understand how the animals will react and to help us estimate the number of animals we will need. At the end of the study, we take as many tissues and organs as possible, to minimise the need to run later studies, we also share the tissues from some studies with other groups, so they don't need to run their own experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This licence application only uses mice, the least sentient animal possible for our studies. Mice are used as they give similar responses to glucocorticoids (steroids) as is seen in patients treated with these medicines. We mostly give the glucocorticoids in the drinking water, so the animals don't need to be handled and stressed as much and this approach reduces the need for multiple injections. None of the mice with genetic changes show any side effects to these gene changes.

Why can't you use animals that are less sentient?

We have investigated zebrafish models and there are some good examples of novel data describing how glucocorticoids act within the cells. There has also been information on how glucocorticoids control development of the zebrafish. However, the systems are too limited to be used to study whether the glucocorticoids are acting in the brain or directly in organs in the body that regulate metabolism. In addition, there seem to be key differences in zebrafish in the expression of enzymes that activate/inactivate glucocorticoids. We have also investigated what is known in zebrafish about the melanocortin system, which is a target of glucocorticoids that this project addresses. Unfortunately, previous work has only studied a rudimentary peptide system in another organ and there is no obvious melanocortin system in the brain to work on.

Therefore, mice are the least sentient animals that mimic the glucocorticoid induced changes that lead to obesity and diabetes as seen in human patients. As the glucocorticoid effects which lead to obesity and diabetes develop over time, we cannot do these studies in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animals in our studies are already closely monitored to ensure they suffer the minimum pain and harm. The small number of animals that undergo surgery get pain medication, and are fed soft food and kept warm after the operation to minimise any pain and suffering. Where animals need injections, the mice will be handled to get them used to this prior to the experiments. We also keep ourselves updated so we are informed of any improvements that we can implement to minimise any harm to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the PREPARE guidelines as well as any advice we receive from the statisticians, vets and NACWOs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To keep informed of advances in the 3Rs, we regularly check the NC3Rs website. We also receive updates from our animal unit and our NTCO about any changes. We also attend the workshops organised by the NC3Rs and our university to keep informed of new advances in animal welfare and the 3Rs.

2. Novel Protein Targets for Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, therapy, brain, metastasis

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to establish novel proteins as prognostic markers and possible therapeutic targets in primary brain cancer and brain metastasis. The proteins have many targets in brain cancer cells and state-of-the-art techniques will be used to elucidate the mechanism of how the proteins trigger brain cancer and/or metastasis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brain cancer is a major unmet need with 5 year survival being 10% only. Identifying a new target in brain tumours might pave the way for further understanding of how the tumours progresses/metastasizes and may be arrested therapeutically.

What outputs do you think you will see at the end of this project?

Establishment of a novel drug target in cancer. We expect multiple publications, datasets and future drug discovery endeavours arising from this study.

Who or what will benefit from these outputs, and how?

Glioblastoma multiforme (GBM) is a highly invasive brain cancer with very poor patient 5-year survival. Since identifying therapeutic interventions for GBM is a major unmet need, multiple scientific groups around the world are focused on this disease. A simple keyword search on pubmed.gov reveals that there are over 39,000 publications on GBM, with over 230 in 2020 itself, while clinicaltrials.gov reports over 480 active GBM clinical trials. Furthermore, finding a kinase (a type of enzyme) that is involved in promoting GBM and could be targeted by drugs would have considerable interest to basic scientists working on how the immune system is controlled, the effects of genes, how messages are sent between and within cells and how cancer occurs It will also be of interest to translational scientists working on the mechanisms of carcinogenesis, pharmacology and biomarkers, through to pathologists and medical oncologists involved in managing patients with brain cancer. Those engaged in medicinal chemistry and personalized medicine may find the results helpful to their work and the ultimate aim is to help patients.

The findings of the project will clearly benefit basic scientists, clinicians, oncologists, and patients.

The project will generate novel data about the prognostic and diagnostic significance of biomarkers in GBM.

The project will also identify mechanisms of how cancer spreads to the brain from the breast.

How will you look to maximise the outputs of this work?

My collaborators in USA will also be involved in developing tools for research and will be in a position to disseminate tools and knowledge to the scientific community in USA and beyond. The fact that the proposal requires a diverse range of state-of-the-art techniques available at our establishment, makes it probable that most of the academic areas that would benefit from the research will be covered when our findings are disseminated at scientific conferences and at seminar presentations. Moreover, the research findings will be published in open access journals to allow anyone to see it.

Species and numbers of animals expected to be used

- Mice: 6100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The initiation and progression of cancer involve a complex interplay between genetic mutations, the cell-of-origin and its microenvironment, cytokines (inflammatory molecules) and growth factors, and the extracellular matrix (the environment the cells are suspended in). In some cases, development of the disease is a multi-step process that occur over months. It is therefore a very difficult process to study in a cell culture system, because we can't re-create all the environmental conditions that might influence how cancer develops and so may not get accurate results. Even the most sophisticated cell culture systems existing today will select for specific properties in a heterogeneous (mixed) cell population and allow certain cells to grow, while other cells, which might be more relevant to the disease don't or grow poorly. This is particularly true in the study of brain cancer where the extracellular matrix is composed of vastly different components as compared to any cell culture. It is therefore essential to use the brain of a whole organism to properly and faithfully reproduce the disease development and maintenance and make discoveries that can help patients suffering from cancer. Onset, maintenance and progression of cancer are complex biological processes that cannot be replicated in lower organisms. Pre-cancerous and fully malignant cells are highly dependent on interactions with the microenvironment and the extracellular matrix and must be considered in the context of the whole organism. The mouse brain is evolutionarily closely related to human, mice are relatively easy to breed, and the mouse genome is amenable to genetic modification to introduce mutations that occur in man. Therefore, adult mice represent the best available model organism for studying cancers.

Typically, what will be done to an animal used in your project?

Animals with specific alterations in the genes which encode the proteins of interest will be bred. Tumour cells will be implanted into these mice and "wild-type" animals (mice which do not bear these genetic alterations), either under the skin or by injection through a small hole in the skull into a specific region of the brain. When we are studying tumour metastasis (spread), the original tumour under the skin may be removed surgically, while we look for deposits appearing in the brain.

What are the expected impacts and/or adverse effects for the animals during your project?

The surgical procedures to create the hole in the skull for injections and to remove any primary tumours could cause pain, but this will be prevented by giving analgesics before and after the surgery, as advised by the vet, and general anaesthesia during the procedure. Tumour development generally leads to weight loss and loss of appetite. Animals will be euthanased before any further welfare issues can arise.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As we are studying tumour development, most of the animals being studied, unless they are control animals, will develop tumours. Analgesia is given for surgical procedures. Any mouse exhibiting early stages of discomfort from the tumour will be killed and organs harvested for further analysis. Where we give drugs, these will have been shown to be safe and so should have no side effects. Overall, as we will use early humane endpoints,

we expect 20% of mice to exhibit moderate severity, with the remaining animals exhibiting mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development of glioblastoma multiforme (GBM) is a complex multi-step process that occurs over months. Onset, maintenance and progression of GBM are complex biological processes that cannot be replicated in lower organisms or cell cultures. Pre-cancerous and fully malignant cells are highly dependent on interactions with the microenvironment and the extracellular matrix and must be considered in the context of the whole organism. It is therefore essential to use the brain of a whole organism to faithfully recapitulate the disease development and maintenance and make discoveries that can help patients suffering from GBM. The mouse brain is evolutionary closely related to human, mice are relatively easy to breed, and the mouse genome is amenable to genetic modification to introduce mutations that occur in man. Therefore, mice represent the best available model organism for studying brain cancers, especially GBM.

Which non-animal alternatives did you consider for use in this project?

Brain cancer cell lines

Why were they not suitable?

Initial proof-of-concept studies will be carried out in patient-derived GBM cell lines. However, onset, maintenance and progression of GBM are complex biological processes that cannot be replicated in lower organisms or cell cultures.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate using 600 animals per year in maintaining the breeding colony and another 620 animals, some of which will have come from that colony, in experimental procedures; a total of 1220 animals per year, or 6100 over the expected term of the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During experimental design, we utilised power calculations and also previous literature in the field to ascertain sample size. We also utilised the NC3R's experimental design assistant to ascertain sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Power calculations will be carried out to ascertain sample size in collaboration with a statistician. Standard immunocompromised genetically altered mouse lines will be purchased from commercial suppliers, but the lines with modifications in the genes of specific interest are not commercially availabe and will therefore be bred in-house. I am experienced in colony management and will use strategies, e.g. those outlined in the NC3Rs Efficient Breeding of Genetically Altered Animals pages, that help to minimise numbers bred. I will take advice on breeding strategies from the NVS (Named Veterinary Surgeon) and NACWO (Named Animal Care and Welfare Officer) responsible for the breeding unit, as required. I will share lines of interest with collaborators and will “batch” breed to allow shared controls for studies where appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

There are three main models which we plan to use. All these models allow us to monitor the tumour growth in mice with minimum harm as appropriate early humane endpoints can be identified.

1. Ectopic tumour growth wherein cancer cells are injected under the skin in an area where the tumour won’t cause any pressure on the surrounding tissue but will allow tumour growth and tumour measurements using callipers to be easily monitored. We will ensure that animals are killed before the tumour causes any outward signs of discomfort.

2. Cancer cells are injected as in (1), with the intention that some will migrate to the brain (a model of metastasis). The original tumour may be removed surgically, so as not to grow to a size that might cause welfare problems. Mice are expected to recover completely in a very short space of time after the surgery. Tumour growth in the brain may lead to weight loss and loss of appetite, but we will monitor animals carefully for these (or any other signs of illness) and animals can be killed humanely as soon as they become apparent.

3. Intracranial injection is where we will implant tumour cells directly into the brain of anaesthetised mice, as a model of primary brain cancer. Mice are expected to recover completely in a very short space of time after the surgery. Tumour growth leads to weight loss and loss of appetite, but we will monitor animals carefully for these (or any other signs of illness) and animals can be killed humanely as soon as they become apparent.

Why can’t you use animals that are less sentient?

We need to monitor tumour growth in live animals which are closely related to human physiology. Mice and human brain are quite alike when it comes to supporting tumour growth while immunocompromised and well established tumour mouse models exist which allows easy execution and interpretation of scientific work. Less sentient or immature animals would not be ideal since they will have neither the matured organs to support the tumour nor will they exhibit the complex blood- brain barrier phenotypes typical of adult mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Analgesic will be administered prior to any surgery, as advised by the vet. Mice will be under anaesthesia for all surgical procedures (including the intracranial administration and the injection of tumour cells into the mammary-fat-pad). All surgery will be performed under strict aseptic conditions and mice will be monitored carefully for any evidence of post-operative pain or discomfort, as well as for signs of tumour development. Drugs given will be non-toxic and the route of dosing, volumes and injections will be those expected to cause the least discomfort possible for the study aim.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The Nc3R guidelines and power calculations from pilot studies will be used to refine all experiments. Published works on the models will also be utilised.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular online reading on the 3R websites (such as the NC3Rs), remaining up to date with the literature in the field of research and departmental emails and alerts, including advice from the Named Information Officer (NIO) and Named Veterinary Surgeon (NVS)/ NACWO (Named Animal Care and Welfare Officer).

3. Vascular-Mesenchymal Crosstalk in Bone

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

bone, regeneration, chemotherapy, radiation, blood vessels

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to explore new ways to promote bone regeneration

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The proposed research will aim to identify novel targets to promote bone regeneration. Musculoskeletal disorders affect approximately 50 % of the human population, thus posing a significant health, psychological and economic burden on healthcare systems. Further regeneration of the bone and bone marrow microenvironment after cancer therapy still remains a problem. Identification of cellular and molecular drivers of bone regeneration would be of immense value in the clinic to prevent, manage and treat bone-loss and bone diseases.

What outputs do you think you will see at the end of this project?

Although there have been advancements in our understanding of vascular and skeletal dynamics in the bone microenvironment, a comprehensive understanding remains elusive. Primarily, our research will explore the cellular and molecular players, involved in bone regeneration. This will further add to existing biological knowledge, scientific publications, and identification of novel therapeutic targets to improve disease outcome and thus patient prognosis.

Who or what will benefit from these outputs, and how?

The work detailed in this project will facilitate healthcare industries to develop improved therapies to prevent, manage and treat bone diseases. Therefore, the primary beneficiaries will be the patients suffering from bone loss conditions. In addition, this research will result in the development of a new experimental system (bone vasculature) to an already multidisciplinary unit at the establishment. Being one of the pioneers in the field, my expertise will be beneficial to multiple scientific communities such as musculoskeletal, vascular, and regenerative biology. My research interests and expertise in bone vasculature will provide ample opportunities for scientific collaborations within the establishment and across the UK.

How will you look to maximise the outputs of this work?

1. Peer-reviewed, high impact and cutting-edge publications.

2. Presentation of the work in international conferences by my team members and me.

3. Publishing of negative data and unsuccessful experimental approaches.

4. Public engagement.

5. Dissemination of new findings through media and social media.

Species and numbers of animals expected to be used

- Mice: 11000 for 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

One of the key aspects of this study is to analyse the crosstalk between blood vessels and mesenchymal cells. The work described in this PPL requires the use of genetically modified adult mice to study the role of vascular niches in healthy skeletal bone versus during bone damage, i.e. following chemotherapy treatment. In the laboratory, we have availability to a wide variety of reagents suitable for mice to study clinical conditions.

Typically, what will be done to an animal used in your project?

To address the outlined research aims, our work requires the use of genetically altered mice which will bred under this project. Mice may receive substances such as Tamoxifen to alter their genetic makeup. Mice may receive a lethal dose of irradiation followed by reconstitution of the bone marrow via an injection of cells. Mice may then receive therapeutic agents to (drugs and inhibitors). Blood samples may be collected via cardiac puncture for further analysis. Mice may be injected with various therapeutics, e.g., chemotherapeutic agents, to investigate bone regeneration responses. Mice will then either humanely killed or undergo imaging under a terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice that undergo irradiation are more susceptible to infection in the first 28 days following the procedure. This may manifest as weight loss, diarrhoea, or general malaise such as hunched posture or ruffled fur. Mice will be given antibiotics in their drinking water to reduce the risk of infection. Once past this time point no further adverse effects are expected. Mice that are given gene altering drugs may experience transient weight loss during the administration phase but are expected to recover quickly once this has been completed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 50% Subthreshold
- 30% Mild
- 20% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are necessary to study the complex microenvironment in the bone marrow as currently other approaches, such as culture techniques, do not provide a realistic alternative. Furthermore, genetically modified mice provide the unique ability to study the role of specific genes in the complex environment of the living organism. We will aim to minimise the use of animal models where possible, whereby we will use the most refined animal model to address our research questions.

Which non-animal alternatives did you consider for use in this project?

Initial studies will be performed on cell-based assays using primary endothelial cells and differentiated cell populations. As, 2D studies are poor representative of in-vivo conditions, our aim is to interpret the physiological relevance of in-vivo cell behaviour by using 3D co-culture models.

Why were they not suitable?

Although in-vitro techniques such as cell culture can provide insight into specific cell types, these techniques cannot accurately replicate the physiological relevance and multifaceted environment in the bone tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mice numbers are calculated based on our previous data and experience. When required, we shall consult with statisticians within the department and apply statistical methods to determine the appropriate number of mice for each experiment. Alternatively, where experimental approaches are used routinely, previous experience will be used to determine the animal numbers used for the experiment, ensuring the least number of animals are used as possible.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Each experiment will be planned to adhere to the NC3R's experimental design. Experimental Design Assistant, a tool used to aid in efficient experimental design prior to embarking on the experimental work. Where possible other approaches, including cell-based culture systems, will be employed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At every stage in our experiments, consideration will be given to ways in which we can reduce the number of animals. We will adhere to the following steps:

1. Appropriate and efficient breeding strategies.

2. Use stored samples, e.g., tissues acquired from other laboratories.

3. Store tissues from our experiments and provide them to other laboratories as required.

3. Perform pilot studies with a limited number of mice prior to embarking on larger experiments.

4. Where possible, use non-animal models such as 3D co-culture assays

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The physiological similarities between mice and humans make them an excellent model system for gaining insights into the regulation of the bone microenvironment in humans.

Moreover, they share similar endocrine systems to humans that allow us to extrapolate our findings to human disorders, including bone diseases. Irradiation may be used in to investigate role of blood vessels during bone remodelling and to study the regenerative potential of blood vessels cells. Lethal irradiation in all our experiments will be followed by an intravenous injection of cells to reconstitute the immune system. Irradiated mice engrafted with hematopoietic stem cells will be continuously monitored for signs of infection, anaemia or other symptoms of irradiation-induced illness (e.g., weight loss) till the end of the experiment. To visualise angiogenesis and follow the interactions of blood vessels with surrounding cell types and microenvironment by in-vivo microscopy will be performed under terminal anaesthesia. This in-vivo imaging approach will be crucial to determine the dynamics of blood vessel growth and the microenvironment. After induction of anaesthesia with volatile anaesthetics, surgery will be performed under general terminal anaesthesia. Mice will be anaesthetised to surgical depth/stage. Aseptic skin preparation will be performed; followed by an incision will be made on one of the bones (e.g., tibia, femur) to expose the bone surface for imaging.

Mice will be continuously monitored. All this will be performed under aseptic conditions. The mouse will be placed on a Biotherm stage warmer at 370C and imaged using a multiphoton microscope. The fluid will be administered and volatile anaesthetics induce and maintain the mice under deep anaesthesia. Either before or during intravital microscopy, mice may be injected with contrast dyes, fluorochromes or other imaging agents via an appropriate route to visualise blood vessels and surrounding cells. Transgenic mice expressing reporters such as GFP may be used to track blood vessels and pericytes. LASA guidance will be followed for aseptic surgery. In-vivo imaging will be critical in providing insights into the endothelial mesenchymal interactions in bone. Most importantly it will be done under general terminal anaesthesia. Any animals exhibiting signs of distress or significant ill health will be immediately humanely killed.

Why can’t you use animals that are less sentient?

Bone regeneration depends on the number of systemic factors. Interactions and dynamics working during regeneration are impossible to accurately replicate in invertebrates. Transgenic mice are currently the only system for analysing the developmentally regulated expression of mammalian genes in the complex environment that exists in the living organism.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In-vivo imaging will be carried out under terminal anaesthesia. This to minimise any stress or suffering of the animal still provide the required information to achieve the scientific objectives.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The dosages of drugs will be decided based on LASA guidelines. LASA guidelines will be used to guide surgery, including injection and surgery of mice for in-vivo imaging under terminal anaesthesia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attendance of internal and external NC3Rs seminars and conferences, in addition to monitoring of their website and signing up for the newsletter. We will also have access to an NC3R's regional manager as well as the establishments Named Information Officer

4. Understanding the Role of Nicotinamide Adenine Dinucleotide (Nad) Synthesis in Immune Cells

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

Immunology, Infection, Metabolism, Therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how Nicotinamide Adenine Dinucleotide (NAD) synthesis from vitamin B3 and its precursors supports immune cell function and underpins their role in infection responses.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Immune cells (white blood cells) importantly protect us from cancer and infectious disease. However, invasive fungal infections remain a significant global challenge that kill more people worldwide each year than breast cancer or malaria. For example, the fungal pathogen Cryptococcus neoformans, which is prevalent in the environment, causes infection mainly within the lungs and central nervous system (CNS) where it can lead to fungal meningitis and is responsible for >200,000 deaths per year. This problem is worsened by increasing rates of resistance to the limited selection of antifungal drugs available. It is therefore now becoming clear that improving immune responses to these

infections is urgently needed as a new approach that will help reduce the mortality rate for these infections.

In the last decade our understanding of how immune cells work has been transformed by the observation that their activity is very closely linked to a series of chemical processes known as metabolism. These processes break down nutrients such as sugar to provide energy and building blocks for the cell. Recent research has revealed that immune cells must dramatically change how they break down nutrients to carry out their protective functions. Additionally, studies in patients with infectious disease, such as chronic viral infection, have revealed that these processes are often impaired in immune cells in these conditions. This is likely also to be the case in fungal infection, although to date it has not been studied in depth. It may be possible therefore that correcting these changes in metabolism can restore normal, safe immune cell activity, and yield better treatment for these diseases.

This project will investigate one possible pathway to control immune cell metabolism and restore their normal function. Specifically, I will test how the production of a molecule called nicotinamide adenine dinucleotide (NAD) is linked to immune cell metabolism and their protective and harmful activity. NAD is produced from vitamin B3 and is required for all stages of the breakdown of sugar and other nutrients in cells. We have already identified that when immune cells are activated (switched on) in the laboratory, they turn on an enzymes which make NAD from vitamin B3. Additionally, when these enzymes are not active, immune cells have much lower rates of metabolism and produce much less of certain key immune signals. In this project we will alter NAD synthesis in immune cells in murine models of fungal infection (specifically Cryptococcus neoformans). This will help us to test whether new drugs targeting this might be helpful in these conditions.

What outputs do you think you will see at the end of this project?

We will generate new information on how NAD synthesis from vitamin B3 and its precursors support the metabolism and function of immune cell populations. We will identify whether targeting NAD synthesis alters immune cell activity and disease progression in murine models of fungal infection . Together these data will enable us to understand whether these pathways could be targeted as novel treatments for fungal infectious disease.

We envisage that this work will lead to several publications in reputable open access journals in the immunology/life sciences field.

We believe that the information generated over the project lifetime will support funding applications to begin human studies.

Who or what will benefit from these outputs, and how?

The project will deliver benefit to immunology and metabolism researchers in the short-term, through the generation of new knowledge and understanding about how vitamin B3 supports the metabolic activity of immune cells. It will also provide key information about how altering NAD synthesis in immune cells influences immune cell activity and disease progression in models of fungal infection.

In the medium term, the work here will be the first of its kind to interrogate the importance of NAD synthesis in the immune system and will identify specific components of this

pathway which could proceed to translational research and the design of novel therapeutic compounds.

In the longer-term, we envisage that this work may lead to the design and use of novel therapies which modulate NAD synthesis in the immune system to better treat infectious disease.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work we have already identified two other groups within our establishment who work on similar models. These collaborations will enable sharing of expertise and optimisation of our experimental models. It will also maximise the chance of success of the project.

We will disseminate knowledge through publications, and for important data these may be released early into the public domain through non-peer reviewed pre-print servers such as bioRxiv. We will also publish data arising from unsuccessful approaches to avoid unnecessary repetition of these by other research groups.

We will promote our research through both internal and external presentations (e.g. seminars, conferences).

Species and numbers of animals expected to be used

- Mice: 5500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used in these studies because: (i) the main components of their immune system are shared by humans; this is essential where complex immune responses as opposed to the function of individual genes or cells is being studied. Lower species provide an inadequate model of the immune system; (ii) a wide range of wild type and genetically manipulated strains of defined genetic makeup are available.

We will typically use adult mice for experiments, since by then the immune system is fully developed. The immune system undergoes substantial changes during development. Since we are interested in how the adult immune response responds to infectious disease it is therefore important to study this life stage.

Typically, what will be done to an animal used in your project?

Animals will be given vitamin B3 and/or its precursors to understand if these affect immune cell function. They will be given either in the diet or drinking water, or via short-term injection. Additionally, we will study the role of NAD synthesis in determining immune cell function during fungal infection.

Fungal infection will be modelled by infecting mice with Cryptococcus neoformans. This will be performed using well-established doses and routes (intranasal and intravenous), as well as well- defined experimental endpoints. The animals will be closely monitored and humanely killed when they reach defined end points. Our protocols and clinical monitoring criteria are designed to keep suffering to a minimum. These experiments will last for approximately 1-2 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

For injections, mice will experience momentary pain, which is expected to be mild and short-lived. Vitamin B3 precursor supplementation in the diet does not lead to adverse effects.

Cryptococcus infection model: Weight loss up to 15% is expected in 80-90% of wild-type animals in first 10 days of infection. Animals may develop other signs of infection, including ruffled fur (piloerection), hunched posture, and oculonasal discharge. These symptoms tend to be observed starting after 7 days of infection but may occur earlier in some strains. These experiments will typically last for 1-2 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect 75% of the animals in this licence to experience no greater than mild severity. The remaining 25% may experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immune cells are part of a very changeable and complex biological system, which involves numerous cells that migrate around the body and interact with each other. Whilst simple in vitro models exist for investigating their behaviour in the lab, these do not always predict how immune cells may behave in the actual body.

In order to study immune cell responses that are relevant to human disease, we must use a species which shares all the major parts of the immune system. Among species that share the main components of the immune system with humans, mice are the least sentient option

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

Which non-animal alternatives did you consider for use in this project?

In vitro co-culture of distinct immune cell populations; in silico modeling of NAD synthetic enzyme activity in immune cell populations;

Why were they not suitable?

We will be undertaking in vitro experiments with human primary cells in parallel to those using animals. Wherever possible we will use these approaches to understand the mechanistic basis of our observations, employing molecular biology, imaging and immunological analyses of cells in culture.

However, the activity of the entire immune system during infection is highly complex, involving numerous cell types including the infected cells, cells of the central nervous system and diverse populations of immune cells, stromal cells and importantly vasculature. It is impossible to recreate these complex intercellular interactions in vitro or the vasculature, which is how immune cells enter and exit infected environments. Therefore understanding the complex consequences of targeting immune cell NAD synthesis within infection would not be possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use several different strains of mice to explore the importance of immune cell NAD synthesis from vitamin B3 in infection. Numbers have been calculated based on previous in-house data alongside pilot data and published literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted the NC3R's Experimental Design Assistant tool during the experimental design phase. We will use an experimental approach which permits detection of differences, even when variables such as differences in sex and age are introduced. The approach controls for these variables by randomly assigning them to control and treatment groups. In this way we can maximise use of mice bred for the licence.

By using pilot experiments we will be able to determine the minimum number of mice to be used - typically we have determined that 6 mice per group will allow us to detect a reasonable treatment effect in most circumstances. However these calculations will be continually updated and improved throughout the life of the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. Pilot experiments

Small numbers of animals will be used in pilot experiments for each new type of study performed to assess intra- and inter-group variation. For most models in this project, optimal group sizes and variation are already well established in the scientific literature.

2. Inbred strains

The use of inbred strains (matched for age and gender) will reduce the amount of intra-group variation thus increasing the power of each experiment and reducing the group size needed to achieve statistical significance.

3. Sensible breeding of transgenic lines

Careful and considered approaches to colony management will be used to minimise wastage.

4. Multiple read-outs from same animal

Multiple read-outs taken post-mortem from experimental animals will further reduce the number of animals required. For example, a single animal can be used for the analysis of fungal burden, type and activity of immune cells present and analysis of diseased tissue for damage, metabolic activity and immune messenger molecules present.

5. Consistency of analysis

Where possible, the same person will perform procedures and carry out analyses. Alternatively, groups will be equally distributed between those performing this to avoid subject bias.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

1) We will use a mouse model with a mutation in vitamin B3 metabolism, this will allow us to study how immune cells synthesise NAD. The mouse model has no harmful phenotype.

2) We will use a model of cryptococcus neoformans infection to study how NAD synthesis from vitamin B3 supports immune cell protective function during this disease, which is a key objective of this research. This will involve intranasal or intravenous delivery

of the fungus, which will cause moderate, short-lived distress to the animal. In both cases the infection then proceeds to cause the mice to experience moderate effects, such as up to 15% loss of body weight. To study the immune response during this infection it is important that systemic infection and this level of severity occur. However, our protocols and clinical monitoring criteria are designed to keep suffering to a minimum. We will use Clinical Monitoring Sheets to ensure that unexpected adverse effects are identified as early as possible and that the severity limit is not exceeded. In most experiments the scientific endpoints are achieved prior to significant adverse effects occurring.

Why can't you use animals that are less sentient?

This work has to be conducted in mammalian species because the immune system, and its role in infection in mammals is much more complex than that seen in invertebrates or other vertebrates. Hence, studying rudimentary immune systems will not lead to a significant increase in our understanding of the regulation of the immune system in health and disease. The mouse is the worldwide standard laboratory animal model and its immune system has been the most intensely investigated, meaning that this information can be used inform future studies rather than having to repeat work in another species. This, in addition to the availability of genetically-altered mouse stains, allows much more rapid progress to be made. Finally, since the immune system changes substantially throughout development and life, it is critical to conduct the research in adult animals, whose immune system best reflects that of adult humans, who experience the diseases in question.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Injections will be given on alternate side to minimise discomfort for the animal and limit potential adverse effects that may occur by using the same injection site repeatedly.

LASA guidelines are used when determining volume to be injected for the various routes proposed and these will not be exceeded in this study.

Handling tubes will be routinely used to assess the animal's condition.

During the cryptococcus infection clinical monitoring will be carried out frequently to ensure that any unexpected adverse events are quickly identified and that severity limits are never exceeded.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult LASA guidelines on the handling and administration of substances.

ARRIVE and PREPARE guidelines will be used to ensure that the principles of good experimental design are applied, and subsequently reported, in order to reduce the number of animals required whilst ensuring that data is robust and reproducible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the NC3Rs website (www.nc3rs.org) and new staff will be directed to these web pages. Where new 3R advances occur we shall work with staff in our facility to adapt protocols or techniques. We will also seek advice and latest information through our Named Information Officer (NIO).

5. Modulating the Gut-Liver-Brain Axis for Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Diet, Brain, Microbiome, Gut-liver-brain axis, Ageing

Animal types	**Life stages**
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to further elucidate the interactive impact between lifestyle factors and the microbiome-gut-liver-brain axis in the context of metabolic disorders and its influence upon the progression cognitive decline. We aim to define novel strategies capable of delaying or preventing metabolic and brain disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Debilitating neurological conditions such as Dementia, characteristically result in a decline in cognitive performance and represent an ever-increasing societal burden worldwide. In the absence of effective pharmacological treatment to prevent or reverse the underlying age-related and/or pathological mechanisms, it is necessary to shift focus towards preventative methods. With further development, lifestyle approaches offer a promising and novel route of mitigation. Increasing evidence highlights the importance of the microbiome and the gut-liver-brain axis upon modulation of brain functions. It is therefore important to undertake this work to further our mechanistic understanding of the microbiome- gut-liver-brain axis, particularly in the context of brain function. Understanding the underlying mechanisms will enable us to propose novel strategies to preserve brain health and prevent disease progression.

What outputs do you think you will see at the end of this project?

This program of work will strive to broaden our understanding of the role that lifestyle factors, gut microbiota and dietary patterns/nutrients play in the prevention of human brain ageing and the enhancement of a range of cognitive abilities. We anticipate this knowledge will enable us to develop novel strategies to delay and/or prevent age-related cognitive decline and pathological decline through the modulation of the microbiome and its communication with the host (gut-liver-brain axis).

It is anticipated we will continue generating high-impact publications in international peer-reviewed journals and to communicate our findings to colleagues in academia via invited talks to conferences and other academic institutions.

Finally, given the direct interest of the industry in finding solutions to improve cognitive heath, it is likely we will work with them to develop new products aiming at ameliorating cognitive performance.

Who or what will benefit from these outputs, and how?

The benefits of the proposed research may be considered both in terms of the potential clinical applications of our findings and the advancement of fundamental knowledge regarding the influence of diet, genetic and metabolic factors on cognitive functions in both normal and pathological ageing. In the short term, this project will provide a mechanistic understanding of the regulation of brain functions through dietary changes and the modulation of the gut microbiota. In the medium and long term, these studies will provide the background for new and promising preventive treatments for tackling cognitive decline and are aligned with a move towards the provision of personalised/stratified preventative strategies, particularly in individuals identified as being at “high-risk”.

How will you look to maximise the outputs of this work?

Output of this work will be published in high impact journals and presented at both National and International conferences. In addition, findings emanating from this research will be posted on social media (Twitter, LinkedIn, etc) which has an important coverage and reach.

We will also collaborate with researchers locally, nationally and internationally. Outputs will in form of high-impact journal publications and grant proposals to diverse funding bodies (UKRI, charities, industry).

Species and numbers of animals expected to be used

- Mice: 7410

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The interaction between the gut-microbiome, liver and brain (gut-liver-brain axis) has implications for numerous systems (e.g., metabolism, immune). It is therefore multifactorial and highly complex, meaning that that it cannot be fully nor precisely reproduced in vitro. For this reason, our research requires the use of mice in order to study such a system in its entirety.

In addition, the mouse models that will be used throughout this project will recapitulate different aspects of human disease and are thus indispensable to dissect the complex interactions occurring in the gut-liver-brain axis during specific processes of disease progression.

Typically, what will be done to an animal used in your project?

Typically, inflammation will be induced through administration of substances. Protocols involving the induction of inflammation will generally be short in duration ranging from a few hours up to a few days.

The route of administration will depend on the inducing agent, but this will generally be via injection or oral gavage. Procedures will generally induce only mild discomfort to the mice. Metabolic disturbances may also be established by maintaining animals on a particular diet such as a Western-type diet, or diets affecting gut-liver homeostasis (e.g high fructose diet).

Modulation of the microbiome will be achieved via administration of substances (e.g. antibiotics), live bacteria/bacterial products (e.g. probiotics, postbiotics) or food bioactives (e.g. fibers, flavonoids, PUFAs, etc.) and may be administered in combination with the different protocols proposed in this project. These substances will generally be administered orally by gavage on one or several occasions or integrated in food pellets or water.

Upon completion of experiments, mice will generally be humanely killed after blood extraction by cardiac puncture under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

The procedures described in this proposal involve transient and moderate stress or pain in well habituated animals, which will be controlled by use of anaesthesia and analgesic treatments where necessary. Doses of drugs used will be within published physiologically-active, non-toxic ranges and so no significant or frequent adverse health consequences are anticipated. Development of adverse health consequences following test substance administration are not expected. Animals will be routinely monitored for acute behavioural

signs of distress, developing changes in body weight (weight loss not to exceed 20% of pre-treatment level), changes in activity level or degree of grooming, ocular or nasal discharge, fever, hypothermia, or other signs of malaise. In the event of any complication or the development of any adverse reaction to the treatment, drug test procedure etc., experiment will be discontinued, and animals will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We anticipate that most of the mice will have a mild severity (90%; administration of substances, dietary challenges, microbiome modulation). 10% of mice may show a moderate side effect due to either surgery (minipumps) or dietary challenges affecting metabolism (western-type diet challenge).

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The interaction between the microbiome, gut-liver-brain axis, influences broad and complex systems such as immune and metabolic regulation which cannot be accurately modelled in vitro. for instance:

In vitro assays cannot model physiological and behavioural interactions.

Cell culture cannot fully replicate the features and interactions of brain cells apparent in vivo.

Bioavailability, tissue distribution and metabolism of compounds cannot be accurately modelled in cell culture.

Metabolic interactions cannot be modelled in cell culture systems because of the multiplicity of cell types.

Cognition cannot be recapitulated nor assessed in cell culture

In addition, a large proportion of the components of the microbiota cannot be cultured, supporting the need to perform our experiments in mice in vivo where we will analyse (specific components of) the microbiome and its influence upon the gut-liver-brain axis and the subsequent effect towards host metabolism and immunity.

The translational nature of our research requires testing microbe-based therapeutic strategies in mice prior to the translation into the clinical setting.

Which non-animal alternatives did you consider for use in this project?

Prior to embarking on animal experiments, as much evidence as possible will be collected in order to determine whether a candidate gene, food bioactives including their metabolites and microbes can influence brain function. Where possible, we intend to utilise brain slices and/or freshly dissociated neurons/glial cells obtained from animals, in order to determine the impact of treatment upon specific mechanistic events (e.g. synaptic plasticity and neuroinflammation)

When possible, we will also perform analyses in human samples obtained from patients/volunteers in collaboration with hospitals in the UK. These analyses in human tissue will complement our mechanistic studies using mice, furthering translational potential.

Why were they not suitable?

These in vitro and ex-vivo techniques are a useful tool to explore specific aspects of our research and will we use them accordingly.

However, none can fully replicate the complex metabolic and immune interactions of the microbiome, intestine, liver and brain in their entirety which is essential for our research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of the procedures and protocols included in this project have been already used in our previous project license. These have generated meaningful and robust results that have been published in high impact factor peer-reviewed journals. Animal numbers are estimated on our current usage and projected proposed studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use several measures to reduce animal numbers.

The experiments are designed to use the minimum number of animals necessary. This includes the use of established immortalised cell lines as in vitro culture models for pre-screening studying basic mechanisms and ex vivo methods to analyse basic concepts of adult stem cell function and only bring the most likely candidates into in vivo studies.

We have calculated the number of animals for each experiment together with a statistician to use the minimum number of mice whilst still receiving meaningful and statistical significant results.

Time-lapse imaging enables serial and longitudinal data to be obtained from one animal over time rather than having to cull animals at predetermined times post treatment

Whenever possible the purchase of older animals will reduce animal use and need to breed and keep ageing/aged animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use homozygous mice in our breeding unless we are generating a new strain We use both male and female mice for our studies.
We isolate tissue from animals from experimental animals and store it appropriately for later use in histological and immunohistological analyses and/or share tissue when appropriate with collaborator and colleagues, thereby reducing the need to breed mice specifically for this purpose.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the standard species for transgenesis and are de facto standard for this work.

The choice of inflammatory stimuli is based upon published literature and their extensive use as a model of (neuro)inflammation. Dietary challenge experiments utilise various refined diets varying in the source and type of fat and carbohydrate content for which an extensive body of literature exists describing the conditions of their use and impact on metabolism and health including resistance vs. susceptibility to disease on which we can base our studies.

When chronic drug/dietary component administration is required, surgical implantation of osmotic minipumps will be preferred. Such technique also allows the direct delivery to the brain by using central cannulation.

The imaging protocols are highly sensitive allowing sequential visualisation of small numbers of animals without having to cull animals at predetermined times post treatment. The timing and number of imaging interventions is minimised through the adoption of established and published protocols using similar assessment and imaging equipment.

Wherever necessary local and general anaesthesia will be used to minimise animal suffering.

Why can't you use animals that are less sentient?

Our research requires whole bodily systems, including the gut-microbiome in order to understand complex physiological interactions in their entirety. The mouse is the least sentient animal that is both physiologically and genetically similar to human and allows both genetical and pharmaceutical manipulation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Welfare of the mice will be monitored after the administration of substances on multiple occasions by the experimenters and then inspected daily by qualified animal carers. Aseptic precautions will be taken to help prevent infections.

Surgical procedures will be carried out according to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Analgesic agents will be administered as required after the surgery. In the event of post-operative complications, animals will be killed unless, in the opinion of the Named Veterinary Surgeon, such complications can be remedied promptly and successfully using no more than minor interventions.

Where the immune status of the animal might compromise health, they will be held in a barrier environment.

Other than in terminally anaesthetised animals dosing and samples procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than a transient discomfort and no lasting harm. Typically, dose volumes will not exceed 20ml/kg for oral gavage, subcutaneous and intraperitoneal injection, topical application and 10ml/kg for intravenous injection. Strict asepsis is employed to prevent infection when a temporary cannula is set. In case hemorrhage, blockage of cannula or swelling around the cannulation site is observed the cannula will be removed.

Blood will be taken from superficial vessels. To avoid hypovolaemia or anaemia, typically not more than 10% of the total blood volume (TBV) will be withdrawn on any single occasion and typically no more than 15% TBV in any 28-day period.

Altered food composition should cause no adverse effects to the animal. Weight will be controlled weekly, and mice will be humanely killed if the weight gain restricts movement to reach food and water.

Animals will be humanely killed before signs of distress (eg loss of body weight, unkempt fur, abnormal posture, loss of muscle tone) become apparent.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All our studies follow the ARRIVE guidelines (provided by NC3R) which are widely accepted by the scientific community. In addition, we keep up-to-date by following updates provided by the Laboratory Animal Science Association (LASA) which, together with NC3R constantly publish improved and refined animal procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All researchers involved in this project will be encouraged to subscribe to the NC3R newsletter and website and review current methods as soon as new guidelines become available. All researchers are also encouraged to subscribe to the Experimental Design Assistant provided by NC3R to design experiments the most efficient way and put stops if necessary.

6. Optimising Skeletal Muscle Structure and Function to Withstand the Challenges of Damage and Ageing

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Muscle, Regeneration, Sarcopenia, Ageing

Animal types	Life stages
Mice	adult, aged, juvenile
Rats	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to develop therapies to improve muscle mass and function in conditions where this is a problem, such as DMD or ageing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The key benefits of this project are expected to be in the treatment of skeletal muscle that fails to work properly in humans. Results from this project will be beneficial in the future to

doctors as they are focused on human diseases, drug companies as well as researchers. Treatment of ill health will include patients with Duchenne Muscular Dystrophy which affects 1 in 5000 boys and leads to death at about 25 years of age. Skeletal muscle loss is found in many kidney diseases, cancers, and HIV infection. However, we are all likely to experience muscle wasting as it is the key feature of ageing which leads to it not only decreasing its size but also its ability to carry out its normal function. This process, called sarcopenia leads to a reduced quality of life and has huge costs associated with it to the economy. At present the only two regimes that are known to attenuate sarcopenia are exercise and improved diet. However, these two approaches are usually inappropriate for the large proportionate of the elderly due to changes in their physiology, hence, new approaches are required. Therefore, advances in developing therapies that reverse age-related muscle wasting are likely to be beneficial not only to those who suffer from it but also all of society since we all pay for their treatment through taxes. Money that can be saved based on our studies can be used to help others.

What outputs do you think you will see at the end of this project?

The key benefits of this project are expected to be in the treatment of ill health and the treatment of compromised tissue function in humans where skeletal muscle is affected. The immediate benefits will be the development of a range of chemical and molecular approaches to improve muscle function. This project aims to exploit our previous work carried out under a Home Office project licence in which we showed that muscle regeneration is greatly influenced by factors other than stem cells. This fundamentally changes the landscape in our understanding of the development of disease and most importantly the spectrum of people who can be treated. This is based on the flawed notion that stem cells were the key determinant of muscle regeneration. Therefore, people who have a deficit in stem cell number could not be treated. We show that this is not the case and so these people who would have been previously excluded from treatment can be considered as ‘treatable’.

The data coming out of this project will identify key molecular and biochemical processes that enable muscle to work efficiently. Findings from this work will be peer reviewed before they are published in internationally available journals. Ideally, we will publish in freely available journals that allows anyone to access our outputs. Furthermore, the outputs of the project will be presented to the scientific community at conferences where we can not only tell others of our work to potentially improve human health but to gain feedback on how to improve our work in the future. Another output could be the development of drugs and proteins that could be used for clinical purposes. We will also present our work at public meetings so that all members of society can hear about the outputs. This will be done at public lectures and at local Science Festivals which are held yearly.

Who or what will benefit from these outputs, and how?

The work carried out in the project can be used by many different groups in society.

The smallest group that will benefit from our work is the scientific community, the medical professionals and potentially the pharmaceutical industry. Studies outlined in the proposal will add to our understanding of the processes that control muscle growth and function. Several studies have identified means of increasing or decreasing muscle size. We have shown that the central idea of muscle biology that ‘big is better’ is wrong.

Secondly, we have shown that muscle regeneration is greatly influenced by factors other than stem cells. Importantly we have shown that changing how muscle uses oxygen can allow it to regenerate even when the muscle stem cells population has been halved.

This data will be of extreme value to our group in developing new projects, to other researchers in the university sector as well as pharmaceutical sectors as they are developing new drug targets.

The second group who will benefit from our research are those affected by specific diseases associated with muscle. Muscle wasting is a feature of many diseases in which it is either the primary affected tissue for example Duchenne Muscular Dystrophy which affects 1:5000 boys) or as an indirect target (e.g., chronic kidney disease). In many cases the outcome in either situation is fatal. It is also a process that is initiated following long periods of muscle disuse (for example bed rest after surgery), a process called muscle atrophy. Maintaining muscle mass is a key feature that not only improves the quality of human life but also decreases the chances of developing diseases. We suggest that our work will accelerate the development of therapies to treat muscle wasting disorders. Importantly we have shown that molecules including proteins can be introduced into disease models that promote muscle growth. These need to be optimised in terms of efficacy and safety.

The largest group who will benefit are the elderly as we hope to develop treatments for muscle loss that accompanies ageing.

Sarcopenia is defined as the degenerative loss of skeletal muscle mass and strength associated with the ageing process. According to the ‘European Innovation Partnership on Active and Healthy Ageing’, the number of people aged 65+ in the EU will increase from 85 million in 2008 to 151 million in 2060 with many older men and women suffering from mobility limitations that increase 1) the risk of injuries

and falls, 2) development of diseases and 3) increased demands on limited healthcare resources. Previous work has shown that skeletal muscle undergoes numerous changes with age including reduction in the size of muscle fibres. Results from work carried out under the previous licence showed that stem cells may not be a limiting factor in muscle regeneration in ageing and other parameters are even more important. We hope to use these discoveries to develop treatments that can be used to promote muscle health in the aged mice.

Lastly, this project will be relevant to a group of emerging diseases that afflict humans. One of the major implications of long-covid happens to be its impact on patients with COVID-19. Herein a large survey of data from around the world which assimilated the findings of over 1000 references found that patients with severe COVID-19 had decreased muscle function which impacted greatly on their quality of life. Therefore, there will be a need, possibly extending decades, for us to reverse this feature of COVID-19. Furthermore, there is extensive evidence that patients infected with the Zika virus also have major issue to do with their skeletal muscle with evidence for muscle necrosis as well as disruption of the muscle regeneration process.

The outputs of the body of work described in this application could be used by the pharmaceutical industry to develop drugs and proteins to slow the progression of muscle wasting in either the disease or the ageing setting or to reverse this process.

The medical, pharmaceutical industry and public will benefit our work in the medium to long term (either towards the end of the timeframe of the licences and afterwards) since a large number of other studies (safety testing, clinical trials etc) are necessary before they can be translated into treatment.

Additionally, the results will be used by other researchers to refine their work since we will make advances on which they can build. Our work will mean that others will not have to conduct similar experiments and based on our work they can refine their studies which should translate into reduction in number of animals used for experimental studies. This group will benefit from our work during the lifetime of the licence.

How will you look to maximise the outputs of this work?

All outputs of this project will be communicated through the most appropriate channels. This will include the publication of results in internationally peer reviewed journals. Where possible we will endeavour to publish in open access journals so as facilitating dissemination of findings. Furthermore, all research outcomes based on this licence be it successful or unsuccessful will be made available to any user upon request. In terms of timelines, outputs and data will be made immediately available upon request for information.

Species and numbers of animals expected to be used

- Mice: 5000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats will be used in this project, as they can be used to develop the symptoms of the diseases that are the focus of this project: muscle wasting associated with disuse, changes in diet, regeneration. Mice and rats at all stages of post-natal life will be used. Genetic strains of mice and rats will vary depending on the nature of the gene modification in which they were carried out.

Typically, what will be done to an animal used in your project?

Typically, mice and rats will be bred so that they have the correct genetic mutation, which develop a phenotype in skeletal muscle.

Some animals may be placed upon an adjusted diet to induce a muscle phenotype.

Thereafter they will be treated with a regime, including substance administration, which is intended to have an outcome on muscle structure and function.

The animals may undergo physiological examination, for example determining how long they can exercise, which will allow us to gauge how well the muscles are working.

Thereafter the animals will be killed, and tissues collected for further investigation aimed at revealing how the treatment has altered the function of skeletal muscle.

What are the expected impacts and/or adverse effects for the animals during your project?

It is likely that only a minor number of animals undergo procedures in this licence that experience pain or show loss of body weight (dietary restriction and starvation). We plan to terminate the experiment when the intervention to induce tissue wasting results in greater than 15% of body weight loss compared to control rodents.

Some animals will undergo surgery and anaesthesia in order to course tendon and nerve transections, as well as minipump insertion, which will require regimes to control pain. Pain issue is resolved usually in a matter of one to two days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The most severe category is moderate which will be experienced by no more than 20% of the animals in this proposal.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Skeletal muscle is a complex tissue made of not only muscle fibres but also blood vessels and nerves. The health of muscle is dependant of not only on features of the muscle fibre, but also on input from surrounding tissue, especially the nerves and blood vessels. These tissues all respond to changes in their surroundings, for example the food that we eat, in a way that we are only beginning to understand.

Although we can grow cells in a test tube, these do not behave in the same way as muscle in an animal. Since these test tube models lack influence from anything other skeletal muscle, they poorly represent which actually occurs in the human body. Therefore, it is still necessary for work on mice and rats that is outlined in this proposal.

Which non-animal alternatives did you consider for use in this project?

With some aspects of the project, experimental animals can be replaced by in-vitro testing, and as outlined in the programme of work such in-vitro testing will replace intact animal experimentation wherever possible in the project. In vitro experiments especially using skeletal muscle cell lines (thereby eliminating the need to sacrifice mice and rats for the

isolation of experimental material) will be used as a matter of choice at the start of any applicable study. For example, cells will be used to assess muscle damaging reagents to gain information about which stage such molecules may impact on the tissue found in the body. At present there is a huge amount of excitement regarding the use of organ culture protocols to understand the workings of a complex tissues. At present, the organ culture protocols specifically for skeletal muscle are at development phase and not as advanced as other systems for example the gut. This is undoubtedly due to the cellular nature of skeletal muscle (the muscle fibre) and its need for complex interactions with both other cells (blood vessels and nerves) as well as relatively undefined extracellular components including the matrix. Therefore, at present it is a necessity to use animal models to investigate skeletal muscle. However, it is inevitable that organoids for skeletal muscle will be developed and we will use these at the first given opportunity if they are a good substitute for animal studies.

Why were they not suitable?

While in-vitro studies are very informative on the nature of skeletal muscle. Skeletal muscle can be induced to differentiate and grow into myotubes, but these are no way near the level of maturity seen in a mammal. They are structurally and functionally very different to myofibers which constitute the cell unit of adult skeletal muscle. For example, they lack the neuromuscular junction as well as the myotendinous junctions which are critical to the normal workings of skeletal muscle.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For quantitative experiments sample size will be set statistical predictions based on the difference we want to detect to give us an indication that a treatment is working. We will draw on our work conducted using the same animal models and how the experiments were run to give similar but unique outcomes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

More generally, advice will be sought from our Consultant Statistician, where appropriate, to ensure a statistical design that is used is efficient and minimises the number of animals required yet maintains sufficient precision and power. For example, advice will be sought when a specific pre-clinical model introduces large subject-to-subject variation.

Furthermore, our studies have shown that the impact of muscle growth promoting molecules effects more than just the primary tissue under investigation, that being skeletal muscle. Therefore, for an intervention to be examined further for possible use in humans, it is now apparent that an intervention should be examine at the organismal level as well as a range of tissues. We have developed a pipeline that extracts the maximal amount of data from each animal by not only determining its behaviour and movement prior to its

death, but then to isolate as many tissues as possible. This approach means that a single animal will generate data related to a wide variety of bodily functions.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The proposal aims to minimize animal usage by drawing on our extensive experience in this area of research. These insights will be deployed not only to keep the number of mice to their lowest possible number but also to conduct the experiments in the shortest time span thus minimizing animal suffering.

We will in all cases initiate experimentation with novel substances by examining their impact on muscle structure and function on a small number of mice or rats (2) before moving on to larger scale studies assuming that no adverse effects manifested.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The choice of models employed in the project reflect the physiology, structure, and regeneration properties of humans, which is critical since this project aims to develop treatments focusing on health. Where possible the use a genetically modified mice or rats will be used to remove the need for surgical or chemical interventions in establishing a muscle phenotype, thus reducing the numbers of animals experiencing pain, suffering and distress.

Rodents have been extensively used to make major breakthrough in our understanding of human skeletal muscle biology since they are mammals, and their tissue architecture resembles that of us. The mouse is particularly attractive as an experimental model as a huge number of genetically modified lines have been generated which allow us to hone into the function of specific genes in the muscle development program. A limitation of the mouse model is that related to the cellular structure in comparison to humans, particularly the composition of muscle fibres. Herein the rat offers significant advantages over the mouse in that its muscle fibre profile is more similar to the human than that of the mouse.

Why can’t you use animals that are less sentient?

Small rodents (mouse: rat) are the simplest appropriate pre-clinical models to study these diseases and their potential amelioration. While there are species differences in physiology between humans and rodents, these are minimal and the use of species genetically closer to humans is not required by the appropriate regulatory bodies and thus is not proposed as part of this project. The mouse is the species of choice due to availability of appropriate genetically modified lines that phenotypically display accelerated ageing. Furthermore,

genetically modified mice, either through gene knock-out or gene over-expression studies allows us to develop mechanistic explanations at the molecular level of the processes of muscle growth. Rats are also appropriate since they have muscle structure which differs from mice (as they are metabolically more similar to humans than mice) and in certain aspects mimics the human condition.

Non-mammalian models including nematode worms and fruit flies do not share the same physiological parameters as humans and are thus not informative for this type of study. Zebrafish are not a relevant model for this project as their muscle structure and functions differ greatly from mammals. For example muscles tend to be composed of single celled fibres in contrast to the human syncytial fibre which is made up of tens of thousands of nuclei.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals may experience stress when undergoing behavioural and exercise tolerance regimes. This will be minimised through a protocol of familiarisation in which the regime is introduced in a stepwise process. Other refinements to decrease harms to the animals will through constantly monitoring to pick up signs of adverse effects during and after any intervention followed by immediate post-operative care and pain management.

Rodents lose a huge amount of body mass following total food deprivation undoubtedly due to their high metabolic rate which can rapidly develop into torpor. We have carried out work over the past 8 years to investigate the impact of starvation on skeletal muscle function and have concluded that food deprivation for a period of 24 hours is adequate for us to reach major outcomes on this tissue rather than as previously maintaining animals on this regime for 48 hours.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will seek to carry out the experiments using best practice advised by differing parties including:

Laboratory Animal Science Association (LASA) for best practice guidelines for administration of substances and genetically modified mouse welfare guidelines.

We will also turn to the Workman guidelines for cancer research (https://www.nature.com/articles/6605642) as these principles are particularly relevant to our study as they describe welfare issues and how to use best practice for models which experience tissue wasting, the core focus of this proposal. Please see:

Workman P, Balmain A, Hickman JA, McNally NJ, Rohas AM, Mitchison NA, Pierrepoint CG, Raymond R, Rowlatt C, Stephens TC, Wallace J (1988) UKCCCR guidelines for the welfare of animals in experimental neoplasia. Br J Cancer 58: 109–113

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will seek advice from the named veterinary surgeon for alternative approaches using either less sentient animals or non-animal systems that allow us to achieve our goals.

Furthermore, we will maintain our knowledge and best practice of 3Rs by attending relevant conferences and meetings as well as referring to appropriate websites, such as NC3Rs.

7. Characterization of Novel Antimicrobial Agents and Treatments

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

infection, antibiotic, antifungal, antiviral, vaccine

Animal types	Life stages
Mice	adult, juvenile, neonate
Rats	adult, juvenile, neonate
Cotton Rats	adult
Guinea pigs	adult
Hamsters (Syrian) (Mesocricetus auratus)	adult,

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This aim of this project is to provide in vivo support services to pharmaceutical and biotechnology companies and academic establishments to support the development of antibacterial, antiviral and antifungal treatments and vaccines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Although there have been tremendous advances in the treatment of infectious diseases there are still many developing and unmet clinical needs.

Antibiotic resistance has been described as a slow pandemic, with the UN estimating up to 10 million deaths a year globally by 2050 unless new treatments are developed as a matter of urgency. As antibiotic drugs support many aspects of modern human and veterinary medicine such as cancer treatments, cystic fibrosis treatment and surgical procedures this has the potential to impact all aspects of society.

In addition to antibiotics, there is a growing resistance problem with resistance to antifungal drugs, causing a significant rise in the number of deaths, particularly in clinically vulnerable groups such as pre-term babies, HIV infected and other immunosuppressed patients. There are estimated to be above

1.7 million deaths globally due to fungal infections.

Although a lot of progress has been made with the development of antiviral drugs, there is still huge unmet medical need. The ongoing SARS-CoV-2 pandemic has illustrated the need for having a range of antiviral drugs available targeting virus families considered to be a risk of causing the next pandemic as well as being able to rapidly develop new drugs when required. There are also established infections such as hepatitis C, influenza viruses and herpesviruses that are killing patients where no effective antiviral treatment is available. Worryingly in recent years antiviral drug resistance has started to develop in HIV infected populations, which is a significant public health threat.

For all three classes of infectious agents vaccines have a critical role to play in the prevention and increasingly treatment of these infections. As with drug treatment, there is still significant unmet need for new and improved vaccines for a wide range of disease such as tuberculosis, hepatitis C and HIV.

The work conducted under this project licence is critical to supporting the early stages of developing new treatments to these three global public health threats.

What outputs do you think you will see at the end of this project?

The studies performed under this licence will contribute to the early stages of drug development projects

This will build on studies performed not using animals where potentially useful treatments are initially identified. The animal studies will provide information on whether a potential treatment or vaccine is effective in a complex organism with similar biological processes to

humans. This will help project teams understand how to improve their treatment, whether their approach to the drug target is not effective in an animal model, or, ideally, provide evidence of efficacy so the treatment or vaccine can be progressed towards safety assessment and human trials.

Where significant results are not subject to confidentiality agreements they will be communicated more widely at scientific meetings or published in peer reviewed journals.

Who or what will benefit from these outputs, and how?

In the short term clients, project teams and funding bodies will be able to make progression decisions to be able to better target their limited financial resources on to the potential treatments with the highest likelihood of clinical success.

In the medium term stopping the progression of projects with little chance of success (either due to lack of relevance of the target or the inability to develop a potential medicine that has a clear beneficial effect in animal models) will also mean that animals will not be used in safety assessment and human volunteers will not be put at risk in clinical trials.

In the long term the successful identification of potential treatments will result in reductions in patient mortality, improved clinical outcomes (including shorter hospital stays) and reduced societal costs.

How will you look to maximise the outputs of this work?

Where there may be broader interest in an animal modelling approach, and if the studies are not subject to confidentiality agreements, these will be published or shared at relevant conferences. Refinements to techniques will be shared with others working in the field via individual contacts made by the establishment Named Persons

Clients and collaborating partners will be encouraged to publish all results in journals or share at relevant conferences.

Species and numbers of animals expected to be used

- Mice: 26,000
- Rats: 4500
- Guinea pigs: 100
- Hamsters (Syrian) (Mesocricetus auratus): 1,000
- Other rodents: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These animal studies serve as a bridge between computer or cell-based experiments and human clinical trials. These studies will, in many cases, be the final studies investigating the likelihood of a potential medicine having a benefit before clinical trials are started.

In the majority of cases adult animals will be used as these are representative of the majority of the patient population. Rarely, where a specific infection or treatment focusses on the paediatric population, juvenile or neonatal animals may be used.

Most animals used in this project will be mice (occasionally including genetically altered animals) as these have been demonstrated to provide information that enables decisions to be made on the progression of treatments. Their reactions to infections and response to antimicrobial treatments have shown good alignment with those seen in human patients.

Using genetically altered animals allows the investigation of human-specific targets and treatments for these targets.

Other species will be used where a specific infection cannot use mice such as investigating skin infections in rats, gastrointestinal disease in hamsters, surgical implant infections in guinea pigs and respiratory infections in cotton rats

Typically, what will be done to an animal used in your project?

Most studies undertaken will be of short duration, lasting less than 7 days.

Animals will typically (approximately 70% of studies) have two injections of a drug to reduce the immune response, then be infected with the infectious organism of interest. Most infections are performed under general anaesthesia to minimise the impact on the animals.

The commonly used infection routes will be into the thigh (to model soft tissue infections), lung (to model pneumonia) or into the blood stream (to model infections that spread throughout the body).

With the exception of vaccination studies, all treatments in these models will only start once the infection has been established. When investigating antibiotics, the animals will normally be treated with the potential treatment several times a day, with studies usually being completed within 5 to 24 hours of infection. This may require the implantation of catheters into blood vessels to allow the more frequent treatment (up to once per hour, or even continuous infusion) to be performed with less pain and distress to the animals. For fungal or viral infections the study may run over several days, but frequency of treatment administration will be reduced, usually no more than 4 times daily for up to 7 days.

Other routes of infection may occasionally be used such as skin, bladder, vagina, bone or intestine to model very specific clinical conditions. In these cases animals will generally be treated less frequently, usually no more than 4 times daily for up to 7 days, but

occasionally may require surgical implantation of catheters into blood vessels to allow for infusion of potential treatments when this is the likely route of treatment in patients.

When investigating treatments for infected surgical implants, the animals are anaesthetized and a small piece of surgical implant material (usually a length of catheter tubing) is placed under the skin. This may already be infected at the time of surgery or the wound may be allowed to heal and then an organism injected into the implant to cause the infection. These animals will be left for several days for the infection to develop then treatment started, usually no more than 4 times daily for up to 7 days.

In small numbers of studies investigating potential antimicrobial treatments blood samples will be taken to measure the blood levels of the treatment or other markers of effectiveness of treatment.

Studies investigating vaccines will usually last up to 6 weeks and the animal will be dosed with the potential vaccine on up to 3 occasions 14 days apart. Initial studies will only require blood samples to be taken to measure the response to the vaccine, but a small number of studies will be performed using vaccine candidates that have produced a robust response where the animals are vaccinated and then infected to determine whether the immune response seen is protective against the infection.

All animals will be closely monitored according to the expected progress of the infection and will be removed from study if they reach the humane end point. Where infections are considered to be painful (for example thigh and bone), pain relieving drugs will be given to the animals, with response to the pain relief assessed as part of the regular monitoring.

At the end of the studies the animals are humanely killed and tissues taken for assessment of the levels of infection in the tissues of interest.

What are the expected impacts and/or adverse effects for the animals during your project?

The most significant impacts on the animals will be a result of the infections. In general infections will cause loss of appetite and so weight loss, reduced activity and changes in core body temperature.

With thigh, bone and systemic infections, pain may also be seen With lung infections an increase is breathing rate and changes in breathing pattern may also be seen. In bacterial models these will be towards the end of a study, usually no more than 24 hours after infection. For fungal and viral models these signs will also occur in the final hours prior the end of the study which may be up to one week in duration

Administration of substances causes brief stress and pain due to handling and needle insertion. These are controlled by skilled handling and minimising the numbers of administration and sampling events.

Some genetic alterations can cause adverse effects which are very dependent on the gene. We plan to only use genetically altered animals that have Mild adverse effects.

Anaesthesia for infection and treatment administration can result in heat loss and short term unpleasant experiences when recovering. Animals will be closely monitored, have heat supplied throughout the infection process and only undergo the minimum number of anaesthetics required to give a satisfactory scientific output.

Surgical cannulation of blood vessels will cause pain that is controlled by the use of pain-relieving drugs: generally this lasts for 48 hours, but the animals are closely monitored in case further doses are required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - 50% Mild and 50% Moderate

Rats - 50% Mild and 50% Moderate

Hamsters - 20% Mild and 80% Moderate

Cotton rat -30% Mild and 70% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Many of the initial studies performed to help in the validation of antimicrobial targets and assessment of potential medicines now take place in computer, genomic, receptor and cell-based experiments.

The hollowfibre infection model can give an intial assessment of how the antibacterial treatments may behave in a living organism prior to being used in clinical trials.

However, even with these advances, computer and cell-based approaches still do not allow the response of the infectious agent to be assessed in a way that reflects the full

complexity of an integrated mammalian system, particularly where the immune system response is a significant part of the expected action of the treatment.

This project aims to provide the data from a complex, integrated organism to allow decisions to be made on whether to progress potential anti-infective medicines or vaccines to the next stage of development.

The use of non-mammalian species such as the waxmoth larva infection model is also seen as a potential replacement approach, and useful information is be obtained from these approaches: however due to the degree of differences at a genetic and molecular level these models are more suited to very early scientific investigations rather than drug discovery and development.

Which non-animal alternatives did you consider for use in this project?

Some or all of computer modelling, genomic, cell-based and non-protected animal approaches will be used prior to undertaking studies on protected animals to minimise the number of studies and impact on the animals.

Clients will be asked to provide information on the work undertaken with approaches not using protected animals and an outline of literature reviewed searching for alternative approaches prior to performing animal studies. It would be expected that molecular and cell-based assays will have been undertaken to have confidence that the potential anti-infective medicines or vaccines is likely to be effective in the animal model. These studies will usually include investigations on the ability to affect the infectious agent, assessing the properties of potential medicines for biological availability and likelihood of reaching tissues of interest and looking for early indications of toxicity liabilities. These test will reduce the numbers of experiments performed and increase the likelihood of those completed to deliver meaningful results.

Why were they not suitable?

There are no non-animal alternatives that can currently replicate the full complexity of an infection in the mammalian body. Now and for the foreseeable future there will need to be animal experiments performed to perform initial investigations into the efficacy of potential anti-infective medicines or vaccines as part of the process of bridging from non-animals studies to clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers are based upon the number of animals used in the preceding project licence, which reflect the scientific and commercial demand for assessment of potential antimicrobial treatments, with an adjustment to reflect that studies using species such as cotton rats and guinea pigs have significantly reduced.

As there is an increased focus on anti-microbial resistance in relation to public health, it is not anticipated that there will be a significant reduction in the overall number of studies being performed in this therapeutic area.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used pre-existing internal data from ongoing models to calculate group sizes that are likely to provide a robust experimental output without using excess animals. These calculations are normally performed using commercially available statistical software (currently StatsDirect).

The minimum number of appropriate control groups and control animals are used, however these are critical for providing robust data so there is limited opportunity to reduce these further. On occasion it is possible to use shared control groups when performing multiple studies with the same infectious agent on the same day.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever necessary pilot studies will be performed (under separate licence authority) to help design the decision-making studies, including identifying the dose level of infectious agent that gives the best chance of identifying a clinically relevant effect with the minimum possible adverse effects.

Prior to infection studies, investigations will be performed to determine whether the anti-infective treatment is tolerated and if possible also how it is absorbed and removed from the body. This allows modelling to be used to predict the doses required for the infection studies.

In some studies tissue samples will be taken after the study is completed to measure how the treatment has moved around the body, and may help prevent further studies being performed should unexpected results be found.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered animals that demonstrate no or only Mild signs will be used.

The majority of studies in this project will be using infection models which reflect conditions seen in the clinical situation. All these studies are designed to have the shortest duration and lowest doses of infectious agent that allow for effectiveness of treatments to be assessed. The severity experienced by the animals is managed with observations at a frequency appropriate for the model, including multiple assessments overnights for more rapidly progressing situations such as the sepsis models.

The use of pain relieving treatments and agreed humane endpoints helps to limit the adverse effects experienced by the animals

The models include:

- Sepsis (blood borne infection),
- Foreign body (usually associated with surgical implants)
- Urinary tract infections (bladder and kidney)
- Vaginal
- Bone
- Skin and skin structures
- Abscess and soft tissues (thigh)
- Lung and respiratory tract
- Clostridium difficile (also known as Clostridioides)
- Gastrointestinal infections (usually Salmonella)

One additional models is the investigation of response to vaccine candidates, which will have severity minimised by careful choice of doses and the use of pain-relief medications to reduce any adverse effects that may occur.

Why can’t you use animals that are less sentient?

Prior to performing procedures under the authority of this licence, some or all of computer simulation, simple receptor or cell-based studies, complex cell-based systems (e.g. organ on a chip) or simple animals (waxmoth larvae) will have been performed to focus on potential medicines that have the highest chance of success.

These simple models do not provide sufficient data to enable the development of a thorough understanding of the effects of the potential anti-infective in a fully-integrated

organism, which allows the complex interaction of the treatment with many body systems to be assessed prior to moving on the human clinical studies.

Most studies will be investigating responses that develop over many hours or days so the use of terminal anaesthesia is not appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

On site, working proactively with the AWERB, NVS and NACWO, there is a culture of constant improvement to animal care, control of adverse effects, performance of procedures and study design.

Scoring systems are used to identify early intervention and end points in studies, pain-relieving drugs are used when there is concern an animal is suffering, and monitoring is performed as often as required, including throughout the night.

Further refinement to technical procedures and housing are implemented when they are shown to be beneficial for the animals and will not reduce the quality of the scientific outputs.

When an established model is identified from the scientific literature and proposed for use under this licence, a small number of pilot studies will be performed under a separate licence authority to ensure the model delivers high quality scientific data whilst allowing the development of adverse event controls and scoring systems that may be able to be used to reduce the severity experienced by the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to Home Office and EU guidance documents, relevant best practice guidance will be sourced from the NC3Rs (e.g. ARRIVE Guidelines, blood sampling, experimental design), NORECOPA (e.g. PREPARE guidelines), LASA (e.g. blood sampling, drug administration, aseptic surgery) RSPCA (e.g. septic shock model guidelines) and model-specific publications.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

On a monthly basis the PPL Holder receives and reviews automated literature alerts on animal models and journals relevant to the project licence.

When a new infection type or specific animal model is proposed, a thorough literature review is performed to determine the most scientifically relevant approach whilst causing the least harm, and a new automated alert generated.

In addition to conference attendance, webinars and discussion groups are participated in by the PPL Holder and scientific staff.

8. Genetic and Cellular Mechanisms of Kidney Development and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

polycystic kidney disease, genetic modifiers, disease progression, treatment, rare disease

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine the role of genetic modifiers in Autosomal Recessive Polycystic Kidney Disease (ARPKD). The project also aims to identify potential genetic and pharmacological treatments that could impact disease progression and treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Rare diseases affect 1 in 2,000 people and with at least 8,000 known rare conditions, they impact millions of individuals worldwide. Autosomal Recessive Polycystic Kidney Disease (ARPKD) is one such condition that mostly affects individuals from early on in life, causing massive stress not only to the patients, but their families. To this day, no pharmacological cure exists and the individuals' only option in many cases is a kidney and/or liver transplant. ARPKD is caused by changes in DNA in PKHD1 and DZIP1L1. Patients with the disease display symptoms such as enlarged kidneys; liver defects and smaller lungs, with death in around 30% of affected neonates. A range of disease severity is observed in ARPKD, with some patients dying in the first 5 years of life, whilst others maintain kidney function until their early 20s.

This project will shed light on the molecular mechanisms of ARPKD and conduct pre-clinical trials on appropriate mouse models to identify promising treatments.

What outputs do you think you will see at the end of this project?

At the end of this project, we will have acquired a better understanding of the role of various genes in ARPKD and this knowledge could inform patient diagnosis and prognosis. It is likely that at least one of these mouse lines will help with the identification of novel genes that modify polycystic kidney disease severity; this could help us with predicting disease prognosis. Furthermore, once fully characterised, some of these lines could be used for pre-clinical trials on compounds that slow down polycystic kidney disease progression. We will also test at least two potential repair factors on mice and be able to determine if they may be of therapeutic value in ARPKD. We hope to find that at least one of them slows down kidney disease, so that future clinical trials assessing the efficacy of this factor can take place. We will publish all the information we have acquired from this project for both specialist and non- specialist audiences and communicate our findings at research conferences and patient information days.

Who or what will benefit from these outputs, and how?

The short-term benefits will be increased knowledge accumulation on the molecular mechanisms of ARPKD. Where genes that are linked to ARPKD are identified, these could be in the future added to genetic screening profiles to aid with diagnosis and prognosis of patients.

Appropriate mouse models will be made available to researchers for the development and testing of targeted treatments.

Any effective repair factors tested and found to be effective, could go on to be tested in clinical trials.

We will communicate our findings to non-specialist audiences, eg. patient families, so as to update them on the research progress and investigate whether their experiences as patients can inform our further work. At the end of the project, our research outputs will be accessible to researchers, clinicians and policy makers and if proven that additional genes impact ARPKD, this would be beneficial to diagnosis, prognosis and treatment.

How will you look to maximise the outputs of this work?

The outputs of this work will be communicated to my current kidney and cilia networks via the Ciliopathy researchers' network and the British and European Renal Associations. We will expand our current network of research collaborations in kidney, cilia and lung to include specialists in liver physiology and to create a global network of multi-organ ARPKD knowledge. Any unsuccessful approaches or negative data will be published to relevant open access scientific publications e.g F1000research, so as to avoid research repetition and inform future research directions.

Species and numbers of animals expected to be used

- Mice: 10,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our work will be exploring the role of genetic modifiers in ARPKD severity in mice. We will be investigating the effect of genes and environmental factors on organ function during development and in paediatric and adult stages, so as to assess ARPKD manifestation and severity at all stages of the disease and thus acquire a thorough understanding of the role of various factors that affect organ structure and function throughout the whole life cycle. Mice are chosen as a species of interest as they have a high genetic similarity to humans and are of crucial importance for pre-clinical trials. Mice have been successfully used in the past to model human Polycystic Kidney Disease (PKD) and the use of a mouse model led to the discovery of tolvaptan, the only drug currently available for dominant PKD. Other animals such as zebrafish or flies are not appropriate for PKD research, as they do not fully mimic the symptoms of the disease.

Typically, what will be done to an animal used in your project?

Already existent genetically engineered mice will be placed in metabolic cages for 24 hours to investigate their kidney function. They will also be exposed to a number of environmental factors for short periods e.g. nephrotoxic agents, repair factors to investigate if they modify organ function.

Factors will be administered orally or by intraperitoneal injection to postnatal or adult mice, for a maximum of four times over a 28-day period. Mice will also be assessed for serum markers of kidney function and they will be video monitored as well as in vivo imaged to investigate how their genetic modifications and interventions by repair and damage agents affect their kidney and other organ function and overall well-being. All mice will be humanely killed at the end of the procedures.

What are the expected impacts and/or adverse effects for the animals during your project?

None of the procedures used should cause lasting harm. Some stress may be associated with the procedures that will be performed e.g. metabolic cage housing, tail bleeding and mice will be closely monitored and appropriate interventions will be applied, should this arise. It is also possible that some mice may develop polycystic kidneys. If this were to occur, their diet will be carefully monitored and daily well-being monitoring will take place. Some of the substances we administer may result in some loss of appetite and weight loss or weight gain, polyuria or polydipsia, however, these symptoms are transient. We will closely monitor mice for signs of ill health such as piloerection, hunched posture, inactivity or inappetence. If any such symptoms are observed, mice will be monitored more frequently. Should the signs persist within a working day, the animal will be humanely killed. In addition, mice will be weighed daily and any animal that loses 15% of its starting body weight will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around 80% of animals will experience mild severity or sub-threshold severity, where animals are bred, genotyped and then killed to obtain tissues and body fluids. Of the 20% of mice remaining, 10% of these mice (used in Protocol 3) could reach moderate severity. A further 10% of the total mice will be used in Protocol 2, however, only one quarter of these mice could reach a moderate severity limit i.e. only those where the gene of interest has been completely removed (homozygotes) therefore the total percent of mice that may reach moderate severity is 10% from protocol 3 plus 2.5% from protocol 2= 12.5%, i.e. 450 mice.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the kidney is a complex organ which helps maintain a healthy digestive and circulatory system, it is not possible to undertake certain comprehensive physiological studies outside the context of an intact organism where all native cell and tissue types are present in their normal numbers and arrangements (e.g. epithelium, mesenchyme, vasculature, lymphatics). In addition to all of these components being present in their normal arrangements (morphology) constituting an entire organ, the kidneys must be connected to an active circulatory system, so as to be able to perform their normal physiological function of removing waste from the body. There is currently no alternative to a whole animal that can reproduce all of these factors together.

Another key reason why we cannot currently entirely replace animal use for this project is that this study focuses on how developmental pathways and their disruption have a long-lasting effect on adult health and disease suffered in the postnatal animal. It is therefore necessary to perform these studies on mice with developmental disorders maturing into effected adults. Moreover, we wish to identify genes that are required to establish normal structure of the whole kidney, e.g. for the kidneys to form their full complement of sub-cellular structures. We do this by analysing the whole kidney both during development and post-natally, if embryonic development is affected, in the context of a mouse carrying a genetic modification in a gene(s) of interest. This type of analysis must be undertaken in whole intact kidneys that have developed in a genetically modified in vivo environment, so that it is not based by epithelial cell types that are predominant in cell lines or kidney on a Chip.

Which non-animal alternatives did you consider for use in this project?

Whenever possible we make use of non-animal alternatives. We have explored the role of genetic modifiers in mouse and human cell lines e.g. kidney epithelial cells. This project is based on results from human kidneys from ARPKD patients obtained upon nephrectomy, but since this is a rare disease, numbers are very limited. Our work on mouse and human cell lines and human ARPKD kidneys has identified specific genes that are dysregulated in ARPKD. These are the genes that we will be further investigating in mouse lines. Throughout the project, where possible, non-animal experiments will be employed e.g. human tissues samples, kidney epithelial cell lines and we will consult various databases of existing human and mouse information. We will monitor for developments in the field and the potential application of non-animal alternatives through the British Renal Association, the European Renal Association, peer-reviewed published work in nephrology journals and nephrology conferences' presentations.

Why were they not suitable?

In vitro experiments do not allow us to study the parallel effect of genetic modifiers in a whole organism, which is crucial for a disease such as polycystic kidney disease, which besides the kidney may also manifest in the liver, pancreas and lungs. Parallel studying the molecular mechanisms of disease manifestation in all these organs may shed more light in disease prognosis and treatment. Human kidneys from ARPKD patients are extremely rare, very hard to find and difficult to genetically modify. Studies on post mortem tissue do not allow us to investigate the physiological function of the kidney. Kidney on a ChIP is not appropriate for this work, as it mainly permits of the growth of one specific kidney cell type and this is not the cell type that is affected in ARPKD.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is estimated based on previous experience of the number and type of experiments we will do over the duration of the project. E.g. in a typical experiment described in protocol 3, 32 mice are required for a backcross and 50 mice for the intercross, as per our previous experience.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where we had previous data from similar experiments available, online power equation calculators were used to determine animal group sizes required to obtain statistically meaningful data. We also employed the NC3R's experimental design assistant where possible to ensure that animal numbers are the minimum required to obtain meaningful data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to make use of databases of human and mouse information e.g. UK Biobank and Mousephenotype.org to obtain information which will reduce the number of animals we need to use.

Using our experience and that of the animal technicians, we will employ efficient breeding strategies; for example, mouse lines will only be maintained whilst there is a justified use for their continued breeding. Any line with no predicted usage will be cryopreserved. Prior

to establishment of a colony of GA mice under this licence, any available breeding data will be sought. Well-established breeding calculations will be used to predict output.

Breeding numbers are calculated taking into account average litter size for that stock as well as known neonate mortality. Breeds are set up in a controlled, time-restricted manner, to ensure that all mice born are the correct age for the study.

Where breeding information is not known (i.e. for new lines) a small pilot breed will be carried out first to assess viability. These mice, if viable, can be used for the first cohort of the study, and remaining larger breeds will be set up taking into account information gathered from the pilot breed.

Where possible, we will maximise the data obtained from each cohort of mice. For example, when mice are sacrificed blood, urine and any relevant tissues will be extracted from the same animals. Where relevant, this may include tissues from other organs such as heart, lung, liver which we will share with our existing collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The severity of the breeding stock will be held to a minimum by the following strategies: Information gathering- Information on any expected adverse effects will be gathered prior to establishment of a line. Welfare assessment - Systems of comprehensive welfare assessment are in place. These will be used to define the least severe humane endpoints for every GA line. Least severe genotype - Where possible the lines will be maintained as the least severe genotype possible (e.g. heterozygotes will be used for stock maintenance where the homozygous state has undesirable adverse effects).

Sampling techniques - The least severe technique will be used to obtain a biopsy for genotyping i.e. from the ear pinnae.

Phenotyping tests - Kidney function analysis will be assessed in metabolic cages. Mice will also be monitored for welfare and imaging techniques will be employed to check their organs.

Where substances are administered to mice e.g. nephrotoxic agents, we will use the minimum amount of agent, by the most appropriate route (typically intra-peritoneal administration) which has previously been shown to cause the desired effect.

Why can't you use animals that are less sentient?

The mouse is the lowest mammalian species in which the full range of genetic and physiological manipulations necessary for the investigation of kidney development and disease can be achieved. It is critical to perform these studies in mammals since there are significant differences between the metabolic systems of frogs and fish to that of humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Increased daily monitoring of animals will take place where substances have been administered, this will include monitoring of body weight allowing us to define more humane endpoints. Pain management will be provided on the advice of the Veterinary Surgeon for any procedure or situation that requires it. Where agents are administered, this will be done as per published protocols, using known drugs. Training is continual, making use of new developments and technologies as they become available.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The establishment where work under this licence will be undertaken is AAALAC accredited. We will follow published ARRIVE guidelines and as well as information issued by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), and the RSPCA. Routes and volumes for administration of substances will be taken from Laboratory Animal Science Association good practice guidelines: administration of substances 1998 (http://www.procedureswithcare.org.uk/lasa_administration.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The scientific literature and conferences are sources of information on new developments and technologies, as are workshops run at our university on the Replacement, Refinement and Reduction of animal use that I will attend. The establishment where this licence is held often develops and introduces 3Rs advances. Our previous work has developed new tools for research into kidney development and disease using cell lines and urine patient-derived cells that replace animal use by generating material from human urine.

9. Pathophysiology of Rhomboid-Like Proteins in Mammals

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Mouse, Rhomboid, Inflammation, Growth factor, Signalling

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our ultimate goal is to discover whether the rhomboid-like proteins are potentially valuable medical targets. To do this, we will investigate the physiological roles, and possible disease significance, of proteins of the rhomboid-like superfamily.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Research has shown that proteins of the rhomboid-like family are unusual proteases – enzymes that cut other proteins – which specifically target membrane proteins. More recently, rhomboid proteases have been discovered to be members of a much broader

family of proteins whose fundamental role is to interact with other proteins in cellular membranes and to control signalling between cells.

Understanding the signalling between cells and what goes wrong in diseases is a major goal of modern biomedical science. It has also become clear that rhomboid-like proteins participate in many important processes of potential medical relevance, including in cancer, inflammation, pathologies associated with or exacerbated by ageing, diabetes, neurological disease. Much of this prior work has focused on invertebrate model systems and cell culture. Little is yet known about their function in mammals and, despite knowledge of how rhomboid-like proteins work at a molecular level, little is known about how they contribute to health and disease. Very recent work with mice, however, has supported the idea that members of this family are medically relevant, specifically in the field of immune system function, inflammation and cancer. For example, the iRhom proteins have been specifically linked to inflammatory processes including rheumatoid arthritis and heart repair after myocardial infarction. We need to understand whether these proteins are valuable therapeutic targets and, if so, in what specific disease contexts.

What outputs do you think you will see at the end of this project?

This work will illuminate the physiological significance in mammals of novel and fundamental cell biological processes. Such discoveries will be published in open access scientific literature so that it is available to anyone for free. These advances will be used by the wider scientific community to extend the limits of our understanding of biological systems that have ultimate medical relevance. Areas of medicine in which current evidence implicates the Rhomboid-like family include cancer, inflammation, metabolic disease, bacterial infection and parasite invasion.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries will be the scientific research community. In the short term, this will specifically be the worldwide community of scientists working on related areas of rhomboid-like proteins and the regulation of membrane proteins. In the longer term, our hope is that the conceptual discoveries that our work will lead to will benefit biomedical scientists working on a wider range of topics including how cells signal to each other, how protein quality control is regulated and how these cellular processes affect the whole animal. Data will also be very useful for other researchers studying a host of processes related to human health and disease (e.g. inflammation, cancer, neurodegenerative diseases) and we will publish it in appropriate journals to ensure that all relevant researchers can benefit from this work.

Longer term beneficiaries will be the public, through expected improvement in health care. Specific areas that are of current interest include cancers, especially of the lung and oesophagus; neurodegenerative diseases like Alzheimer's Disease; and metabolic diseases such as diabetes. But the fundamental significance of the biology we study means that many other diseases may also become relevant as we learn more. These

ambitions are not imminent but our work seeks to build the foundations for new therapeutic and/or preventative strategies. To realise such potential, we will work in collaboration with pharmaceutical or biotechnology companies as appropriate.

How will you look to maximise the outputs of this work?

We frequently find it is more efficient to collaborate with other expert groups to maximise our ability to exploit our discoveries. The nature of our research leads us into a wide range of physiological and disease contexts where our own experience is limited. Well targeted collaborations accelerate progress.

We aim to publish in open access, free to all, scientific literature all our research that is rigorous and reproducible, regardless of whether the results are positive or negative. Disseminating knowledge about unsuccessful approaches can be as valuable as more obvious breakthroughs. We now publish all our work on preprint servers so that our results can be distributed prior to the slower process of peer reviewed publication in leading international journals, where all the work will eventually end up. Our work will also be communicated through conference presentations by me and members of my group.

We have frequently discussed with the commercial sector the potential exploitability of our research. These conversations are ongoing, continuously looking for opportunities that can be pursued by those routes.

Species and numbers of animals expected to be used

- Mice: Mice, up to 10,000 over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Because our starting point is understanding fundamental cellular mechanisms, our work always starts with biochemical and cell culture experiments that do not involve animals. As we begin to reveal those basic mechanisms, we then need to apply that emerging understanding to animal models to ask the question of the overall biological significance of what we are studying. The physiological role of proteins can vary substantially between species, explaining this need to validate all the previous work in a system much closer to human biology. Specifically, mice are the organism of choice because they are mammals, and thus quite close to humans in evolutionary terms. They are also the mammal with the most sophisticated genetic technology available to allow us to perform our experiments with maximum efficiency. Without these experiments, our work cannot be used to infer the real significance of the cellular mechanisms in whole animals, reducing its potential benefit.

A few specific examples of rhomboid-like proteins have been implicated in disease processes including their role in the invasion of host cells by apicomplexan parasites, which include the malaria parasite Plasmodium; their now well established central position in promoting and regulating inflammatory signalling, which in turn has relevance to diseases as diverse as rheumatoid arthritis, cancer, metabolic disease, and neurodegeneration; and their role in regulating T cell immune homeostasis, growth factor release in cancer, and mechanisms of antibiotic resistance in some bacteria.

The clear preliminary evidence, outlined above, of the potential medical significance of members of the rhomboid-like superfamily, provides the incentive and justification to learn about their physiological role in mice and, by extension, humans.

When we do use mice, they can be at any stage of life. Most of our experiments are performed on adult mice. But we also occasionally use pre-weaning animals if we see evidence that our genes of interest affect those early stages. We also allow some mice to live to old age, to investigate potential roles in aging of the genes we study. For example, as humans age, systemic inflammation is associated with neurodegeneration, so the link between rhomboid-like proteins, inflammation and neurodegeneration may have relevance to human age-related disease.

Typically, what will be done to an animal used in your project?

Most of the mice we use are genetically modified to alter genes that we are interested in. The mice are obtained by breeding, non-surgical embryo transfer and, in some rare cases, surgical embryo transfer. To infer the roles of the genes we have modified, we then typically observe them to look for changes to their development, physiology or health. Beyond breeding the genetically altered animals, the most common experiment is to humanely kill the animal and then dissect and study their organs post- mortem. In some cases, to assess the potential role of the genes of interest in ageing or metabolism-associated pathologies, we will age the mice and use models of diabetes. The duration of these experiments is kept to the minimum that allows us to collect the necessary data.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals used under this licence will experience no detectable clinical harm or suffering until they are humanely killed before they are 15 months old. They will simply be bred with an alteration in a gene that does not detectably affect them.

For some of our experiments, we will age mice up to 2 years. Ageing mice may develop conditions such as dermatitis, cataracts, dental diseases or tumours. Animals that show signs of ill health associated with any of these or other conditions will be killed humanely.

One of our protocols can lead to the onset of diabetes. In this protocol, we will keep mice up to 1 year on a high fat diet. Blood glucose level will be measured in these mice to monitor the onset of diabetes.

Some genetically modified strains that we currently maintain can produce moderate clinical signs. Although some homozygous genetically modified pups die within a few hours of birth, those that survive more than a day are indistinguishable from their heterozygous and wild-type littermates until about 10 days after birth. Around day 10, these surviving homozygotes become recognisably smaller than normal, but appear otherwise healthy and show no other signs of harmful effect. Between days 14 and 21 (exceptionally later), they develop signs of failure to thrive and rapidly decline; if left, they die within 2-3 days after that stage. The signs that we have detected in this final phase include subdued behaviour, prostration and weight loss. Pups of these strains are therefore monitored and weighed daily from day 5. All these animals gain weight, although the homozygous genetically modified mutants do so at a slower rate. Eventually, the homozygous mutant animals start to lose weight. When the weight of an animal drops by 15% from its peak, it is humanely culled. This should prevent any animal from showing signs of suffering but, in addition, any mouse will also be culled at the first indication of prostration or subdued behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 80% Sub-threshold, 5% Mild, 15% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice are well established as the best model system for identifying the function of specific genes in mammals. Usually this is done by removing or knocking out the relevant target gene, or by expressing it in abnormal places or levels. The consequent effects on the mice or on cells derived from them are observed and they give strong clues about the function of the gene/protein of interest. In fact, we do all of our initial research in cell culture and using the fruit fly Drosophila. This allows us to obtain most of our results without using mice, thereby minimising potential suffering. However, where we need to extend our results into mammals, to investigate their relevance to human and animal health, we need

to use mice. For example, we have evidence that the iRhom1 and iRhom2 genes regulate inflammation; that the TMEM115 gene is involved with metabolic control; and that the RHBDL2 gene regulates immunity. We need to use mice to explore whether these functions are physiologically and pathologically significant. These questions cannot be addressed in cell models or Drosophila.

Which non-animal alternatives did you consider for use in this project?

- We do as many of our experiments as possible in vitro, in tissue culture cells. For example, we always start by creating new mutant cells that can be used to investigate much of the fundamental biology without using mice. This is usually the best approach to analysing molecular and cellular mechanisms. We limit our use of animals to asking questions about whole organism consequences of our experimental manipulations.

- We use in silico databases (such as Protein Atlas, BioGPS, UniGene, etc) to check the patterns of expression of the genes of interest, avoiding the need to take samples from mice.

- We systematically monitor information from mouse knockout projects (for example the International Mouse Phenotyping Consortium) to ensure that we do not remake GM strains that already exist and to capitalise on their existing phenotyping data. Where possible, we can import relevant GM lines, avoiding the need for us to remake them.

Why were they not suitable?

Ultimately, the information we acquire from biochemistry, cell culture and computer-driven approaches needs to be validated and understood in the context of whole animals, which are much more complex systems than these reductionist approaches can explore. At that stage in our work, we need to be able to ask the question about whether what we have discovered does apply to whole animals. We typically address this question first in the fruit fly Drosophila, but need ultimately to extend the logic into mammals. Only where appropriate GM strains do not exist in publicly accessible databases, do we need to make them ourselves.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We carefully design all our experiments to ensure that they are as efficient as possible, so that we can produce the maximum amount of statistically rigorous data from the minimum

number of animals. For example, in the case of majority of our mouse work, breeding GA animals, this means that we first calculate how many mice we will need to analyse a phenotype. Then, based on our prior experience, we only breed that number, producing as few mice as possible. In the smaller number of cases where we need to do an experiment that involves treating mice with substances the same principle applies:

we determine in advance, using a pilot experiment, what is the smallest number needed to produce statistically robust data, and we use only that number in our experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our focus on using systems other than mice for all the early stages of our work, combined with planning to breed only the number of mice we specifically need, make us confident that we are using the minimum number of mice possible for our work.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As described above, our mouse work is a very limited proportion of our overall experimental approach. As well as efficient breeding, pilot studies, sharing data and tissues with collaborators, our whole approach is to use animals only when there is no alternative.

We also consult mouse phenotype databases to ensure that we do not duplicate work that is already in the public domain; this information also helps us to give priority to genes with phenotypes expected to be of interest.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Wherever available, we use genetic models of disease that are the most precise and efficient way of mimicking in mice the relevant human disease. We take great care that all procedures done on mice are performed by state of the art methods and only by people who have appropriate training. We use a range of scientific communication methods (work published in journals, conference presentations, informal networks, online resources) to learn about best practice so that we can ensure that our methods are as refined as

possible. We hold regular team meetings to ensure that this information is spread across our group, and with collaborators. We also attend regular meetings among the wider scientific community to stay current with best practice.

To assess possible metabolic defects, where there is mechanistic evidence to suggest a role of a specific rhomboid-like protein (eg in the case of TMEM115) we will maintain mice on a high fat diet. This is a standard method to induce obesity and type II diabetes in mice. This is a non-invasive model that will allow us to address if specific proteins of the rhomboid-like superfamily affect onset of obesity and diabetes.

To assess any age associated phenotype, we will maintain mice up to 2 years. This is just natural ageing and is therefore the most refined technique to allow the observation of any late onset phenotypes. As mice become older, after 12 months, we pay extra attention to their health and observe them carefully for any clinical signs.

Why can’t you use animals that are less sentient?

Our general approach is to perform most preliminary organism studies in simple invertebrate model organisms including the fruit fly Drosophila, or even in yeast. Not only do these systems allow much more rapid mechanistic progress than using mammalian models, but this approach also reduces substantially the need to use mammals for early phases of our experiments. A successful outcome of the Drosophila work allows us to have a clearer view about the physiological role of a gene. This approach is based on the highly conserved nature of rhomboid-like genes. Although the overall physiological role of rhomboid-like proteins in mammals cannot be inferred from their function in invertebrates, all current evidence supports the conclusion that their basic cellular mechanisms are conserved. Ultimately, however, it is essential to extend our invertebrate studies into mammalian model systems, partly to validate the models, partly because however good a model is, mammalian biology is almost always more complex, and partly because some of the genes we study (eg RHBDD2) are only present in mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise the welfare cost of procedures, we will monitor carefully animals for any sign of adverse effect. If an animal exhibits any adverse effect, we will take action according to procedure detailed on each specific protocol which include increased monitoring and attempt to ameliorate these initial signs. For example, in some specific cases we will maintain mice on high fat diet for up to a year. During this procedure, blood glucose level will be measured to detect the onset of diabetes. Also, during ageing, animals will be carefully monitored for age-associated conditions such as the presence of palpable masses, skin abnormalities, or dental overgrowth. After surgical embryo transfer under general anaesthesia, we will monitor how the animal recovers from the anaesthetic. If the animal exhibits any sign of pain, peri-operative analgesia will be administered and continued after surgery for as long as required to alleviate pain.

For genetically modified strains that can exhibit moderate clinical signs, such as TMEM115, we set up a more refined breeding strategy. For these strains, it is only the homozygous genetically modified animals that exhibit moderate clinical signs; the heterozygotes are indistinguishable from wild-type littermates. We therefore maintain the colony with heterozygous animals by crossing heterozygotes with wild-type. Only when we need homozygous animals for an experiment do we cross heterozygotes with heterozygotes to produce homozygous pups. Some of these homozygous genetically modified pups die a few hours after birth, and those that survive longer show signs of harmful phenotypes within a few weeks after birth. To reduce suffering of these pups, we perform most of our experiments just after birth. Only when it is experimentally required, do we maintain homozygous animals for a few weeks. In this case, pups are weighed daily and closely monitored for any sign of harmful phenotype.

When the weight of an animal drops by 15% from its peak, it is humanely culled. This should prevent any animal from showing signs of suffering, but any mouse is also culled at the first indication of prostration or subdued behaviour.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure that experiments are conducted in the most refined way, we rely on best practice guidance provided by the Named Information Officer and available on the following websites:

www.nc3rs.org.uk https://norecopa.no https://www.lasa.co.uk

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly monitor information from the NC3Rs (www.nc3rs.org.uk); there are active email circulation lists operated by the university's named information officer; we attend termly animal welfare meetings in which developments in 3Rs are regular agenda items, often led by expert speakers; and we are greatly supported by the local network of Named Animal Care Welfare Officers, vets and animal technicians, all of whom have great experience in animal welfare and experimentation, as well as having their own networks.

10. Developing a Treatment for Osteogenesis Imperfecta

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

collagen, osteoblast, therapy, b**ones, stem cells**

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to test the efficacy of innovative treatments to counteract bone fragility.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In human, osteogenesis imperfecta (OI) is a rare genetic disease characterised by bone fragility, short stature and skeletal deformities in response to a genetic mutation in the genes encoding type I alpha 1 or alpha 2 pro-collagen. This is a severe and debilitating skeletal disease that starts to manifest in the womb. There is currently no cure for this pathology. This project tests the potential of new therapeutics to improve skeletal health, with the view to translate these findings to the clinic.

What outputs do you think you will see at the end of this project?

Our outputs will include:

- publication of results in peer-reviewed journals and presentation of the project at national and international conferences in relation to the mechanisms of OI disease progression and the development of innovative therapeutics

- press releases and communication of findings with the public via social networks

- communication of findings with the OI community via social platforms and conferences

Who or what will benefit from these outputs, and how?

- in the short term, this work will benefit the researchers working on this project (career development,) and other scientists working on developing bone anabolic agents.

- in the long term, this project will benefit clinicians because we will develop and test new therapeutics.

- beneficiaries also include our ongoing clinical trial (BOOSTB4), which is currently testing the safety and efficacy of stem cells injection.

- ultimately, the long-term benefit will be the improvement of the quality of life of children with OI and that of their families.

- reduction of care costs for the healthcare system

How will you look to maximise the outputs of this work?

To maximise the outputs of this work, we are closely working with our collaborators who are also using OI mice colonies to study cellular stress in response to mutations in genes encoding type I collagen. As we are collaborating with this group for another project using the same mice, we will benefit from their advice on this animal model.

New knowledge will be distributed internally (work in progress and seminars) as well as externally (publications, conferences, press).

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using this mouse model of brittle bone disease because it is the most widely used and a good model for severe osteogenesis imperfecta (OI) in humans.

We currently have an ongoing clinical trial (BOOSTB4) where babies are injected with stem cells in utero, at birth and repetitively thereafter as we have documented that the effects of mesenchymal stem cell (MSCs) transplantation do not last long. This is due to the dynamic biology of the skeletal system, where old bone is constantly resorbed and new bone deposited.

The cells currently used for the clinical trial are isolated from the human liver of terminated fetuses, expanded in the laboratory to obtain sufficient cells, and injected in OI patients.

However, this may raise ethical issues for some patients as mesenchymal stem cells are isolated from terminated donors. In addition, when we expand the mesenchymal stem cells in the laboratory, those age quickly and therefore we need to isolate and characterise more cells from new donors on a regular basis.

We are now testing the possibility to replace the use of human fetal MSCs isolated from termination of pregnancy by another type of MSCs. Specific cells (epithelial cells) found in the urine of the patients are being rejuvenated (induced pluripotent stem cells), subsequently edited to remove the genetic cause of the disease (personalised medicine), before being differentiated into induced mesenchymal stem cells (iMSCs).

Therefore, we are using this mouse model of the disease to determine the efficacy of iMSC injection and other treatments, such as transplantation of the vesicles released by iMSCs (to develop cell-free therapeutics) in order to translate this information to humans and develop the next generation of cell therapy for the treatment of bone fragility.

Typically, what will be done to an animal used in your project?

Typically, pregnant mothers will be left with their litter (from heterozygous x heterozygous breeding or from homozygous x homozygous breeding) until weaning. The pups will be injected intraperitoneally at birth (0-5 day of age) with a sterile saline (PBS) solution containing either human or mouse cells, exosomes, or only sterile PBS (not containing cells nor exosomes), or not injected al all. The pups will then culled at 8 weeks of age.

What are the expected impacts and/or adverse effects for the animals during your project?

There is no expected adverse effect of the treatment (intraperitoneal injection of cells, saline solution or exosomes) for the animals. Our previous work showed that stem cell injection decreases long bone fracture rate by 2/3.

The presence of the naturally occurring mutation is associated with fractures, small size and skeletal deformities in homozygous mice only. It is possible that homozygous mice may exhibit other pathologies such as poor mobility, limping, swollen limbs/joints, signs of pain and discomfort.

Heterozygous mice do not show any phenotype because the mutation responsible for bone fragility is recessive.

Our previous work using the same model and same endpoints has established the potential of human fetal mesenchymal stem cells (MSCs) isolated from the liver of terminated fetuses to counteract bone fragility in this model which best mimics severe human brittle bone disease. The current work aims to test the efficacy of a different type of MSCs called iMSCs, i.e. instead of being isolated from terminated donors, iMSCs are differentiated from induced pluripotent stem cells that have been derived from the epithelial cells found in the urine of the patients following a genetic correction of the disease-causative mutation. We are also testing the efficacy of only transplanting the vesicles released by MSCs to develop personalised cell-free therapeutics.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

When we will cross heterozygous males with heterozygous females. The mutation is recessive. Therefore we will obtain 25% homozygous pups, 25% wild type pups and 50% heterozygous pups. Only homozygous mice present a harmful phenotype of bone fragility.

The heterozygous mice are not phenotypically different from wild type mice and do not present any harmful phenotype (they do not have skeletal deformities and have no fractures).

Based on our previous work (PPL 70/6852), we expect the breeding and maintenance of heterozygous mice to be mild ; breeding and maintenance of homozygous mice to be moderate and the experimental mice to be moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are using an animal model of a human pathology to be able to analyse the impact of the mutation responsible for the disease on the skeleton in various bones, and to determine the efficacy of cell and cell-free therapy on improving the shape and strength of the whole skeleton at the macro, micro and nano level. These analysis will be performed post-mortem.

Which non-animal alternatives did you consider for use in this project?

We are currently developing a human bone-on-chip model of the disease to study the impact of the treatment at the cellular level.

Why were they not suitable?

The in vitro disease model has several limitations. For example it is not possible to study fracture incidence, skeletal morphology and long bone structure and mechanical properties at a macro level.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A statistician has been involved in the preparation of the proposal from. We will use a fully randomized design to reduce the biological variability. We used the power analysis software G*power version 3.1 to determine the number of mice/group, 2 tails, a power of 0.95, and a significance level <0.05, with n1=n2. We determined sample size using the data we obtained in our most recent study where we showed that stem cells improve OI bone properties and quality following a single injection into oim neonates. We will analyse the bones of transplanted mice in a similar manner and therefore will have the same endpoints. Trab number: 1.3±0.19 (mean±STD) vs. 1.7±0.2; ES=2.05; n=8; Bv/Tv: 3.9±0.7vs. 5.2±0.7; ES=1.85; n=9; Bone min density: 0.03±0.01 vs. 0.06±0.01; ES=3; n=5; Total porosity: 7.2±0.7 vs. 5.4±0.5; ES=2.96; n=5; In consequence, we need about 10 mice per sex analysed per group (so 20 mice per group) to attain sufficient statistical power for microCT analysis. We counted 30 mice transplanted per group, in order to take

into consideration a 25% possibility that the bones might be broken and hence unsuitable for analysis, and 25% possibility that other cell types might have a smaller effect than the cells we studied before.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use homozygous mice to study the impact of the treatment with cells or exosomes on bone strength. We will analyse the results as we go along to ensure group size are minimal (using power calculation).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All the bones from experimental animals will be used for analysis. We (and our collaborators) do not have any archived tissues for that purpose.

We do not have any tissues archived to be shared with collaborators and vice versa.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The osteogenesis imperfecta mouse (oim, B6C3Fea/a-Col1a2oim/+) has been used as a model for human osteogenesis imperfecta (brittle bone disease). It was the first animal model of human osteogenesis imperfecta and has been extensively studied.

Why can’t you use animals that are less sentient?

Because this model presents the same phenotypical characteristics as the human condition and enable the efficacy of treatment to be studied at the macro level.

We cannot use strains of OI Zebrafish as those lack the impact of weight bearing on the skeletal, and therefore do not represent the best model for the human pathology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be handled by empathetic capture and handling (e.g. tunnel capture or cupped hands) rather than by scruffing or by the tail, to minimise fractures. To reduce the risk of bone fractures in homozygous mice, easily accessible food and water (e.g. soft/wet/powdered food and TransGel/HydroGel at floor-level) will also be provided. Oim homozygotes are smaller than wild-type or heterozygous mice but animals showing visual signs of weight loss will be provided with appetising food supplements in the first instance such as peanut butter or condensed milk. Animals will be provided with sufficient non-tangling nesting material, refuges to permit natural behaviours, defuse aggression and alleviate anxiety as well as floor-level enrichment such as tunnels. However, to reduce the incidence of fractures, balconies will be removed from the cages to reduce the impact on bones after jumping. We will use special labels to seek attention to the homozygous mice.

We will use the welfare sheet previously developed by ourselves and our collaborators in consultation with the NACWO and NVS, which details husbandry considerations and refinements for the strain. The welfare sheet will include the minimally invasive daily checks that should be carried out as well as the humane endpoints. The sheet will specify whether and how the mice should be handled to avoid fractures. The welfare sheets will then be further refined as the study progresses.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

National Centre for the 3 R's: https://www.nc3rs.org.uk/

LASA guidelines: https://www.lasa.co.uk/PDF/AWERB_Guiding_Principles_2015_final.pdf
Understanding Animal Research: https://www.understandinganimalresearch.org.uk/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

we will regularly check the Home Office website https://www.gov.uk/guidance/research-and-testing- using-animals and the NC3Rs website https://www.nc3rs.org.uk/. We will also remain in close contact with our collaborators.

11. Immune Cell Function in Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, metastasis, immunology, genetically engineered models

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the role of the immune system during cancer progression, cancer spread (metastasis) and therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important to gain fundamental insights into immune cell function during cancer progression, metastasis and therapy. These results may be useful to develop immunotherapies in the future.

What outputs do you think you will see at the end of this project?

Data generated from this project will include new information on the role of immune cells in cancer progression and spread (metastasis), which will result in publications and datasets that will be made publicly available.

Who or what will benefit from these outputs, and how?

These findings will benefit researchers studying immunology and cancer biology, as this will provide a greater understanding of the connection between cancer cells, immune cells and other components of the tumour microenvironment and of the mechanisms that drive cancer progression and metastatic disease. The impact of these benefits are likely to be long-term, as it will enable researchers to generate more informed hypotheses and will improve experimental design in accordance with the 3 R's (replace, reduce and refine).

How will you look to maximise the outputs of this work?

We expect the output of this work to lead to the establishment of collaborations with other research groups working in similar fields. We will look to disseminate any new knowledge by manuscript publication and the presentation of novel data at conferences to seek out potential collaborators. We will also promote new developments through social media networks as a way of informally communicating with scientific colleagues, but also sharing our findings to the wider public.

Species and numbers of animals expected to be used

- Mice: 45000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Genetically engineered mouse models of cancer are the most representative models of human cancer available, since they progress through the same stages as in humans and metastasize to the same sites. Our choice of mouse models is based on the same mutations that occur in human cancer. In these models, tumours arise in adult mice.

Typically, what will be done to an animal used in your project?

Mice with genetic alterations will be bred and used in experiments. The majority of mice in the project will not suffer any adverse effects because they will not express all the right gene mutations to develop cancer. With regard to the mice carrying the right gene mutations, most will develop cancer as adults and be humanely killed without additional procedures when they show symptoms of cancer. Cancer will be induced in some mice using an injectable agent, typically on one occasion only. In a small number of cases, in order to study particular key aspects of human disease, including the process of metastasis, surgical techniques may be used to implant tumour cells grown in the laboratory into organs affected by metastatic disease, such as the liver or the colon.

Some mice will be used in preclinical trials, in which they will be administered with treatments designed to potentially benefit human patients. These treatments can include drugs, which can be administered orally or by injection, or can include radiotherapy using a specially designed small animal radiotherapy machine. In a small number of cases, tumour growth and response to treatment may also be monitored using advanced imaging techniques which are commonly used for human patients in the clinic, such as MRI, ultrasound or CT scanning. This will require mice to be anaesthetised for short periods of time while images are collected.

All experimental animals will be humanely killed and tissue specimens collected for analysis to maximise the data available from every study.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of mice in this project will have a subthreshold severity, meaning that they will show no harm, and will undergo no procedures other than earmarking for identification purposes. About a quarter of animals (25%) will have a predisposition to develop cancer, of which a proportion will exhibit no more than mild adverse effects, as they will be sampled at timepoints prior to manifestation of clinical symptoms of ill-health. The remaining animals will be expected to develop moderate adverse effects associated with tumour development. With respect to procedural burden (e.g. imaging, therapeutic intervention, metabolic labelling), some animals will experience one or more procedures, which will never exceed a moderate severity.

Under this project, cancer-related genetic changes will be targeted to a tissue of interest, such as the intestine, pancreas, liver or mammary gland, which will result in a specific predisposition to cancer development in that tissue. These animals will then be continually monitored for clinical signs which may indicate tumour growth. These signs can include anaemia, weight loss, swelling of the abdomen and development of palpable or visible tumours. Highly trained staff will monitor for these symptoms, and they are observed to interfere with normal behaviour, reach the limits allowed in the guidelines or have any consequences that are outwith the guidelines, mice will be humanely culled and tissues harvested for analysis. Typically mice might exhibit mild clinical signs, which do not impact

normal behaviour for around 1-2 weeks, and moderate clinical signs for 24-48 hours before they are humanely killed. Animals which undergo surgical implantation of tumour cells under anaesthetic, may experience transient discomfort (~48hrs), which will be alleviated through administration of pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Tumour-bearing mice typically experience moderate severity, while tumour-free mice experience sub- threshold severity. Across all cohorts, we expect that 50% of animals will experience sub-threshold discomfort with 50% of animals experiencing mild or moderate discomfort.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Genetically engineered mouse models (GEMMs) of cancer are the most representative models of human cancer and can be easily manipulated to enable tumour development. These models are driven by a combination of activated oncogenes and mutated tumour suppressor genes that occur in the human cancer, and these display similar tumour progression, metastatic dissemination and clinical manifestations found in human disease. Additionally, mice with a fully competent immune system can be used to study the dynamics of tumour cell/immune cell interactions during tumour development.

Combining GEMMs with the loss of specific immune system components (such as genetic depletion of individual cell types) then enables the impact on tumour growth and metastatic dissemination to be assessed in the context of immune dysregulation.

Which non-animal alternatives did you consider for use in this project?

Where appropriate, non-animal alternatives such as cell culture will be used to address our objectives, in accordance with replacing and reducing animal experimentation. Often this is considered when investigating a mechanistic pathway following a significant finding from animal modelling.

Why were they not suitable?

It is not feasible to study the complex interactions between cancer cells and immune cells or the crosstalk between different immune cells in humans and animal models. To accurately model the tumour microenvironment and provide more faithful models of tumour progression and metastasis, a whole immunocompetent organism is required. Mice contain specialized organs that lower organisms do not possess, specifically an intact immune system which enables us to study the co-evolution of immune responses with tumour development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used were based on previous usage, breeding pairs required, output of breeding pairs with correct genotype for each model, experience with each model and power calculations for specific experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We make use of multiple tissues from every mouse so that less animals are needed. We also routinely perform power analysis to determine the cohort size needed to achieve significant results, this is often informed by pre-existing data gathered from pilot experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breedings are carefully designed to establish efficient breeding pairs, which in turn reduces the number of mice needed to generate tumour-bearing cohorts. Breeding pairs are also closely monitored to avoid animals reaching ages where adverse effects are evident, and we also monitor breeding efficiency to prevent excessive breeding pair numbers.

Often we implement pilot studies, and try to use cell culture models where appropriate, alongside power analyses to predict cohort sizes that would return significant results, which reduces the numbers of mice potentially used throughout this project.

Finally, when establishing a project we often bank various tissues/organs for future use, which prevents the unnecessary generation of additional mice. Furthermore, the

collaborative nature of our research encourages the sharing of tissue if needed for pilot studies, which reduces the number of mice used across multiple projects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically engineered mouse models of cancer as well as tumour transplantation models because they contain an intact immune system. Whilst spontaneous tumour development is a central part of this project, appropriate steps will be taken to ensure the wellbeing of animals and to minimise the potential harms may have upon normal animal behaviour. We do not seek to keep animals that are suffering significant adverse effects and plans as far as possible to avoid animals reaching the stage where adverse effects are present. Mice are checked daily by animal staff as part of welfare checks, and up to three times weekly by researchers to monitor for any unexpected or expected phenotypes during tumour development. We have extensive in-house experience with the models detailed in this project, and have well-defined limits of humane endpoints, which are applied to prevent excessive suffering.

Why can’t you use animals that are less sentient?

We will use adult mice with a fully competent immune system to mimic cancer in humans. A fully competent immune system is crucial, as tumours develop within an inflammatory fibrotic matrix that influences tumour progression, metabolism, invasive potential and metastatic dissemination. This is best modelled in mice with competent immune systems that develop tumour spontaneously and which mimic human disease through genetic mutations, disease progression and clinical manifestations.

Terminally anaesthetised animals are not appropriate, as we aim to study the progression of tumour over months, where the co-evolution of immune responses and tumour growth will be studied.

Additionally, this co-evolution cannot be modelled in less sentient animals, or through experiments in the lab, as they do not recapitulate an immune competent setting.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Currently, we use frequent monitoring, post-operative care, pain management and advanced training of staff to minimise harm to animals. We have adopted non-aversive handling methods and avoid single housed animals to reduce stress and encourage social behaviour. We will continue to review our practices over the course of the project to ensure that we use the most up-to-date refinement methods available.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to ARRIVE guidelines and the NC3Rs strategy documentation to ensure compliance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Me and my team will regularly visit the NC3Rs website to remain up-to-date with 3R resources, the publication of new methodologies and also to ensure adherence to ARRIVE guidelines. We will also attend conferences where we can discuss the implementation of 3R policies with other members of the scientific community.

12. Breeding Genetically Altered Mice

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Breeding, Maintenance, Reproducibility, Supply, GA mice

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To breed and maintain genetically altered mouse models relevant to the study of normal and abnormal biological and pathological processes in mammals. To carry out breeding as a service to scientific groups throughout the UK and occasionally abroad.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Undertaking this work as part of a standardised breeding programme is essential to increase reproducibility, maintain the genetic integrity of mice used in genetic research and offers the opportunity to reducenumbers for specific projects.

1) Breeding cohorts under one breeding licence allows us to control the breeding strategies and ensure background strains are consistent, genetic backgrounds reproducible and describable for publication. We can also ensure that controls and experimental mice are bred using the most appropriate breeding strategy to minimise experimental variables and cohorts are produced in appropriate timeframes.

2) Breeding of newly generated GA lines will be done on this licence before they are sent to researchers. This allows us to increase stock numbers and archive the lines, whilst gathering important welfare information and carrying out any additional Quality Control (QC) measures to ensure newly modified alleles are fully characterised.

3) Quality controlling inbred strains of mice ensures that subsequent experimental cohorts bred using these strains have a known, reproducible genetic background. Conclusions about the phenotype caused by the introduced genetic alteration are easier to interpret and more robust and reproducible using inbred strains rather than non-standardised or uncontrolled backgrounds.

4) Central holding of GA stocks means that several researchers can be supplied from the same colony without the need to keep duplicate colonies which would use more mice.

What outputs do you think you will see at the end of this project?

1. Cohorts of mice will be maintained and bred for specific projects and transferred to other project licences either at the primary establishment, or at other establishments. Cohorts of mice will also be bred for tissue preparation and collection at the establishment. These cohorts will be used for many types of research in many different areas. Often the outcomes of these projects will lead to a greater understanding of biological mechanisms and underlying disease. In turn this can lead to better diagnosis of human conditions, and the potential to use the mouse as a model to test therapeutics. It is difficult to predict the numbers accurately as these will be dictated by scientific justification of the individual projects, however we are likely to breed around 30-50 of these cohorts per year. These mice will be bred under strictly controlled conditions, for example producing age matched cohorts with relevant controls on an appropriate background. By using our extensive knowledge of breeding GA lines and keeping ourselves current with recent developments in the field, we will strive to produce cohorts of mice that are high quality. The alternative would be to ship breeding pairs which would require multiple breeding steps at another establishment. Many establishments do not have access to facilities available at the establishment, such as supply of quality controlled inbred wild types, quick and efficient genotyping, an extensive database in which to track all breeding parameters and knowledge of breeding a large variety of GA strains, both in terms of mouse welfare and complexity of alleles. This could result in mice being bred on mixed or inappropriate background strains, cohorts being produced over unsuitable time frames using inefficient breeding schemes, and suboptimal production of control mice, leading to an increase in the variability of results as well as reduced reproducibility.

2. A number of mouse lines for a peer reviewed initiative to refine and deliver better mouse models for biomedical research will be bred on this licence. These lines will be established on this PPL and bred for dissemination to the biomedical community. It is anticipated that around 30 new genes will be modified per year, with the potential for multiple different alleles being produced for each gene. The mice may then be transferred to different PPLs in order to phenotype and characterise the lines further. All mouse strains from this initiative will be archived and freely available to the scientific community. Carrying out the initial breeding steps on this licence allows full quality control (QC) of the modified alleles, including checking for the off-target effects of genome editing and fully sequencing the target locus to check for any unwanted changes (Mianne. 2017). Carrying out these QC steps is critical to properly characterise the lines and understand what genetic changes have been made. This ensures correct interpretation of how the genetic change impacts the phenotype and ensures lines with unwanted changes are discontinued in a timely manner. Additionally, breeding for another generation before supplying allows welfare data to be collected and passed on to researchers using these strains in the future.

3. Mouse lines for a peer reviewed programme encompassing researchers around the UK will initially be bred on this licence. The programme is a multi-million-pound initiative to bring together clusters of researchers from around the country and partner them with experts in mouse genetics. The aim of the clusters is to accelerate understanding of human disease and improve diagnosis and treatments. The research clusters will have individual PPL's for experimental characterisation in their specific discipline (including cancer, mitochondrial disorders and neurodevelopment), however initial stages of breeding may be carried out on this PPL for practical reasons such as QC and use of shared lines/resources.

4. Wild type mice will be biopsied on this licence in order to perform genetic testing thereby ensuring they are of high quality. Frequent checking highlights any gross contamination and more in-depth sequencing (done less frequently) informs us of the genetic integrity of the inbred strains and helps inform when we should restock in order to reduce genetic drift. If these checks were not carried out, the mice could be bred without the need for a project licence, however, we would be unable to detect any contamination in the background and would have no information of the genetic drift of the colony. The subsequent reduction of genetic integrity could have serious effects on phenotyping results and confound many experiments.

5. GA lines that are in the intermediate stages of genome editing will be bred. With more complex editing using CRISPR/Cas9 becoming possible, there are often occasions when either, a large genetic change is needed that takes multiple steps, or, changes need to be compounded on top of one another. For example, a specific mouse allele may be altered to introduce the human sequence and

then the humanised allele may require the addition of point mutations to mimic a human patient cohort. In these cases, GA mice will need to be bred to supply the genome engineering team for generating further complex strains.

6. On this PPL we will breed standardised GA stocks that are needed by multiple users. This includes common recombinases and reporter lines. Keeping these mice in one colony allows us to reduce numbers, which would inevitably be higher if each group were to keep their own colony, it will also minimise genetic drift.

Who or what will benefit from these outputs, and how?

The expected benefits of this project are production of high-quality GA mice or tissues for research in biomedical sciences.

In the short term this will lead to more reproducible experimental data. Longer term this will have lasting impacts for basic research, as well as better understanding of the benefits and caveats of using mice for models of aspects of human disease and pre-clinical models for drug development. With more appropriate control strategies and standardised cohorts, models will be better understood, allowing them to be used more specifically for drug development and understanding of disease mechanisms.

New lines generated through peer reviewed programmes will be supplied to approximately 16 Higher Education Institutions per year.

How will you look to maximise the outputs of this work?

The knowledge gained through constant re-evaluating of our breeding strategies feeds directly into training courses that we run several times a year on managing mouse colonies. Several members of the establishment breeding team are also members of an NC3R's working group that have written advice on breeding and are available to question through an email helpdesk.

All new lines have welfare information gathered and the archive is annotated with any relevant information so it can be passed on to future researchers.

The Scientific Manager and Director frequently speak at conferences on reproducibility in mouse research, focussing on what we can do about the breeding and environment to produce the best possible research.

Any specific welfare issues of interest to the community will be published, for example, tarsal damage in C57BL/6N mice.

Species and numbers of animals expected to be used

- Mice: 135500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are needed for this project as it is a service licence to supply genetically altered mice to other research programmes. There is no need to age mice on this licence, but we will need mice at all other life stages for breeding.

Mice bred on this licence will be used to supply projects that have been through peer review and/or have a PPL that has been assessed for the necessity to use mice. For GA projects not part of large national programmes, researchers will provide information on peer review and the assessment of alternatives to animal use. For projects where peer review is more difficult to assess (e.g. small biotech companies) requests to use the breeding licence will be assessed by the AWERB.

Typically, what will be done to an animal used in your project?

Mice will be born, they will have an ear clip taken for identification and genotyping and then they will be housed, either for transfer to another licence/project, kept as stock for potential future breeding, or breed with other genetically altered or wild type mice. Any mice not moved on to other projects will be killed. Embryos may also be harvested for tissues after killing.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of mice on this licence will have no adverse effects. In the case where we are breeding experiment cohorts for transfer to another licence the majority of time these mice will be transferred to other projects with authority to use them before adverse effects develop. For lines where adverse effects are unknown, new lines, or crossing certain combinations for the first time, mice will be carefully monitored. It is not the intention to keep mice with adverse effects on this licence, since for breeding it is preferable that all mice are healthy. Mice will only be kept if they are needed for breeding and the adverse effects are unavoidable (e.g. the mice cannot be bred efficiently with a different genotype, the adverse effects cannot be ameliorated by treatment) and within the humane endpoints. In cases where individual lines have known adverse effects that are present before mice can be transferred to the experimental licence or that are present in breeding stock, these will be individually justified in the protocol.

It is possible that some crosses will result in some genotypes being sub-viable or lethal. In these cases mice may not be born in Mendelian ratios, or they may die suddenly soon after birth, before weaning or very occasionally later in life. For lines where there is a

known higher than expected mortality rate the expected rate and details will be justified on a line by line basis in the protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90% of mice on this licence will have a severity of mild or below. 10% of mice may have a moderate severity due to the appearance of phenotypes whilst still needed for breeding.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of this licence is to provide a service supplying high quality, controlled and reproducible mice for genetic studies. Many of these strains assessed for suitability as pre-clinical models. Breeding and then phenotyping (on a separate licence) to ascertain whether that particular mouse line is useful in recapitulating aspects of human disease in a way that is useful for therapeutic development. Some of these lines will be generated through the Genome Editing Mice for Medicine (GEMM) or National Mouse Genetics Network (NMGN) funding from the MRC. These lines will be answering a specific research question that has wider implications for more than one research group, and/or will be generating models that mimic the genetic changes found in human disease in order to better understand newly diagnosed genetic disorders. For many of these disorders the primary mechanism is not yet known, therefore studies in a mammalian systemswill be more appropriate and relevant than studies in-vitro and in-silico. All GEMM and NMGN projects have been individually assessed to examine in-vitro or in-silico approaches and only when these approaches are no longer sufficient for the scientific requirement, will we proceed to use mice.

In terms of the other aspects of this licence, such as quality control of inbred lines and holding centralised colonies of well used mouse strains. These must be done in mice due to the nature of the projects.

Which non-animal alternatives did you consider for use in this project?

At this stage, non-animal alternatives are not considered as this should be done as part of the peer review of projects or on the PPL's that the mice will be moved on to. New mouse lines generated through the GEMM and NMGN programmes will justify the need to use mice as part of the application process, and other lines will be moved on to PPLs with authority to use them and explanation of why animal models are necessary. Where work is only to be carried out on service licences, evidence of peer review and the need to use animals will be sought and recorded as part of the commissioning process.

Why were they not suitable?

Breeding and quality control of inbred lines is essential for all the genetic research carried out at the establishment. For specific GA models, in many cases non-animal models are used alongside or prior to work in mice. Mice are also used to generate cells for use in ex-vivo tissue culture. Mice are only used at a point where they are necessary to adequately answer questions that cannot be studied in other, non-animal systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each breeding scheme is calculated based on the information from the strain and the genetic background. As an estimate, based on current work for this licence, numbers have been calculated using C57BL/6J baseline data, since the majority of our work is on C67BL/6J or C57BL/6NTac at present.

1. An example of a standard cohort breed:

15 homozygotes needed of each sex. Taking into account average litter size, neonate mortality of C57BL/6J mice and non-productive matings. 28 heterozygous females will need to be set up in 14 trio matings, to produce 160 pups.

15 homozygotes of each sex, 30 homozygotes in total.

Probability of getting one homozygote from a heterozygous intercross is 1 in 4. Therefore 120 mice need to be weaned to get a better than 50% chance of generating the required number of homozygotes.

Average neonate mortality of 25% for C57BL/6J means that 160 mice need to be born for 120 mice to reach weaning.

An average litter size of 7 means 23 litters are needed to generate 160 mice.

For cohort breeds that are set up for only a short period of time ~15% of females do not get pregnant. To compensate for this, 28 females will be mated in 14 trios.

The breeding step to generate the females and males needed for this breed will also be calculated and in this example (using the same breeding data but different ratios depending on the cross) will require a total of 149 mice. Therefore for the two steps of this breed, we will use 309 mice.

If we estimate we will do 50 similar breeds a year for 5 years that is 77250 mice.

2. In addition to cohort breeds, it will be necessary to keep a proportion of lines in a breeding cycle to supply future cohorts or until phenotyping is complete. This type of breed will generate 40-50 mice approximately every 5 months. We estimate we may have 30 of these lines at any one time, approximately 18,000 mice over 5 years.

3. Hold and supply of colonies for use by multiple groups will use approximately 200 mice per colony per year. Holding 12 such colonies would use 12,000 mice over 5 years.

4. Breeding mice for establishing, archiving and QC of genetic alteration and initial welfare assessment will use 50-80 mice per line. For 50 lines a year over 5 years this is 16250 mice.

5. Genome editing GA line that are in intermediate phases of generation requires between 2-5 sessions of micro-injection, each using approximately 20 heterozygous females. This means that between 110 and 260 mice need to be generated per line, an average of 185 mice. Approximately 10 lines will be bred per year for this purpose. 9250 over 5 years.

6. Finally, the genotyping of inbred lines to ensure genetic integrity is carried out on ~200 mice per month which will form the future breeding stock of the inbred colonies. This equates to 12,000 mice over 5 years.

Overall, this equates to 144750 mice over 5 years, approximately 30% of these will be wild type.

This is an estimate based on current knowledge of future work, complex breeds and different genetic backgrounds may change this significantly, therefore the total numbers of animals needed will be under constant review.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We calculate individual breeding strategies taking into account several factors. Including up to date breeding data such as litter size, mortality and fertility, from inbred lines, and where possible, on individual GA strains.

Binomial distribution statistics are used to assess viability of strains.

The design of each experiment is discussed at the outset with members of the Scientific management team. The sample size and the justification for that are discussed, as well as how to generate the cohorts using the fewest mice possible. For example, if the cohort can be split into the batches that can be used more than 7 weeks apart, the breeding stock can be reduced by ~50%.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All lines generated as part of the GEMM project are freely available to the scientific community so are sometimes shared between several groups.

In cases where the viability of the line is unknown, a smaller pilot breed will be carried out in the first instance to ascertain whether there are any unexpected welfare concerns. Statistical analysis shows that we need a minimum of 28 pups to make a reasonable assessment of viability.

For single allele breeds, tried and tested strategies will be used for the most efficient breeding. For more complex crosses, often several strategies are considered and assessed for efficiency in terms of timing, mouse numbers and to reduce welfare impacts. The selected scheme may not always be the breeding scheme that produces the least mice overall, but the scheme that produces the most relevant biological controls and then breeding those as efficiently as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All genotyping will be done on this licence using ear biopsy, which is also used as a method of identification (except in <1% of cases where a second biopsy is needed). This should cause no more than slight and transient pain and have no healing difficulties.

With the exception of non-schedule one killing of embryos, all other procedures will be carried out under terminal anaesthesia.

GA models will be bred in a way that causes the least harm to the animals, for example, if when carrying homozygous mutations, a mouse strain has a harmful phenotype, we will avoid using homozygotes for breeding and instead use heterozygotes. It is not the scientific intention for any mice on this PPL to suffer from adverse effects, in fact that opposite is true, that mice used for breeding need to be healthy. Mice bred for cohorts will be moved on to PPL with authority to have mice with those adverse effects before the adverse effects become overt. In the case where these adverse effects are present before mice can be moved to another licence, or in breeding stock that, specific justification will be detailed in the protocols.

In some cases it is not possible to breed without some adverse welfare as an impact of the genetic alteration. In these cases stringent humane endpoints will be in place and if possible, breeding limited to an age before the mice become unwell.

Additionally, a large proportion of lines on this licence will be new, or bred in specific combinations for the first time. In these cases, it is not possible to know what the adverse effects will be. Specific humane endpoints will be put in place based on an extrapolation of the symptoms in humans and predicted adverse effects in mice. For example, where humans have a neurological disorder with movement abnormalities, we might expect tremors or gait abnormalities in mice.

Why can’t you use animals that are less sentient?

Mice used on this licence have to be of an age that is suitable for breeding.

Projects will be carried out on this licence when it is necessary to assess the gene function in a mammalian system. The ability to modify genomes in a complex way is more advanced in mice than in other species, although simple modifications are now possible across other species due to the advent of CRISPR/Cas9 technology. Additionally, and critically for genetic studies, there are a large variety of mouse inbred strains in which a genetic modification can be assessed in the context of a standardised genome. Such inbred strains are significantly rarer or not available for the majority of species. Mice have a wealth of baseline data from which to draw comparisons with, both at a phenotype and genetic level. For bespoke breeding projects not part of large funded programmes (e.g. IMPC, GEMM and NMGN) evidence of peer review and the necessity to use mice will be required prior to breeding on this service PPL.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The majority of procedures carried out on this licence will be ear biopsies and >80% of the time this will be done in conjunction with an ear clip taken for identification.

Other procedures are carried out under terminal anaesthesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The establishment has full AAALAC and ISO (9001:2015) accreditation. To conform to these standards we must ensure a high level of quality control on all aspects including husbandry and administrative processes.

For terminal procedures routes and volumes for administration of substances are taken from LASA guidelines.

All procedures, including husbandry tasks, are carried out to strict standard operating procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PPL holder and managers working on this licence will attend national and international conferences focussed on the 3R's in animal science such as the 3Rs symposiums, and the national NC3R's meeting. As well as IAT, LASA and similar international conferences where they will attend talks, give talks or run and/or take part in workshops focussed on increasing reproducibility, reducing animal numbers and refining practices. The PPL holder will also attend more specific disease based conferences to gather information on replacement in that specific field.

Developments in the 3R's are a fixed agenda point at every stock meeting to promote the sharing of ideas between the research group and the animal house staff.

13. Information Encoding for Cognition in Mammalian Brain Circuits

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

neuroscience, dementia, therapy, circuits, information processing

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how brain circuits give rise to cognitive processes such as memory, how they dysfunction during neurodegenerative disease, and how they are affected by therapeutic treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Dementia, a term describing a range of progressive neurological disorders which result in impairments to cognitive function, currently affects over 850,000 people living in the UK, and around 50 million worldwide. The most common form of dementia is Alzheimer's Disease (AD). While we know much about the molecular changes that occur in Alzheimer's Disease, such as the build-up of plaques of amyloid protein outside cells, and tangles of tau protein inside cells, we still have a limited understanding of how this disrupts brain circuitry and leads to cognitive degradation. Here we will study how the cognitive functions (such as spatial, episodic and working memory) that are impaired in AD arise from the activity of brain circuits in normal (unaffected) brains, and how they degrade during the progression of AD. As well as improving our understanding of aspects of brain function that are important to all of us, this will enable us to characterise how new treatments affect cognitive neural circuits – providing important information, not otherwise available, that will help to direct research on therapies for AD towards those that will have greatest effect, leading to enhancement of quality of life for dementia sufferers.

We need to use live animals for this work because cultured cell lines do not show AD pathology, and we cannot perform behavioural tests in cell cultures or brain slices. We also perform in vivo work because we want to test the effects of drugs in the brain to demonstrate that they work, and to see if there are any secondary effects, which could be harmful to patients.

What outputs do you think you will see at the end of this project?

Outputs will include (i) publications describing contributions to our understanding of how brain circuits support cognitive operations, how they are affected by neurodegenerative disorders, and how they can be repaired by therapeutic strategies; (ii) datasets collected in the course of our experiments, which may be of wider applicability for understanding brain function and dysfunction; (iii) technological advances made in the course of these experiments which improve our ability to carry out neuroscience experiments of this type.

Who or what will benefit from these outputs, and how?

These outputs will benefit:

Starting immiediately, neuroscientists studying the basic mechanisms underlying cognitive function – who will benefit from information presented in our scientific papers, which will allow them to make further progress on understanding brain function.

During the project, neuroscientists studying neurodegenerative disorders – who will benefit from information presented in our scientific papers, which will allow them to make further progress on understanding the mechanisms of dysfunction in brain circuits. In particular, our data will inform new developments of therapies for Alzheimer's Disease.

Over the longer term (beyond the project duration), clinicians who work with patients suffering from neurodegenerative disorders will benefit from the above advances in our understanding of brain mechanisms of neurodegenerative disease, through having new treatments enter clinical trials.

Over the longer term, patients will benefit from new treatments for neurodegenerative disease, by having an improved quality of life; this will follow indirectly from our research, as the results are translated into the clinic. The wider population will then benefit from the increased productivity of a large and growing sector of society who would otherwise require care.

How will you look to maximise the outputs of this work?

We will use a number of approaches to maximise outputs:

Collaboration with specialists in techniques beyond the core expertise of our laboratory (such as molecular and cellular biology, drug development, etc) will maximise the pace and breadth of research progress, and provide additional opportunities (e.g. access to newly developed mouse disease models and drugs), maximising outputs.

We will collaborate with pharmaceutical partners to test new drugs using our approach, thus ensuring that outputs can have immediate effect on therapeutic development.

We will use outreach to patient groups to help disseminate knowledge of our work, as well as to incorporate patient views at the earliest stage of research to help direct our efforts.

We will use a variety of approaches to disseminate our knowledge, including the traditional routes of journal publication and conference presentations, but also including social media threads, podcasts and interviews.

We will make our datasets freely available in an online database (such as zenodo) at the point of publication, which will allow others to make best use of our data, potentially resulting in additional publications. We will publish methodological papers in addition to papers describing our scientific results, in order to help move the whole field forward and increase the rate of progress.

Species and numbers of animals expected to be used

- Mice: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice of all life stages. We use mice because of the availability of transgenic mouse models of neurodegenerative disorders, and because it is the mammalian preparation in which genetic tools are most developed. In some cases we will need to begin procedures prior to birth, in order to introduce DNA into developmentally defined cell types, whereas other procedures will begin in juvenile or adult mice. Experiments will be typically be performed on mice from young adulthood through to old age. We need to do some experiments in old mice, as we are studying neurodegenerative disorders which progress with age.

Typically, what will be done to an animal used in your project?

A typical mouse in this project will undergo surgery under anaesthesia, in which a dental drill is used to remove a small piece of bone over the cortex, a solution containing a virus is injected into the hippocampus, a glass imaging window is implanted into the cortex down to the level of the corpus callosum, allowing imaging of the underlying hippocampus, and a head-fixation post attached with dental cement. The wound margin is closed up and the animal allowed to recover for a period of several weeks. After this, the mouse begins behavioural training by being habituated to handling and to head restraint through clamping the head-fixation post to the behavioural apparatus, initially for brief periods (minutes) and then longer periods. Behavioural training will occur under conditions of water restriction, in which on weekdays the animal receives its normal fluid intake only in behavioural training sessions, with body weight carefully tracked and welfare monitored. During the behavioural experiments, the mouse is able to explore a persistent visuotactile environment consisting of a carbon- fibre chamber floating on an air-bed; as it explores the environment, the chamber moves relative to the head-fixed mouse. Initial behavioural sessions will involve familiarisation to head-fixation under the microscope; in subsequent sessions, the mouse will explore and make navigational decisions within a maze. While the mouse is performing these behavioural tasks, we will monitor brain activity using a laser-scanning fluorescence microscope (laser scanning of brain activity is imperceptible and, at the intensities used, causes no harm to the animal). Behavioural sessions will last for approximately 60 minutes, and be carried out over the course of several months, in order to track changes in brain circuits. These experiments will be performed in both transgenic mice (which develop amyloid plaques in the brain over the course of their lifetime) and wildtype control animals. As well as using mice genetically altered to produce amyloid pathology, we will also use mice genetically altered to express fluorescent proteins in particular cell types in the brain. This is a non-harmful phenotype.

In other experiments, time-pregnant female mice arrive from a commercial breeder and are housed for a 1-week acclimation period. After one week the ventricles of embryos are injected with DNA via a micropipette through the uterine wall of the pregnant mouse (in utero electroporation) under anaesthesia. The pregnant mouse is allowed to recover and monitored. After the surgery the pups continue to develop, are born, and continue to develop normally.

Another typical mouse (expressing fluorescent proteins in subclasses of neurons, and produced by either transgenic mouse breeding or by in utero electroporation as described above) will be placed under non-recovery anaesthesia in an isoflurane chamber. Once twitch reflexes are abolished, the mouse will be quickly removed from the chamber and killed, in order to extract fresh brain tissue for in vitro experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect our animals to undergo anything beyond moderate suffering. Some animals will be genetically altered to induce amyloid pathology in the brain. Although this is expected to induce cognitive impairment, this does not in itself lead to suffering. Animals will usually undergo a surgical procedure (always under general anaesthesia) and will be closely monitored and provided with pain relief before and after surgery. Animals will have restricted access to water, and may experience thirst. Thereafter, animals will learn to perform simple tasks for reward, that are mentally stimulating. Animals may remain in behavioural assessment for up to several months. Rarely, in less than 5% of cases, complications can occur including weight loss and failure to recover from anaesthesia. However, animals will be constantly and closely supervised by trained individuals. If any animal is deemed to be suffering, they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)

Expected severity

- Non-recovery 60%
- Mild 20%
- Moderate 20%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals in this project as it involves investigation of the neural mechanisms underlying cognitive processes such as memory and perception. To understand these processes (and dysfunctions of them) requires measuring signals from real brains which exhibit such phenomena.

Which non-animal alternatives did you consider for use in this project?

We considered the use of three-dimensional stem cell (brain organoid) cultures, and the use of computer modelling.

Why were they not suitable?

Brain organoid cultures allow us to assay some aspects of spontaneous neural activity dynamics, however as they do not possess sensory inputs or motor outputs, and do not exhibit cognitive phenomena such as memory or perception, it is not possible to use them to replace all of our animal work. We will make use of such organoid cultures to complement the in vivo animal work and assist in translation to human genetics. We will also make use of computer modelling, however this requires animal experiments to constrain parameters and validate predictions, and thus does not replace animal work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A maximum of 4000 animals are required for breeding (and 500 for in utero electroporation) in order to generate the maximum of 2500 mice that would be undergoing scientific experiments. Of these mice undergoing scientific experiments, many (maximum of 1500) will be used for in vitro brain slice imaging experiments; this number is determined by the number of slice experiments that can be done in a laboratory of our size, which limits the amount of science that can be done. The remaining 1000 experimental mice are used for in vivo brain imaging and behavioural experiments. The number of mice needed for these experiments has been determined by careful statistical experiment design, based on data from pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used modern statistical experimental design techniques to determine appropriate experimental structure and sample sizes, in order to ensure statistically valid conclusions while using the minimum number of animals, with a particular focus on the number of

animals used for brain imaging during cognitive tasks, the part of our project with most consequence for individual animal welfare. Our statistical design approach, although done from first principles, is very similar to the approach taken by the NC3Rs Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We follow advice provided by The Jackson Laboratory for optimal breeding and colony maintenance protocols for each individual strain, ensuring that production of experimental animals is optimised. We will use pilot studies to validate techniques and determine experimental design parameters. In particular, by using inter-individual variation in behavioural performance in relevant tasks as a proxy for variability in the large neural populations recorded, we will reduce the number of animals needed to establish these parameters. We use computer modelling where possible to extrapolate results from animal experiments, reducing the number of animal experiments that need to be performed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice. Mice are a very good animal model for our purposes, because their brains are similar in terms of circuit structure to human brains, and because we can use genetic technologies to mimic human diseases and probe circuit mechanisms. We at all times strive to minimise harm to animals, performing experiments under terminal anaesthesia except where it is necessary to simultaneously measure brain activity and behaviour. Animals are constantly and closely supervised by trained individuals and advice sought from the veterinary team if there is any cause for concern. If any animal is deemed to be suffering beyond the limits specific in the license, it will be humanely killed. Overall, we use anaesthesia, analgesia, and humane endpoints to limit suffering.

Our scientific aims require recording neuronal activity from large populations of neurons deep in the brain while mice are performing many trials of a cognitive task. Surgical implantation of an imaging window is the only way to achieve this. Head-fixation is required for two-photon microscopy (which is needed to distinguish individual cells in three dimensions in tightly packed brain circuitry). Our approach of training mice to perform tasks by exploring an environment (virtual or real-world, as in our apparatus) while able to

run “in place” on a floating platform has been shown to improve habituation and lead to lower stress on the animal, in comparison to tasks where head-fixed animals cannot move, and thus is we believe the most refined approach available.

We will use transgenic mouse models of Alzheimer’s Disease. We have been using the 5xFAD model (and will continue using this to finish off projects currently underway). During the course of this license we will begin using the APP NL-G-F knock-in model, a more refined model that expresses amyloid precursor protein at wild type levels, as opposed to the over-expression of 5xFAD and other earlier models. Earlier AD models such as the APP23 model showed some epileptic activity resulting in 25% loss of animals due to seizures. 5xFAD mice show sub-clinical epileptic activity (as indeed do some human AD patients) but with a very small fraction of mice lost to seizures. Neither epileptic activity nor seizures have been observed in APP NL-G-F mice. We thus see the APP NL-G-F model as the most refined, with the 5xFAD model also being more refined than previous models, while also providing important information relevant to clinical AD patients.

Why can’t you use animals that are less sentient?

We are studying the neural mechanisms of cognitive processes such as memory, and how they degrade in neurodegenerative disorders such as Alzheimer’s Disease. This requires use of animals at the adult life stage. We consider that mice have the minimal level of sentience to study cognitive processes of relevance to the human condition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will work to continuously refine our practice in animal procedures in conjunction with veterinary and animal services staff. This may include improvements to monitoring, with the potential for technological advances to make improved automated homecage monitoring feasible, and we will continuously work with veterinary staff to maintain best practice in post-operative care and pain management. The NC3Rs Working Group on High-Yield Behavioural Techniques has already yielded some improvements in training of animals, and we will work with colleagues to continuously refine training procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs website provides a wealth of published best-practice guidance which we will follow. This includes documents on environmental enrichment, the use of rodent grimace scales to assess pain, housing and husbandry, animal handling, anaesthesia, etc. Of particular relevance will be the publication from the NC3Rs Working Group on High-Yield Behavioural Technique, which is soon to release a White Paper directly relevant to this project.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of the NC3Rs Working Group on High-Yield Behavioural Techniques, and in the course of the project, will be working with this group on the publication of a White Paper reflecting the state of the art in 3Rs relevant to this project. I will continue to engage with this group and the NC3Rs following the publication of the White Paper, and follow complementary work emerging from NC3Rs activities, and the broader scientific literature, on animal welfare. We will discuss 3Rs issues regularly during our laboratory group meeting, in order to continuously implement advances in 3Rs throughout the project.

14. Repairing the Damaged Brain after Traumatic Brain Injury

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain injury, mild traumatic brain injury, neuroscience, axon regeneration, neuroprotection

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to establish a model of mild and repeat mild traumatic brain injury (TBI) and use these models to understand what happens to the brain after a traumatic brain injury, why the brain fails to repair and regenerate after injury, with a view to developing therapeutic agents to counteract this and ultimately preserve function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK alone, there were almost 160,000 admissions to hospital with brain injury (including traumatic brain injury (TBI)) in 2016-2017, an increase of 10% since 2006. Men are 1.5 x more likely to be affected with brain injury but admissions for brain injury in females has risen by 23% since 2006.

The main cause of brain injury is motor vehicle accidents, followed by falls and interpersonal violence and increasingly, sports-related injuries. Brain injury costs the UK economy £15 billion per year and is a significant personal burden to the individual, causing immediate symptoms such as headache, speech problems and dizziness but long-term problems such as sensory deficits, sleep problems, memory and mood changes and eventually mental health issues. Cognitive deficits occur but take several months to develop, however, visual problems occur more quickly, including blurred vision, double vision or loss of peripheral vision also occurs after a TBI and this is something we are interested in. Non-invasive imaging methods exist that can be used to scan the eye and determine the extent of brain injury. Brain injury can also cause chronic inflammatory changes which eventually go on to cause mental health problems. For example, there have been some high-profile cases of professional Rugby players in the UK that have been diagnosed with early onset dementia as a result of brain injuries caused during sport. One in five people who suffer a TBI go on to develop mental health problems and so TBI has a multitude of consequences. Currently, there are no known therapeutic agents that counteract the problems associated with brain injury nor are there strategies that promote axon regeneration after injury and the loss of brain function that ensues, leaving an urgent medical need for effective therapies. We wish to identify and test therapeutic targets and agents that will promote the regrowth of axons, counteract the negative effects of injury to the brain and ultimately preserve/promote its useful function.

What outputs do you think you will see at the end of this project?

The primary outputs of this work will be to gather new knowledge on what happens to the brain after a TBI, what goes wrong and what processes cause the eventual long-term changes that lead to dysregulated neuronal functioning. We wish to understand the metabolic changes and cellular changes that occur to neurons and their supporting cells of the brain that causes the eventual damage to nerves, scarring, cell death, oedema and how we can best use this knowledge to derive therapeutic strategies to overcome repair and regeneration in the brain. We also wish to know what changes occur to the visual system after TBI as visual problems are frequently reported by patients. We will do this through non-invasive eye imaging techniques and analyse the nerves and eye once the tissues are harvested.

As a consequence of the information we will obtain on new pathways and signalling molecules, we will also identify new therapeutic targets to not only prevent the negative consequences of injury to the brain but also to develop strategies aimed at promoting the

repair and regeneration of injured nerves. Moreover, we will determine if imaging the eye can be used as a surrogate of brain injury. A major potential benefit from the work proposed will be the acquisition of new knowledge for dissemination in peer-reviewed journals. Functional outcomes after brain injury are poor at best and presently only palliative drug treatments are available for patients. At the moment nothing is available for patients that can reverse the damage to the brain caused by the injury. Therefore, there is an urgent unmet clinical need for new therapies aimed at enhancing functional repair responses of damaged brain.

Specific identifying outputs will be to publish the findings. This is important for the development of the project but also to provide a knowledge base for other academics working in this field.

Other product outputs will be to support the development of the new and existing intellectual property which will allow us to facilitate translation into a clinically and commercially viable proposition.

Who or what will benefit from these outputs, and how?

In the short term, the benefits would be to provide new knowledge of what molecules and signalling pathways are affected in the brain after a TBI and identify potential targets where drugs can be developed to improve outcomes in future studies.

In the longer term this work has the potential to identify new therapeutic targets that could be used to develop new therapeutic intervention for those afflicted with TBI. There is currently no treatment that reverses the pathological effects of brain and coincident eye injury and the functional loss that occurs as a result is permanent. Our discovery strategies would provide key information on the pathological processes after brain injury, allowing us to identify opportunities to test and develop therapies aimed at reversing or protecting against the negative effects of injury. As a result, we will identify opportunities to preserve or repair brain function.

Examples of other potential beneficiaries of the success of this work are spinal cord injured or stroke affected patients who will benefit through the development of new treatments that are neuroprotective, pro-regenerative and anti-scarring, since the same pathological processes after brain injury also occur in these groups of patients. Additional beneficiaries could include health care providers, particularly the NHS.

The UK economy spends £15 billion treating brain injured patients every year and represents a significant financial and personal burden. Effective therapies that protect brain from death and promote its repair and regeneration, if successful, would relieve the pressure on the NHS and significantly reduce the personal and financial costs of treating brain injured patients.

How will you look to maximise the outputs of this work?

We will maximise the outputs of the work by collaborating with colleagues and companies working in this field to maximise the use of the data we obtain. We will rapidly disseminate the outcomes of the tests, whether negative or positive, to inform the academic community and support other researchers developing technologies in this area. We will seek partnerships with appropriate pharmaceutical companies when potential therapies have been identified, giving us the potential to translate our therapies into the clinic for patient benefit.

Species and numbers of animals expected to be used

- Rats: 1040

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult rats for all of our experiments since they more closely mimic the human molecular responses to brain injury than mice for example. We cannot use lower sentient species like zebrafish as they regenerate their brain after injury. As in the human, the adult rat brain also has a poor intrinsic capacity to spontaneously repair and regenerate its central nervous system and hence is invaluable in finding new therapies for adult human brain injury.

Typically, what will be done to an animal used in your project?

All animals will receive pre-emptive pain relief as a precaution since there is no evidence of pain such as headache, and undergo a regulated procedure to cause a mild TBI (mTBI). Some animals will undergo a repeat mTBI at 3 days after the first injury to assess the impact of repeat mTBI. This is regarded as a moderate severity injury. All animals will receive pain relief prior to undergoing mTBI and after the procedure, as a precaution, to minimise any potential discomfort that may be experienced.

Animals will then receive injections of therapeutic agents and undergo non-invasive tape sensing and removal sensory test and ladder crossing locomotor function tests once weekly for up to 12 weeks.

Animals will then be killed humanely before collection of tissues for histological/protein/mRNA analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Mild TBI: We expect no discernible physiological changes after injury. However, only if challenged in sensory and locomotor tests will we be able to see minor deficits in neurological function affecting their fine movement and sensation. Therapeutic substances/biomarkers are carefully selected from published literature or pilot studies to cause as little discomfort as possible and any discomfort will be transient.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals will experience a moderate severity injury.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst some elements of brain injury can be modelled in cell or brain slice cultures, the complex, clinical picture and interaction of the whole-body systems, including in particular the immune and nervous systems cannot all be currently modelled in cell-culture or computer-based models. The use of live animals is therefore unavoidable and essential for discovery science, drug discovery and to demonstrate the activity of drugs in a situation relevant to the human condition. Neurons are not present outside the animal kingdom and so an animal is required. Only mammals have a sufficiently developed immune-system to readily compare to humans, and rodents are the animals of lowest neurophysiological-sensitivity required to achieve the scientific aims. Zebrafish or other lower sentient animals cannot be used since these species spontaneously repair injuries to their brain and are therefore not representative of the human condition. Therefore, there is no feasible alternative that can entirely replace the use of a living animal that would allow our objectives to be met. However, we will use in vitro and ex vivo work to inform our animal studies.

Which non-animal alternatives did you consider for use in this project?

There are currently no alternatives to animal work for the brain injury model.

No cell culture-based models exist that encompass all of the aspects of disease for any of the models described in this project. However, individual aspects will be modelled in vitro and ex vivo. For example, we regularly use in vitro neuronal and glial cell cultures to detect therapeutically useful molecules in terms of neuroprotection and axon regeneration to then take forward into animal studies.

Why were they not suitable?

The fundamental reason why the use of animals is required is to understand these complex processes that occur in a damaged brain, which at present no in vitro methods can model the complexities of the systems involved in this condition. It is almost impossible to use primary cells to culture all of the different types of cells in the brain since they require different growth mediums and factors for survival. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment. Technologies are being developed to address this gap, including the development of 3D cultures. However, none of these model systems are yet able to phenocopy the integration and interplay between the numerous cell types that constitute brain injury.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals have been based on pilot data, in-house and published data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used the NC3Rs EDA system to calculate animal numbers to be used for this project with calculations setup to achieve a statistical significance of α $p<0.05$ with a power of 0.8. Whenever possible, we used our own published data to feed into the EDA system to generate samples sizes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will seek to refine protocols, such as the development of other quantitative measures for injury such as associated biomarkers that can predict potential injury severity and recovery and imaging methods such as optic coherence tomography to non-invasively monitor mTBI changes that can be detected in the eye, which will facilitate “reduction”.

Experiments will be planned so that they can be published in accordance with the ARRIVE 2.0 guidelines.

Wherever possible, we will use archived samples and share control groups across different experiments.

As part of good laboratory practice, we will write a protocol for each experiment including: a statement of the objective(s); a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group), and the experimental material; and an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated). We will make appropriate arrangements to randomly assign animals to experimental groups and blind studies.

At the end of the experiment, we will harvest the maximal possible number of tissues and biofluids. Tissues not immediately analysed will be archived and will be made available to other researchers working on similar questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Due to the nature of the scientific question, the only appropriate model is the mTBI model in rats. In the human condition, most mTBI patients develop only have transient headaches and so do not seek medical help as his resolves over a few days. However, the biological consequences can go on from minutes to years after a mTBI. Animals do not show overt outward signs of TBI and hence it is the most refined method of injury as we use lighter weights, short drop height, attach a protective metal disc to prevent injury to the skull and use a thick polyurethane sponge to not only absorb the forces delivered by weight drop but also to protect against contrecoup injury. In addition, we will provide peri- and post- operative pain relief despite there being no evidence of pain, such as headache, as a cautionary measure. The model we will be using has been refined over 20 years by our colleagues in Italy and we will make every effort to ensure the approaches cause the least possible distress, suffering or harm.

Why can't you use animals that are less sentient?

We cannot use less sentient species (e.g. zebrafish) for this work, because unlike mammals, they are able to repair injuries to the brain spontaneously. Rats will be used for our experiments since they share similar pathophysiology to humans after injury to the brain. We do not use mice to model the human TBI since the responses in the CNS of a mouse are generally further away from the responses in rat to TBI. Some in the field have argued for larger animal models to be used. For example, rabbit, sheep, swine and monkey models have been proposed, however, all of these models require a craniotomy and have high levels of mortality. Neither of these parameters are common in human TBI and hence are not representative. Moreover, there are only a handful of studies using these models and little is known about the pathophysiology of TBI in these models compared to the rat which has received a lot more attention. Therefore, our rat model is the best model for use in understanding what happens after a human mTBI.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The weight-drop mTBI model has been refined extensively. For example, a stainless- steel plate is glued to the skull prior to weight drop. This prevents injury to the skull and causes a generalised head injury as experienced by humans. The thick polyurethane foam pad that the animal is placed on prior to weight drop prevents contrecoup injury after the weight drop since it is able to absorb the energy and prevent whiplash injuries occurring to the rat.

The use of surrogate biomarkers in peripheral blood and CSF has also reduced the need for increased animal usage since these samples can be harvested from the same, live animals and hence additional injury stratifying parameters can be developed. In addition, imaging the back of the eye has allowed changes in the eye to be used as surrogate markers of TBI. All of these additional measures reduce the need for additional animal experiments.

Non-invasive imaging of the eye is a potential surrogate marker of brain injury since neurons in the eye are also affected after mTBI. Hence, we may be able to develop new knowledge of how the eye can be used to both diagnose and prognosticate mTBI.

Some of the potential therapeutic agents can be evaluated and optimised in vitro prior to in vivo application. Others will be optimised in small pilot experiments with drug doses based on published literature. We keep our experimental time points in longitudinal studies to a minimum and use archival control results where possible. Multiple analyses are done on harvested tissues. We use the minimum number of interventions and minimal volumes for drug delivery during experiments and continually seek methods to reduce these by studying alternative drug delivery strategies. Although there is no evidence of pain such as headache, all animals will receive pain relief prior to and after the procedure as a precaution. They will also be picked up using refined handling techniques to minimise distress and the technical staff are well versed in recognising the signs of distress in these

animals as they have many years' experience in handling and caring for our injured animals. We use bespoke welfare sheets that include body conditioning scores to monitor animals post-operatively. All of these refinement steps significantly reduce the animal welfare burden.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment.

Experiments will be conducted in accordance with the guidelines published by the Laboratory Animal Science Association (LASA).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE 2.0 guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed of advances in the 3Rs through attendance of seminars and conferences, as well as discussions with the named veterinary surgeon and the named animal care and welfare officer.

We will review each experiment on completion to determine any refinements that can be applied to future experiments.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

We will also stay up to date with guidance published by LASA on the most refined experimental methods. We are already signed up to receive the NC3Rs newsletter and will attend local events such as conferences and follow advice in webinars hosted by NC3Rs.

15. Genetically Altered Rodent Generation, Breeding and Maintenance.

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Physiology, Genetic Manipulation, mice

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The creation, breeding and supply of novel and established lines of Genetically Altered (GA) mice. A GA mouse is a mouse that has had its genome altered through the use of genetic engineering techniques. Genetically Altered mice are commonly used for research as animal models of human diseases, and are also used for research on genes. Mice will be of high health status and defined genetic quality for use in research projects at this and other establishments. Cryopreservation of such lines provide health and genetic security. Mouse embryos or sperm are frozen in liquid Nitrogen, to avoid loss by contamination, unexpected disasters eg fire in a facility and genetic drift. Genetic drift is where genetic changes happens constantly, even small changes might have an impact on future research and replicability.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is recognised how important genetically altered mice are in understanding the pathophysiology of many disease conditions including cancers, cardiac and metabolic diseases, as well as improving our knowledge of basic physiology. Creating, breeding and maintaining genetically modified animals we will ensure that such animals generated are produced to the highest standards of health and welfare enabling more reproducible and publishable research. Thus we are able to recruit top quality research scientists.

Cryopreservation provides security against genetic drift and health status contamination whilst meeting the 3R's.

What outputs do you think you will see at the end of this project?

Provision of GA models to researchers, resulting in new knowledge of physiological and disease mechanisms and dissemination via peer reviewed publications

Who or what will benefit from these outputs, and how?

Researchers here and their collaborators, other research facilities who do not have the technical expertise to create GA mice.

How will you look to maximise the outputs of this work?

Peer reviewed publication of the subsequent work on these animals, including encouraging publication of any failures of the approach, collaborations with other institutions.

Species and numbers of animals expected to be used

- Mice: 17700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are a well recognised species for work involving genetic alterations and there are standard protocols, methods and reagents used that have been optimised for this species and acknowledged benefits for use.

Typically, what will be done to an animal used in your project?

The majority of the animals will be used for the breeding and maintenance of genetically altered or mutant animals. Some animals will undergo surgery as follows-

Typically female mice will be mated with vasectomised (sterile) male mice to induce pseudo-pregnancy (in mammalian species, pseudo-pregnancy is a physical state whereby all the signs and symptoms of pregnancy are exhibited, with the exception of the presence of a foetus, creating a false pregnancy).

They will then undergo a minor surgical procedure, under general anaesthesia, to implant previously genetically modified embryos into the oviduct. During this procedure analgesia will be administered. The females will be allowed to recover and give birth. Aseptic technique will be observed throughout. The resulting offspring will have a small piece of ear tissue removed to confirm the genotype.

What are the expected impacts and/or adverse effects for the animals during your project?

Superovulation -There may be momentary pain on 2 occasions when an I. P injection into the abdomen is administered.

Recipients -Surgical: A female mouse will have a small, less than 1 cm incision, to expose the Uterus, enabling delivery of embryos into the uterus. Mice recover rapidly and, in our hands, without complications. Anaesthesia, analgesia and aseptic technique used to prevent pain and infection. -Non- surgical: A female mouse will have a small speculum inserted in the vagina and positioned around the cervix, the catheter is then inserted into the speculum and through the cervix, at this stage embryos are expelled into one of the uterine horns. Anaesthetic will be used.

Vasectomy -Minor surgery from which mice recover rapidly and, in our hands, without complications. A small incision approximately 5mm, is made into the scrotum and the Vas deferens is cauterized to render the mouse infertile. Anaesthesia, analgesia and aseptic technique used to prevent pain and infection.

Breeding of genetically altered animals with mild phenotype (the observable traits eg eye colour is a phenotype). These animals are not expected to show any deviation from normal wild type mice. A

typical breeding female will have 6-8 litters in her lifetime.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority, approximately 60%, of the mice are perfectly normal and will suffer severity which is sub- threshold. Approximately 30% of the mice will have 2 injections into the abdomen which is mild severity. Some mice, approximately 10%, will undergo minor

surgery will have moderate suffering which is expected to be brief and resolve without complication.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

New technologies are improving the field of genetic engineering in animals and they will allow the generation of new mouse models to be applied in biomedical research. First steps in a scientific project will involve in vitro approaches, the final characterisations and applications will require the use of genetically altered animals. The different animal models will integrate the complete range of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes

Which non-animal alternatives did you consider for use in this project?

We have an established cell engineering service as a potential alternative to in vivo models in vertebrates.

Why were they not suitable?

In-vitro assays cannot adequately model the complete array of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes.

Invertebrates are a useful adjunct to animal studies in that large throughput of gene alterations can be screened but the differences in circulatory, neurological systems etc limit their use.

Prior to importing or creating a new strain, consideration will be given to the scientific evidence gathered from in vitro data e.g. receptor binding assays to identify appropriate targets and PCR analysis of gene expression. The breeding method and proportion of affected animals produced will also be considered.

All of these factors will be used to justify the introduction and creation of strains under this licence with advice and discussions taken with the researcher and NVS (Named Veterinary Surgeon) as required

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are predicted, based on analysis of the number of animals used in the last five years to meet the demand of our researchers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Switching to an IVF (In Vitro Fertilization) -based approach to generate mouse embryos in place of traditional overnight mating's reducing the number of mice used by half.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Using efficient breeding techniques including using the Home Office genetically altered animal breeding guidelines

Switching to an IVF-based approach to generate mouse embryos in place of traditional overnight matings reducing the number of mice used by half

Integrating CRISPR-Cas9, a gene editing technology, which has greatly reduced the numbers of mice required to make a new transgenic strain for many allele types.

Developed our own method to generate high efficiency long single stranded DNA (lssDNA) donors for gene knock in projects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are a well-recognised species for work involving genetic alterations and there are standard protocols, methods and reagents used that have been optimised for this species and there acknowledged benefits for use.

Embryos, gametes, sperm and ovarian tissue will be collected from donor strains. They may be cryopreserved or used for the following purposes.

- Fresh or frozen embryos and sperm will be used for rederivation of infected mouse strains to improve health status.

- Gametes, embryos/sperm or/and tissue will be archived by cryopreservation for strain storage in support of the breeding colonies.

- Gametes, embryos/sperm or/and tissue will be used to replace a strain for storage where there is no longer a research requirement to avoid wastage from maintaining ‘tick over’ breeding programmes.

- Gametes, embryos/sperm or/and tissue will be used where possible instead of live animals to transfer strains to other establishments within the United Kingdom and abroad

Why can’t you use animals that are less sentient?

It is fundamental that the GA embryos are implanted into a receptive female and she is then allowed to complete gestation. The resulting offspring will be used in research projects for which the whole mammalian body systems are required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

One of the chief benefits of undertaking this work under a service licence is that all the techniques to be used are undertaken by a small group of highly experienced technical staff which minimises suffering. It also ensures that the highest standards of asepsis are maintained and that appropriate and effective analgesia is always used.

We are looking into using NSET (non-surgical embryo transfer) for some of our projects, but at present NSET is not suitable for the majority of our pipelines as these involve microinjecting 1-cell embryos.

For NSET these would have to be cultured to blastocyst, the problem we experience is that 1 & 2-cell embryos culture well to the blastocyst stage (80 to 90%) but when they are transferred into the uterus the implantation rate is quite poor. Therefore, we feel that surgical transfer of 1-cell embryos is still the most refined method.

We are a part of an NC3R's funded project to develop a genetically sterile male mouse which could replace the vasectomy surgery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will consult with colleagues across the field and sources such as AWERB

International society for Transgenic Technologies Animal Welfare and Management Discussion Group NC3R's Efficient Breeding Strategy

Institute of Animal Technology

Efficient Breeding of Genetically Altered Animals Assessment Framework(Home Office)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advice has been sought from NC3R's project manager on the development of this PPL application and will continue to be sought during visits to this facility on a weekly basis.

16. Imaging and Modulating Ocular Immune Responses

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Uveitis, Immunity, Retina, Immunohistochemistry, Intravital

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To increase our knowledge of the role of the immune system in the eye during health and disease employing advanced imaging techniques to allow better diagnosis and treatment of conditions that lead to blindness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sight loss is profoundly disabling and affects huge numbers of people across the World. It is progressively clear that abnormal immune responses are implicated in almost every ocular disease, including uveitis, age-related macular degeneration and diabetic retinopathy. Together, these diseases account for over 70% of blindness registrations in the UK and cost the NHS an estimated £3 billion in direct costs and the wider social care system £6 billion per year. Their incidence is projected only to increase as a result of obesity and a rapidly ageing population.

Current methods for the diagnosis and monitoring of these diseases are limited, often requiring surrogate or proxy measures that can result in over or under-treatment. Despite progressively improved treatment options, many patients continue to fail to respond adequately, lose sight or come to harm from side-effects of medications.

There are now huge opportunities to address these unmet needs by deploying advances in ocular imaging and post-mortem tissue analysis technologies.

What outputs do you think you will see at the end of this project?

New information: The proposed work will expand our understanding of ocular inflammation and immune responses in relation to blinding diseases. We will apply novel techniques such as adaptive optics retinal imaging and highly multiplexed immunohistochemistry to reveal previously unknown aspects of pathology. By studying the effects of therapeutic treatments, new pathways to increase their effectiveness or reduce their side-effects could be discovered.

Publications: Following on from our established track record, we will continue to publish our work in international, peer-reviewed scientific journals such as PNAS, Molecular Therapy, eLife and Science Translational Medicine. Wider outputs will include presentations at international and domestic scientific conferences such as Association for Research in Vision and Ophthalmology (ARVO) annual meeting or RCOphth and British Society for Immunology congresses. We will continue to engage with patient groups and research charities to ensure continued engagement and participation in the benefits of the research.

Who or what will benefit from these outputs, and how?

Short-term: Immediate scientific benefits to the research group will be derived from an increased understanding of ocular biological processes and the continued development of research expertise and techniques.

Medium-term (2-5 years): The work is expected to benefit researchers in the fields of ocular disease and immunology, reached through the dissemination of our findings through publication, collaboration and scientific conferences. Discoveries will be shared with the public and patients through outreach activities.

Long-term (over 5 years): This project will benefit medical specialists working in ophthalmology and patients through the development of better biomarkers and monitoring of ocular diseases. A greater understanding or novel discoveries relating to therapies will benefit patients after engagement with clinicians and industry.

How will you look to maximise the outputs of this work?

Collaborations: The impact of our work will be maximised through continued collaborations with scientists across other disciplines. We already have established links with engineering, physics and computer science colleagues who can employ data produced in our investigations to develop new approaches to modelling and image processing.

Dissemination: Our discoveries will be shared at scientific conferences, through scientific publications and public and patient engagement activities. We are committed to publishing unsuccessful approaches for wider public benefit and have in the past published negative results from clinical and scientific studies.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used as the least sentient species for which established models of the ocular diseases exist to undertake the proposed studies and answer our research questions. In addition, mice are the most amenable to the genetic alterations needed to label immune cells. Adult mice will be used as the imaging techniques required are easier to perform at this stage of eye development.

Typically, what will be done to an animal used in your project?

The purpose of the project is to better understand the role of inflammation within the eye in relation to blinding eye diseases and to inform and improve our therapeutic approaches in patients. A proportion of the mice used this project will be genetically altered and bred, however these are not expected to have harmful effects or cause suffering.

Most of the studies will involve the initiation of the disease by injection of substances systemically, into the eye or by damaging the retina with a controlled laser treatment. All of these will be performed under general anaesthesia, so mice do not experience pain or discomfort. The eye diseases induced are mild and not painful, and whilst the animals may experience a degree of sight loss this does not result in alterations to their normal

behaviour, as mice are more reliant on other senses such as smell, hearing, taste and touch.

Typically, following disease induction, the eyes of mice will be examined (usually twice weekly), under general anaesthesia, to monitor the progression of the inflammation. In addition, small blood samples from the tail may be collected and some of the animals will be given treatments aimed at preventing or minimising the severity of disease. This is usually by giving a drug by injection. At the end of the study the mice will be killed using a humane method.

What are the expected impacts and/or adverse effects for the animals during your project?

The disease models used in this project are mild. While some sight loss may occur, it does not cause pain or result in the animals changing their behaviour. Furthermore, in the mouse, vision is a much less important sense than smell, taste, hearing and touch using their whiskers.

Most of the procedures are conducted under general anaesthesia, which ensures discomfort is minimised. However, as a consequence the animals will experience several anaesthetics during the course of the study which can be cumulatively burdensome.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Half the mice will be used for breeding and will only experience the mild severity category. The remaining animals will be in experimental protocols in a moderate severity category as that is the maximum potentially achieved, though for the vast majority it is not expected to exceed a mild severity in practice.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the studies use imaging to study dynamic immune responses, a living intact retina, a circulation and viable immune system are required. The only way this can currently be achieved is through the use of animal models. The mouse is the least sentient species that has a relatively comparable anatomy to the human retina and models of ocular inflammation - such as experimental autoimmune uveoretinitis (EAU) and laser injury are already established. The mild visual loss caused by these models is attenuated by the dependence of mice on other senses given their typically nocturnal environment, such as smell, taste, hearing and touch. Their normal behaviour is rarely affected and minimal distress occurs. No alternative animal model has a less severe disease course.

Which non-animal alternatives did you consider for use in this project?

We looked into computational modelling and also at stem-cell and organoid models. We have previously used human stem cells treated to become RPE ocular cells to look at specific responses to cytokine stimulation and this could be used to refine potential candidate immunotherapeutics, but cannot replace all of the experimental approaches required.

Why were they not suitable?

Computational or in vitro models currently are not able to provide the required biological data, given the complexity of studying multiple cell types, cell motility and emergent properties in the full tissue environment proposed in this project. Some of the most advanced models capable of looking at detailed immune cell interactions can only handle three cells at one time.

Stem-cell and organoid modelling is currently at a stage where different cell types can be grown, but the precise anatomy is not retained and combining the many different immune cell types and blood supply required to model an immune environment has not been achieved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals needed to generate and maintain the genetically altered (GA) mice needed for the study is estimated at 300 animals per year. This figure is based on the number required to maintain the different transgenic lines and supply the mice required for experiments (Protocol 1).

Experimental usage (Protocol 2) is estimated at 400 per year based upon the scientific objectives of current funded projects and equates to around 10 experiments (each with up to 3 replicates) to an average of 30 experiments per year. In estimating group sizes we have undertaken analysis of data from previous experiments and performed calculations using statistical and design packages as detailed below.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Standard online tools and packages were consulted but they largely assume the use of large numbers and parametric statistics, which are often inappropriate for the readouts and assessments of models of ocular inflammation and assessment by immune cell counting. We therefore used dedicated packages such as the Experimental Design Assistant (EDA) from NC3R, which we will continue to use going forwards.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use efficient breeding and allocate males and females to specific disease models based on susceptibility to induction (e.g. EAU with females, laser models with males). Tissue sharing will be continually encouraged, made easier through belonging to a large ophthalmic focused research institute. Open data sharing as per grant requirements and the University data management policy will be prioritised and this will also support computational groups within the department.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models that replicate key ocular inflammatory diseases (e.g. uveitis and neovascularisation or degeneration as seen in age related macular degeneration) will be used. Genetically altered animals are needed for many experiments, although the alterations have no adverse effects on the animals. Care has been taken to select mouse models that induce only mild disease and none are known to be painful or of significant distress in most cases. The associated loss of sight does not impair the animal’s ability to perform its normal behaviour, as mice are more reliant on the other preserved senses. Careful monitoring and assessment of disease will be undertaken using non-invasive

imaging methods conducted under general anaesthesia so involves minimal distress to the mice. The delivery of therapeutics or collection of blood samples will be undertaken using well-established techniques that cause no more than mild transient pain and no lasting harm. We will implement intermittent breeding in line with recent NC3Rs guidance to minimise unnecessary wastage of animals.

Why can’t you use animals that are less sentient?

Mice are the least sentient of animal species to have eyes that are anatomically similar to humans and for which established disease models for ocular inflammation exist. Their immune systems are also recognised as sufficiently similar to man and despite some caveats have been already used to successfully design clinical therapies and drugs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continue to refine our methods for the induction and monitoring of ocular inflammation and have published on this before in the scientific literature.

By using non-invasive ocular imaging with developing and advanced methods of tissue analysis, we can avoid the frequency of more invasive sampling such as for blood. We can also extract more data from each animal, reducing the overall numbers required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We participate actively in 3Rs seminars, presenting our approaches and learning from others in the ophthalmic research community, with weekly seminars at the University and special interest groups at international vision research conferences such as ARVO. We will ensure all our work is compliant with ARRIVE guidelines and consult the latest refinements from NC3Rs and LASA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group takes part in continuing education including attending and contributing to 3Rs focused seminars and lectures and through conferences and publications discussed at journal clubs. We will engage with regional NC3Rs programme managers and training programmes offered by the University Biological Services Unit.

17. Developmental Defects Caused by Mutations in Chromatin Genes

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

chromatin, gene regulation, developmental disorders, heart development, brain development

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand why mutations in chromatin genes, which should be required in all tissues, affect certain organs more than others (most commonly the heart and the brain).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

More than 100 human genetic disorders are caused by mutations in chromatin genes. From what we understand about these genes, they should function in all tissues. However, when they are disrupted they only cause problems in some tissues whilst leaving others

unaffected. Before we can research treatments that could help patients with these genetic diseases, we first need to understand why they have such different effects on different types of cells. This is important because otherwise potential treatments might cause side-effects by disrupting organs and tissues that were previously unaffected by the mutation.

What outputs do you think you will see at the end of this project?

- 3D images of developing mouse embryos carrying mutations in chromatin genes.
- Atlases of gene expression in heart and brain tissue from these embryos, showing where the mutation has caused other genes to be improperly switched on or off.
- Datasets showing how the mutation has affected the way DNA is folded, packaged and protected inside cells.
- Software tools for integrating these different datasets.
- Research publications that explain the datasets and use them to identify why the mutations have specific effects on heart and brain development.

Who or what will benefit from these outputs, and how?

Researchers working on these diseases will be able to use the datasets to identify genes disrupted by the mutation and target them with new therapies that might help reduce disease symptoms.

Researchers working on the basic biology of the genes we mutate will be able to use these datasets to gain new insights into the mechanisms of those genes.

Researchers working on the genetics of other diseases affecting the heart and brain will be able to use the datasets collected from our healthy controls to examine whether DNA packaging and folding might be a contributing factor to their diseases of interest. They will also be able to use them to identify previously unknown regions of DNA that might be responsible for switching on or off the genes that they are interested in.

Researchers working on the biology of other tissues will be able to repurpose the software tools we will develop for the analysis of their own datasets.

How will you look to maximise the outputs of this work?

Datasets will be released as soon as possible after they are generated (after a maximum of 12 months). Each dataset will be accompanied by a full description of the methods used to generate it and details of the mutations, sex, and age of the mice. An area of the lab's website will be dedicated to cataloguing these outputs and will be advertised in talks, poster presentations, primary publications and through social media. I will also create interactive pages allowing other users to explore the datasets without having to download and reanalyse them. This policy of releasing research outputs prior to primary publication maximises their potential for re-use by other scientists and minimizes the possibility of

other researchers duplicating the same experiments. It is particularly important for research on rare genetic diseases where very little data is already available. We will also publish the details of any unsuccessful approaches to prevent other researchers wasting resources.

Species and numbers of animals expected to be used

- Mice: 11000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The human diseases we are interested in generally cause problems with the heart and the brain during early development (i.e. before birth). We use mice because they have hearts with four chambers, similar types of cells in their brains and because many of the genes involved in forming their hearts and brains are the same as in humans. It is also relatively easy to introduce the types of mutation we are interested in into their DNA. We use mouse embryos because we are interested in the process of their early development in the womb and how these types of mutations cause that development to go wrong.

Typically, what will be done to an animal used in your project?

Most mice will be born carrying "conditional" mutations that will not cause them any health issues. These mice will then be bred in such a way that the mutation becomes detrimental only in the developing embryos. Pregnant females will be humanely killed and tissue taken from the embryos for analysis.

In some cases, we need to administer a substance to activate the conditional mutation in the developing embryos. Typically, this will involve the pregnant female being fed an additional substance either in their diet or drinking water or once per day through a feeding tube for up to five days. The pregnant female will then be humanely killed and tissue taken from the embryos for analysis.

In some cases, we need to administer a substance to be incorporated into the cells of the developing embryo and label them. Typically, this will involve the pregnant female being given an injection under the skin. The pregnant female will then be humanely killed and tissue taken from the embryos for analysis.

Rarely, we may need to combine these approaches, such that the pregnant female is fed a substance via a feeding tube once per day for up to five days and then receives an injection under the skin. The pregnant female will then be humanely killed and tissue taken from the embryos for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are not expected to suffer adverse effects related to their breeding or genetics.

Animals may experience adverse effects from the administration of substances:

- Injection under the skin of a pregnant female may cause redness or inflammation at the injection site. If this is observed any further injections will be halted and advice will be sought from the vet on an appropriate treatment (e.g. an anti-inflammatory cream). Pain or suffering could last for a maximum of 24 hours, as the animal will be humanely killed if its condition has not improved after this time.

- Injection into the body of a pregnant female may cause miscarriage or reabsorption of embryos. Any pain or suffering will be brief because the animal will be humanely killed immediately in the event of such symptoms.

Animals may experience adverse effects from the substances themselves:

- Animals may experience transient weight loss. Animals will be monitored by condition scoring and any under-conditioned animal will immediately be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice 90% sub-threshold, 5% mild, 5% moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are interested in the processes by which the heart and brain are formed, and how these go wrong in certain genetic conditions. Normal development requires a complex set of interactions between different organs and tissues. These processes and interactions are currently not possible to study in depth using non-animal approaches.

Which non-animal alternatives did you consider for use in this project?

We have searched databases for scientific publications and data pertaining to the genetic conditions that we are interested in. We will continue to do this through the life of the project to ensure that we avoid wasting any animals duplicating experiments already performed by others, or conducting experiments whose hypotheses have already been addressed by others. We regularly download and re-analyse publicly available datasets. Often these come from wild-type mice with no mutations mimicking human conditions, but these are useful to design our experiments and ensure that we are targeting the appropriate cells. This avoids unnecessary use of animals in pilot studies.

As alternatives to animals in this project we have considered the use of human patient tissue, culturing of stem cells derived from human patients, introducing mutations into normal stem cells to study how this affects the formation of brain and heart organoids and the use of cell lines derived from heart or brain cell types.

Why were they not suitable?

The genetic diseases we are interested in studying are rare, so human tissue is very hard to obtain. More importantly, the processes that we are interested in take place during pregnancy, so we would only be able to obtain human tissue samples years or decades after the period of development we are interested in.

Methods for growing cells in culture to form structures that functionally resemble the heart and the brain are improving every year, these are called cardiac organoids or brain organoids respectively. However, none of these techniques is perfect and all of them are only useful for exploring particular processes or types of cells. Because so little is known about the diseases we wish to study, it is impossible to judge whether any of these techniques might be suitable. Our approach instead is to conduct the early stages of this project in whole animals, then hopefully to progressively move to these alternative approaches as we understand which particular cell types we should focus on to better understand the disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We first make a list of the experiments needed to address our aims. We then use available tools to estimate the number of embryos required for each experiment, such that we use the minimum number required to obtain robust and statistically meaningful results. Because we know the average number of embryos carried by each pregnant female, we

can calculate the number of female mice needed, and the number of male mice needed to breed with them. Finally, we calculate the number of breeding pairs required to generate the male and female mice to be used in each experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3R's Experimental Design Assistant to ensure our experimental designs are robust and to identify appropriate methods for analysis of the data, which is an essential first step to minimising the number of animals required for an experiment. We also refer to the PREPARE guidelines published by Norway's 3Rs centre Norecopa whilst designing each experiment. All experiments will be conducted and records kept such that publications arising from this project will comply with the ARRIVE guidelines

2.0 maintained by the NC3Rs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For each experiment, we compare all possible ways of combining male and female breeding animals to determine the approach which minimises the number of animals required. This includes ensuring, as far as possible, that:

The generated embryos will all be usable in our experiments (i.e. they will either carry the mutation we are interested in or will be suitable for use as an unaffected control).

Each litter has a chance of containing both experimental and control embryos (such that comparisons can be made within litters, minimising the variability between experimental measurements).

Experimental and control embryos are produced in roughly equal numbers so that there is no excess of one over the other.

In addition, whenever we are using only part of an embryo (e.g. only the heart, or only the brain), we will endeavour to cryo-preserve material from other tissues and organs such that it can be used in our future studies or shared with other interested researchers.

Where the safety of substances we want to administer to mice is not fully known, or it is not known whether the substance will affect the taste of diet or water, we will use pilot studies to establish, amongst other parameters, the minimum number of animals that should be included in a full study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are interested in human genetic conditions that cause developmental syndromes. To study these conditions, we need to examine the effect of the mutations that cause these conditions in whole embryos, so that we can observe the process of development and account for the interactions between different organ systems. Any animal model for these diseases must share genetic pathways for heart and brain development with humans, such that findings can be translated for medical benefit. It must also be possible to introduce mutations into the DNA of the animal model to mimic the effects of mutations identified in human patients. Mice are the most appropriate species for this project because they are the least sentient species that satisfies these two requirements.

Introducing potentially harmful mutations into mice could cause them pain, suffering, distress or lasting harm. To avoid such effects, we use "conditional" mice, in which harmful mutations are not found in parents and only become active in offspring when two unaffected adults are bred. These conditional models confine harmful effects to embryos at early stages of their development, where they have less capacity to experience pain, suffering and distress.

In some cases, we need to activate the harmful mutation at a specific time point during mouse development, which requires us to administer a substance to pregnant mice that converts the mutation to its harmful form. We administer substances using whichever method causes the least pain, suffering or distress to the pregnant mouse whilst still delivering our scientific aims. Usually, this means the substance is delivered through food, drinking water or a feeding tube.

Why can’t you use animals that are less sentient?

Animals less sentient than mouse embryos cannot be used because they do not have brains similar enough to humans for results to be medically actionable.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When we administer substances to mice, we will monitor the animals daily to note any change in appearance or behaviour that might indicate a harmful event, and animals will be humanely killed if they exceed any of the specified end points. When substances are administered by injections under the skin on consecutive days, we will vary the site of injection to reduce the risk of inflammation. If there is any indication of reaction, advice will

be sought from the vet on an appropriate treatment. For example, if the skin is red at the site of an injection an anti-inflammatory cream may be applied. If the animal's condition does not improve after 24 hours, the animal in question will be humanely killed.

Pregnant mice will be handled using tunnels wherever possible and will be housed either in pairs or with a non-pregnant companion animal to reduce stress. Cages containing pregnant mice will be supplemented with a dome to provide additional safe enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will primarily use the resources provided by the NC3Rs (including the Experimental Design Assistant and the ARRIVE guidelines), Norecopa and the members of the Federation of European Laboratory Animal Science Associations. I will also periodically seek out any newly published guidance from the establishment Named Information Officer and Named Animal Care and Welfare Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Everyone involved in the project will attend internal and external meetings and conferences focused on the 3Rs during the project. We will subscribe to the NC3Rs mailing list to ensure we are kept up to date about new events and developments. I will also consult with the regional NC3Rs manager wherever relevant.

18. Understanding Speciation and Adaptation in Cichlid Fishes

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

biodiversity, pollution, evolution, behaviour

Animal types	Life stages
Haplochromis spp.	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand which genetic changes are important in affecting behaviours involved in reproduction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding the genetic basis of reproductive behaviour can help us understand how populations become reproductively isolated and eventually become different species. Understanding reproductive behaviour can also help us identify any changes in this behaviour that environmental pharmacological pollutions could have, so that we

understand the wider ecological consequences of behavioural changes caused by pollution.

What outputs do you think you will see at the end of this project?

Outputs at the end of this project will mostly be publications, including post graduate theses. These will all be publicly available in repositories, and will typically include associated blog posts or press releases to widen accessibility of the results.

Who or what will benefit from these outputs, and how?

In the short term, most beneficiaries will be within the academic community, but longer term, understanding how biodiversity evolves will have conservation benefits. Understanding how pollutants such as SSRIs affect animal behaviour will also have relevance to e.g. environment agency, and other NGOs. Genetic tests of the effects of vision mutations on behaviour may also allow a fuller understanding of the genetic pathways involved in vision, which may ultimately provide medical benefits for humans.

How will you look to maximise the outputs of this work?

Videos and code will be made available so that the work is as reproducible as possible. Results will be published on BioRxiv ahead of publication in a peer reviewed journal, to maximise availability of the work, and will be accompanied by press releases or blog posts, and publicised on twitter to maximise dissemination. Results will also be presented at scientific conferences.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

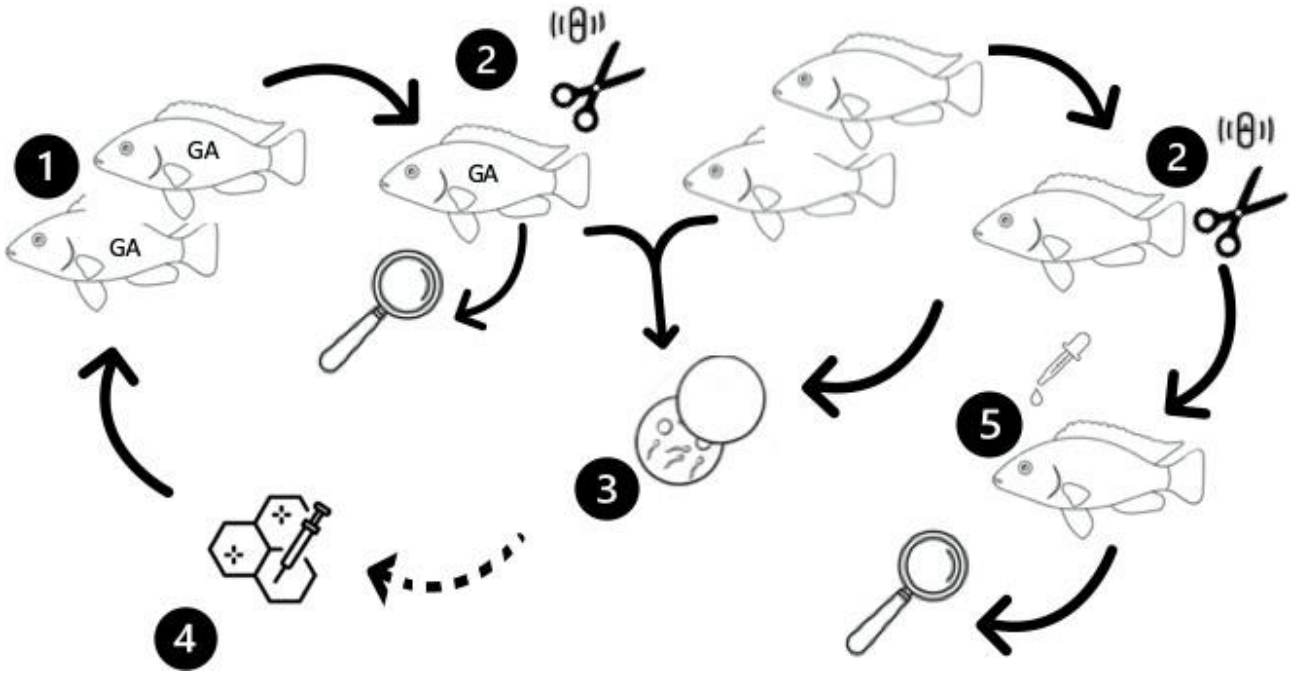
We are using these types of animals because they are a well studied model in evolutionary biology, and there is already a wealth of knowledge available upon which further work can be based. We plan to study the reproductive behaviour of these species, so we need to use adults for this. Where we genetically modify fish to better understand how specific changes to visual genes might lead to changes in behaviour, we use embryos, and raise these to adulthood so that we can observe reproductive behaviour.

Typically, what will be done to an animal used in your project?

Our project will involve inserting a small microchip in the abdominal cavity of the animal, similar to microchips used in identification for pets. This will enable us to identify individual animals and keep track of which other procedures they have undergone, so that they can be housed in stock tanks with multiple animals, which will reduce stress since they are naturally social animals. We will be able to record their movement across territories within their tanks. We will also take a small tissue sample so that we can extract DNA and identify what genetic changes the animal has - this will be either a small piece of fin no more than 1mm, or a skin swab with a cotton bud. Some of our animals will have a drug treatment, before being observed, to see how the treatment affects their reproductive related behaviours. This treatment will be administered in their water and will continue for 2-4 weeks, after which time they will be returned to normal water conditions.

One component of our project involves genetically altering fish, and this will be carried out at the egg stage, within one hour after the egg is fertilised. The genetic changes we make will mirror changes we find naturally in other closely related species, so we don't expect the animals to suffer any adverse effects.

The protocols involved in this project allow us the create and maintain genetically altered fish, and to treat fish with pharmaceutical drugs. Once we have done this, we will monitor and test their behaviour. The behavioural experiments themselves are observations and therefore are not regulated procedures. For this reason they are not explicitly described in any protocol, although the generation and maintenance of fish to use in these observations is.



There are 5 protocols in this project, and fish may be used in multiple protocols. In the diagram above, numbers correspond to protocols. Fish bred in captivity may be fin clipped and PIT tagged (2), then treated with pharmaceutical compounds (5) before being observed in behavioural experiments.
CRISPR-cas9 will be used to generate genetically altered fish (4) which will be bred and maintained in the aquarium (1) and maybe fin clipped and PIT tagged (2) if they will then be observed in behavioural experiments. Any fish, genetically altered, PIT tagged, or not PIT tagged may be used for producing gametes (3). The dotted arrow indicates that although genetically altered fish may be used to produce gametes for maintaining stock, they won't be subject to further alteration. Genetically altered fish will not be treated with pharmaceutical compounds.

What are the expected impacts and/or adverse effects for the animals during your project?

We anticipate that any adverse effects are very mild, and short in duration (i.e. for a couple of seconds during fin clipping or microchip insertion). These will be carried out under anaesthetic, post-operative analgesia will be used after consultation with the NVS using the most appropriate analgesic type and route of administration for the procedure involved. Typically when we carry out these procedures, the animals return to normal behaviour very quickly and live a long life in our aquaria.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities for all the procedures and animals are mild.

What will happen to animals at the end of this project?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to understand how changes at the genetic level, can lead to changes in reproductive related behaviours that can lead to changes in mate preference, reproductive isolation and eventually speciation. It isn't possible to monitor adult behaviour, without using adult animals.

Which non-animal alternatives did you consider for use in this project?

This project could not be carried out with non-animal alternatives.

Why were they not suitable?

Non-animal alternatives are not available for the study of animal behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will try to use the minimum number of animals possible, but need to ensure that we use enough animals to account for the variability within the population. Behaviour is notoriously variable, and so samples need to be big enough to take this into account (details and power calculations are provided later). When making genetically altered fish, a large number may be required because there will be a relatively large number of fails but many fish will need to be screened in order to test this.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used data from previous experiments (ours and others') to assess what typical numbers might be needed for these experiments. We also designed the experiments so that there is periodic unblinding and analysis, so it is possible to stop adding replicates once a significant change in behaviour is detected.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To reduce the number of animals kept under regulated procedures we will strive to maintain the smallest number necessary to carry out a particular experiment, e.g. for each mutation line, only F0 animals with confirmed germ line transmission will be mated (or alternatively, sperms of which will be used to fertilise eggs from wild type (WT) females) to breed into adult F1 fish. We will also endeavour to preserve lines that are not currently being used by sperm freezing thus only maintaining actively used animals in the facility. In addition, the use of homozygous mutant animals allows us to reduce the total number of animals to characterise a gene.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use haplochromine cichlids in these experiments, for mild procedures with no lasting harm. We will carry out the procedures under general anaesthetic, and using post-procedure analgesic to reduce suffering.

Why can’t you use animals that are less sentient?

We can't use animals at a more immature life stage because we need to understand the effects of SSRI and/or vision gene changes on reproductive related behaviours, in order to understand the impact for evolution, and this is not possible on juvenile fish. Teleost fish are the most suitable because they have complex social interactions and reproductive behaviours, but are less sentient than other possible choices e.g. mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will minimise welfare costs by using anaesthetic and analgesic, and regular monitoring post procedure, including water quality where relevant.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Peer reviewed scientific publications centred around fish welfare, specifically with respect to tagging and behaviour, and the use of analgesics.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advances in the 3Rs are shared on our intranet, I follow relevant researchers who share their findings and publications on twitter, and attend animal behaviour conferences, including RSPCA/NC3Rs conferences.

19. Regeneration and Tumorigenesis of the Respiratory Tract

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Respiratory, Regeneration, Cancer development, Repair, Stem cells

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine the cells and molecules responsible for maintaining an optimal function of the respiratory tract (nose, throat, airways, lungs, and ear) in healthy individuals. Also, to study the processes and factors that drive respiratory diseases and tumour development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The respiratory tract mediates the vital processes of supplying oxygen to the blood and removing carbon dioxide. When air enters, it is distributed throughout the lung lobes by a highly-branched system lined by a continuous epithelial cell layer. This layer differs in terms of its structure and cellular composition along the tract, and consequently in its reparative and regenerative capacity. The respiratory tract is susceptible to injury as well as to the effects of aging and a range of diseases such as asthma, fibrosis and cancer. The cells and the mechanisms that control lung stability and those that drive regeneration and tumour formation remain poorly understood, but will be crucial in developing treatments for these conditions. That is why this project is important to increase our understanding of the factors regulating the respiratory tract balance and how aberrations in these can drive lung diseases and cancer. In addition, it will allow us to improve and identify new therapeutic approaches to ameliorate patient outcomes.

What outputs do you think you will see at the end of this project?

We will increase our understanding of respiratory tract biology in health and disease and in the development of cancer. This will enable us to identify and/or develop new therapeutic agents/approaches that could be used to treat human respiratory diseases, including cancer. The results will be submitted to scientific journals for publications, and could form part of intellectual property in case a new molecule or mechanism is discovered.

Who or what will benefit from these outputs, and how?

Patients with lung cancer and lung diseases suffering from poor quality of life will benefit from these outputs in the longterm. Data generated in this project will be used to increase our understanding of the mechanisms driving lung pathogenesis and, on identification of novel therapeutic potential, as preclinical data for drug development or establishment of a clinical trial.

Outputs from this project will also benefit the scientific community in the shorter term as our work will be disseminated through presentations and publications and this could lead to even greater scientific advancements.

How will you look to maximise the outputs of this work?

We are members of multiple consortiums and collaborations with world-leading experts working on mouse models of lung diseases and intent to make use of these to optimise the approaches used and to share new techniques; we will continue these collaborations for the upcoming years. We will also disseminate knowledge through presentation and publication.

Species and numbers of animals expected to be used

- Mice: 9500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To best mimic the human condition, the mouse models we intend to use have been chosen because they are widely accepted to be the most appropriate and relevant models.

The life stage chosen will be different in each protocol. For example, all ages will be used in the breeding and maintenance of genetically altered mice whereas only juvenile and adult mice will be used in tissue and cell grafting for regeneration as we want to understand the process in adult patients. The life stage chosen will always be the best to mimic the human condition.

Typically, what will be done to an animal used in your project?

• Animals will be dosed with different agents – the most common routes of administration are: instillation through the nose and/or the throat, The most commonly used include: aspiration through the nose and/or the throat, administration of agents via oral gavage, intra-peritoneal and/or intra-venous injection, application of agents topically or subcutaneously, change in diet and/or drinking water. These procedures are quick and will not take more than 2 minutes per animal.

• In some instances, surgery may be carried out to implant the agents, for example, in the kidney capsule, under the skin or in other specific locations in the oral-respiratory tract. This procedure takes more time and is done under general anaesthesia for no longer than 30 minutes.

• In some instances, animals will be pre-treated or treated with agents to modulate gene expression, injury or repair among other things.

• Animals may be imaged using minimally invasive imaging modalities.

• Where necessary, tissues/organs may be retrieved under terminal general anaesthesia with or without perfusion with a solution.

• All other animals will be terminated using a Schedule 1 method, after which time tissues may be collected

They may also be irradiated to facilitate tissue engraftment and some mice will be injected intraperitoneally with BrdU/EdU prior to termination of the experiment. These options will not be part of a typical experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals will be used in models of lung disease, tumour development or airway tissue engineering. These animals may develop tumours but these are generally well-tolerated. Some animals may experience reduced mobility, reduced lung function and some short periods of respiratory distress, but are not expected to show prolonged signs of breathing difficulties. In addition, some animals used in this project will experience weight loss but this will be closely monitored. A small proportion of animals will undergo a surgical procedure but these procedures are expected to pose minimal risk to animal welfare. Furthermore, some animals used in this project will be immune- compromised but these animals will be carefully looked after to minimise chances of infection. Studies will be designed to ensure only the minimum number of animals required are used. Throughout studies, animals will be regularly monitored; if any animal causes concern, action will be immediately taken to alleviate this and if this is not possible the animal will be humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity will range from mild to moderate. Around 32% of mice will be under the mild severity category, and 68% in the moderate category, based on data from previous years.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The respiratory tract is extremely complex, with interactions between various cell types and different processes. This cannot be adequately mimicked using in vitro studies and therefore the most appropriate approach to mimic this is using a whole animal.

Which non-animal alternatives did you consider for use in this project?

In vitro, ex vivo and in silico experiments were considered. We intend to use these experiments to establish whether in vivo experiments are necessary.

Why were they not suitable?

Although non-animal alternatives will be used to establish whether in vivo experiments are necessary, the diversity of cell types and the complexity of the interactions cannot be mimicked using these techniques. The respiratory tract needs to be studied in a whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on previous experience and experimental plans.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We plan our studies so that only the minimum number of animals required is used and made use of the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will also make use of minimally invasive imaging techniques to enable us to monitor changes in a process longitudinally in a single animal, which will eliminate the need to use more animals at different time points. Wherever possible we will make use of alternative methods to genetically modify mice rather than by doing this through mouse crosses, which will reduce the number of animals generated unnecessarily. Wherever possible inbred strains of animals and littermate controls for genetically modified strains will be used to minimise the effects of genetic variation, which should reduce the number of animals required in an experiment. In addition, wherever possible we will use both male and female animals, which will reduce the number of genetically modified mice that are generated but not used in further protocols.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse models of lung diseases we intend to use have been chosen because they are widely accepted to be the most appropriate and relevant to the human condition they mimic. We have extensive experience in each of the chosen models, which allows us to reduce the number of animals required, to limit the invasive procedures carried out and to limit the discomfort experienced by the animals.

Why can’t you use animals that are less sentient?

Since we are interested in studying the respiratory tract, we need to use mammals, and the mouse models are well established and are the gold-standards in the field as they are the closest mimics of the human condition. Not only that, but the mouse respiratory system has been extensively studied and there are many reagents available that wouldn't be available for other animals. This project needs to be conducted on live animals to be able to study the mechanisms and interactions ongoing between the different cell types over time, and to allow us to study interventions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Throughout this programme of work we will continue to monitor our own practices and the literature and the NC3R website to look for ways to refine our procedures; this could include monitoring the animals more closely and more frequently, providing additional nutrition and hydration to aid recovery after a procedure, changing pain management and giving antibiotics when needed. This makes administration of substances via this route significantly quicker and causes less distress to the animal. Environmental enhancement will be used to minimise stress (for example, soft bedding and wet mash where necessary). For chemically induced tumour induction models, in which animals are regularly treated for prolonged periods, animals are handled by the researcher prior to commencement of the experiment to allow the animals to acclimatise to the researcher and to minimise distress during the course of the experiment. In addition, in these experiments where chemicals are applied to the back of the mouse, a restrainer may be used to minimise the time required to apply the chemical, which minimises distress.

Wherever possible we will incorporate these improvements into our protocols to further refine, reduce and replace the use of animals. We will continue to use non- invasive imaging to monitor animals, which should enable us to identify earlier end points and to reduce the number of animals required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE and PREPARE guidelines from NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to monitor the literature and check the NC3R website regularly to be up-to-date with advances in the regulations. These changes will be incorporated into our protocols wherever possible. We will have regular discussions with the NVS and NACWO and will attend training offered whenever possible.

20. Investigating Disorders of Glucose and Energy Homeostasis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Metabolism, Energy Homeostasis, Diabetes, Obesity, Inflammation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will investigate the impact of altered energy homeostasis and how this affects organ systems and whole-body metabolism. By examining the effects of energy dysregulation on organ function and integrity, we hope to identify the underlying mechanisms that may lead to disorders associated with impaired energy homeostasis, such as diabetes and obesity

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The incidence of metabolic disorders such as diabetes and obesity are increasing exponentially. With an increasingly aged population, the incidence of complications associated with such conditions will become a substantial financial and societal burden. Improving our understanding of the mechanisms underlying these complications may improve our treatment strategies and minimise the long-term consequences.

What outputs do you think you will see at the end of this project?

The immediate outputs of this project will be scientific publications in high quality, peer-reviewed, high impact journals appropriate to the field of research, communication to relevant national and international scientific conferences and press releases disseminating the research findings

Who or what will benefit from these outputs, and how?

The findings of this research will, in the short term, improve our understanding of factors that may contribute to the development, progression and complications associated with metabolic disorders. For example, suppose a gene has been identified in a genome-wide association study (GWAS) relating to disturbances in glucose regulation. In that case, a GA model may be generated to look at the mechanism that may contribute to the manifestation of these conditions. In recent years the role of inflammation in the development of metabolic disorders such as insulin resistance, obesity and Type 2 diabetes is becoming more apparent. Indeed, there is debate whether inflammation is the cause or consequence of many disturbances in metabolism. Using in vivo models, we will explore the physiological (cardiovascular, renal, pancreatic), hormonal, inflammatory and cognitive consequences of changes in energy homeostasis. For example, the role of the GSK3/Nrf2 axis in beta cell decline in Type 2 diabetes will be investigated in a Diabetes UK funded project grant. Using GA modified mice, the constitutive levels of Nrf2 and GSK3 (alpha and beta) will be modulated to determine the potential role in the development of Type 2 diabetes. This work will generate mechanistic data to test the hypothesis that the GSK3-Nrf2 axis plays a crucial role in beta cell biology and identify therapeutic opportunities to prevent beta-cell damage, hopefully reducing the need for insulin therapy in type 2 diabetes.

In addition, the peripheral and cerebrovascular consequences of glucose and insulin dysregulation will be assessed in transgenic (e.g., Db/db.) and diet-induced obese (DIO) models of obesity and diabetes. This will provide mechanistic data to explore the links between diabetes and obesity with co- morbidities such as cardiovascular disease, cerebrovascular disease and Alzheimer’s disease (AD).

These findings will be disseminated to the broader community through interaction with our clinical collaborators, published in peer-reviewed journals, and presented at local, national, and international meetings. In the long term, the findings of these studies will be translated into the clinic. By working closely with our clinical colleagues, we hope to ensure that our animal models recapitulate the human condition as much as possible.

How will you look to maximise the outputs of this work?

The output of this work will be published in peer-reviewed journals and presented at National and International conferences. We will continue collaborating with fellow experts in metabolic disorders and other collaborators within the clinical research space. A paper is prepared to describe techniques that we have optimised (e.g., blood sampling from the tail vein without restraint) to disseminate this knowledge to the broader scientific community. The publication of negative data is crucial to minimising unnecessary experiments being performed, and this will take place via platforms such as BMC Research Notes.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult rodents (mouse) in this project as they are widely used in this field of research and share a similar physiological response to altered metabolism as make humans, i.e., weight gain and insulin resistance during nutrient and calorie excess. The use of transgenic models enables us to examine the impact of individual genes on metabolic disease progression or response energy deprivation/excess. The complications associated with metabolic dysfunction usually occur over several years in humans, and therefore, we will study adult rodents in this project

Typically, what will be done to an animal used in your project?

The animals used in this project will be studied throughout sustained energy imbalance (typically high- calorie feeding). Transgenic models aimed at disrupting key systems/signalling pathways involved in energy homeostasis will be utilised for in-depth analysis of the roles of these pathways in maintaining energy homeostasis and for investigating the physiological impacts of disruption of these systems in an in vivo model. We will then assess the effects of altered energy homeostasis on aspects of metabolic function and glucose handling in models of altered energy-sensing (transgenic,

pharmacological or diet-induced obese (DIO)). These experiments will typically last 2-3 months.

What are the expected impacts and/or adverse effects for the animals during your project?

We anticipate that animals will gain excess body weight (primarily fat mass) due to feeding of high- calorie diet (dietary-induced obesity – DIO) and begin to display symptoms of impaired glucose handling and insulin resistance following prolonged periods of positive energy balance. Symptoms may include polyurea (increased urination) and reduced physical activity. Animal husbandry will be adjusted to maintain a comfortable housing environment for these animals (remove and replace wet bedding) and body condition scores will be utilised to monitor animal welfare. So that we are able to "fix" the glucose levels in the body (referred to as "clamping" the glucose levels at a set concentration)animals may need to have permanent vascular catheters inserted into blood vessels in the neck under general anaesthesia. All animals undergoing surgical procedures will be given appropriate analgesia to minimise pain. Weight loss is likely to occur in the first two days following surgery, but support measures such as soft food will be provided to minimise weight loss. Guidance will be sought from the Named Veterinary Surgeon (NVS) and Named Care and Animals Welfare Officer (NACWO) should any animal display signs of abnormal behaviour or any unexpected change in physical appearance.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Adverse effects depend on the studies being performed. They mainly relate to surgery or the development of diabetes and obesity (approximately 50% of our studies), very much as we see in humans. Animals developing diabetes and/ or undergoing surgery are expected to reach the moderate severity category (approximately 20%). Genetically altered mice are not usually expected to display any clinical signs (subthreshold or mild severity), although some may develop diabetes and therefore potentially reach a moderate severity level (approximately 10%). Overall severity is expected to be 40% moderate, 60% mild/subthreshold.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Metabolic disorders such as diabetes and obesity are complex conditions characterised by a chronic energy imbalance, elevated blood sugar (glucose) and fat (lipid) levels, fat mass gain and alterations in insulin sensitivity (Type 2 diabetes). Although we can model some aspects of these conditions in vitro (for example, the exposure of cultured cellular models of metabolic tissues to nutrient and fuel excess), this doesn't fully replicate the interaction between different cell types or tissues that have a fundamental role in the development of many of the co-morbidities associated with conditions of chronic energy imbalance and altered metabolism, such as diabetes or obesity. Replicating the complex and variable conditions that occur in a disease state such as diabetes is extremely difficult and limits the applicability of these in vitro models to disease.

Which non-animal alternatives did you consider for use in this project?

Where possible, we perform studies in cell systems first to ensure that a candidate gene or pathway is essential to the things we want to study. Subsequently, highly specialised techniques have been developed to measure the animals' response to challenges, such as high-calorie diets. This means that we can compare much smaller groups of animals. Techniques have been developed to study the animal while awake and conduct repeated tests in the same animal rather than using lots of groups.

Why were they not suitable?

Replicating the complex and variable conditions that occur in metabolic disease states such as diabetes in vitro is extremely difficult due to the complex interaction between cell types, hormonal secretion and organ systems (pancreas, brain, liver, muscle, adipose tissue), and this limits the applicability of these models to disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals required for this project has been calculated based on previous experience using similar models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design will align with ARRIVE guidelines and follow NC3R guidance using the Experimental Design Assistant (EDA). Studies will be kept as simple as possible to maximise the

information obtained from the minimum number of animals. Advice will be sought as necessary from statistical sources, locally or online, concerning the minimum number of experimental animals required to allow a sufficiently robust statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use highly specialised techniques to measure the animal's response to challenges, such as a high-calorie diet. This means that we can compare much smaller groups of animals. Plans have been developed to study the animal while awake and conduct repeated tests in the same animal rather than using lots of groups.

The mouse models that we propose to use in this project are well-studied models used frequently in metabolic research, which helps compare results to other groups. Transgenic models generated and studied during this project will be developed on well-established genetic backgrounds (e.g., C57BL6) for accurate comparison with existing literature.

In all cases, tissues will be collected and archived for subsequent analysis by both our group and others working in energy homeostasis disorders.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will induce diabetes (or glucose dysregulation) in many of the animals in our studies. Where possible we do this non-invasively by using high-fat or it naturally due to genetic changes. In some cases, we have to use a chemical by injection that destroys the cells that produce insulin in the pancreas. We have refined our injection protocol to make the solution less irritant and we ensure that diabetes caused is as stable as possible, using special small implants under the skin to release low levels of insulin if needed.

We minimise welfare costs by using highly trained staff to conduct all our studies with many years of experience working with animals and using our techniques. New staff are

rigorously trained. All studies are carried out following recommended guidelines under the guidance of the local veterinary team and in a facility with highly trained staff

Why can't you use animals that are less sentient?

Metabolic conditions are complex, and complications associated with these conditions develop over time. We cannot use non-mammalian models to study diabetes as this cannot occur other than in mammals. It is also not possible to use only animals under terminal anaesthesia as it alters the hormonal and biochemical response to fluctuations in fuels and therefore does not replicate the human condition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

1. Before any experimental procedures, animals will be handled for a minimum of 1 week to acclimate the animal to the user and vice versa. Whilst on a study, animals will be weighed, and body condition assessed weekly by PIL and trained staff at the animal resource unit. Following surgery, post-operative care and pain management will be provided following advice from the NVS. Wherever possible, procedures will be performed in the animal's home cage following appropriate handling. Whenever possible this includes taking blood samples from the freely moving animals from the tail vein. This is a well-established procedure in the lab, and we have demonstrated it causes minimal stress to the animals.

2. The equipment used to assess whole-body energy metabolism (CLAMS) does so by indirect calorimetry, which allows for detailed measurement of energy expenditure. The CLAMS device allows for multiple, detailed non-invasive measures of energy expenditure in small groups of animals, reducing animal numbers required to measure each endpoint. The system assesses calorimetry (indirectly) via a closed system that takes measurements of energy expenditure at different temperatures by measuring changes in gases (02 and CO2) within each cage. Rodents have increased brown adipose tissue (BAT) compared with many other mammals and this means that temperature challenge is the best means of assessing energy balance in the body (energy homeostasis) dynamically.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance for experiments will be acquired from LASA, NC3R and other appropriate websites.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will regularly visit the NC3Rs website and others recommended by the local named information officer.

21. Immunity to Influenza Viruses in Pigs

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

influenza virus, pig, influenza vaccine, immune response, mucosal immunity

Animal types	Life stages
Pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand protective immunity to influenza viruses in pigs. We will also determine how best to induce protective immunity by vaccines and evaluate novel therapeutics and monoclonal antibodies to prevent disease and virus transmission.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Globally approximately 1.5 billion pigs are produced annually for pork production, which accounts for more than one-fourth of total protein consumed worldwide. The demand for pork has led to intensification of production, with farms often housing thousands of animals leading to rapid pathogen transmission. Influenza virus infection in pigs is a major farming problem, causing morbidity, mortality and loss of productivity. Economic losses due to swine influenza (SI) are among the top three health challenges in the swine industry.

Furthermore, pigs are natural hosts for the same subtypes of influenza A viruses as humans and are integrally involved in virus evolution with frequent interspecies transmissions in both directions. The emergence of the 2009 pandemic H1N1 virus (H1N1pdm09) illustrated the importance of pigs in the evolution of zoonotic strains.

What outputs do you think you will see at the end of this project?

1) Characterisation of the specificity, magnitude, and duration of mucosal and systemic immunity to current and emerging influenza viruses.

2) Identification of early key events in the innate immune response that determine the outcome of infection and severity of disease.

3) Evaluation of the capacity of influenza vaccines and therapeutics to prevent clinical signs and limit virus transmission. The role of local and systemic immunity and how best to deliver vaccines and therapeutics to induce universal protection against different strains will be established. The part of the respiratory tract that should be targeted by vaccines or monoclonal antibodies for optimal protection will be identified.

4) Characterisation of the turnover of tissue resident memory cells (TRM) and their distribution in the respiratory tract.

The outputs of the project will be new knowledge about the nature of the disease caused by different influenza viruses and what are the protective mechanisms of immunity to influenza in pigs. In the short term we will also obtain information about the efficacy of novel influenza vaccines and therapeutics in preventing clinical signs of disease and limiting virus transmission. In the medium and long term these outputs will enable improvements to be made in the prevention of influenza virus infection in pigs and in humans. The outputs of the project will be disseminated primarily via scientific publications and conference presentations.

Who or what will benefit from these outputs, and how?

Pig farming industry: A key deliverable of this proposal is to determine how to make better and more efficient vaccines and control measures to limit the spread of disease. The beneficiary will be the pig farming industry. Both productivity and animal health and welfare will be improved, and secondary infections and severe disease reduced.

General public and human health: A more efficient immunisation strategy against influenza virus infection will also reduce transmission and the zoonotic threat posed by swine influenza viruses. Increased productivity in the pig industry will lower costs for the consumer.

As both pigs and humans are readily infected with influenza A viruses of similar subtype, the pig is a robust and appropriate model for investigating both swine and human disease. Like humans, pigs are outbred, and physiologically, anatomically, and immunologically similar to humans. The porcine lung also resembles the human in terms of its lung structure, physiology, morphology, and distribution of receptors bound by influenza viruses. Any knowledge gained from the pig model could be easily translated to humans for development of better immunisation strategies and treatments.

Food security and environment: Consequences of improved pathogen control include reduction in antibiotic treatment for secondary bacterial infections, the risk of contamination of the food chain and the environment, as well as the risk of developing antibiotic resistance.

Benefits to the commercial private sector: The knowledge gained in this project can be applied to other respiratory tract infections in pigs and also to other livestock species and humans. Our close relationships with industry will allow us to fast track the new immunisation strategies into field use. We will identify new correlates of protection that evaluate pulmonary as well as systemic immunity to respiratory tract infections and this will accelerate vaccine development in pigs, other livestock and humans.

Benefits to policy makers; International development: Development of control measures and better vaccines for animals and humans will have an enormous impact on health policy and quality of life throughout the world. Diagnostic and consultancy services are commissioned by the UK Department for Environment, Food and Rural Affairs (DEFRA) and equivalent organizations worldwide (EC DG- SANCO, the World Organisation for Animal Health and the Food and Agriculture Organisation), who will therefore also be primary beneficiaries.

How will you look to maximise the outputs of this work?

Knowledge generated by this project will be widely disseminated to the research community as soon as practicable through open-access peer-reviewed journals and presentations at national and international conferences, collaborative discussions and interactions with members of the scientific community. Outputs of this work will also be

distributed to other stakeholders and the general public through press releases and social media channels.

Species and numbers of animals expected to be used

- Pigs: 480

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We propose to use a mammalian host (i.e. pig) appropriate to the influenza viruses we are studying, such that key information, e.g. clinical/pathological data can be used by the farming industry, veterinarians, animal keepers and national veterinary authorities responsible for disease surveillance, disease outbreak management and policy formulation.

Pigs are a natural host for influenza viruses and their immune and respiratory systems are very similar to humans. Pigs are susceptible to some strains of human influenza viruses, especially H1N1pdm09, and human viruses or human-origin gene segments frequently adapt to transmit efficiently in pigs. The similarity of clinical disease and pathogenesis of influenza infection in the two species, make pigs an excellent animal model to evaluate novel vaccines. In our experience vaccines which are protective in mice and ferrets are not always protective in pigs, further emphasizing the difference between small and large animals.

The pig is therefore the most suitable animal to study immunity to influenza virus infection and to evaluate the effectiveness of vaccines and therapeutics. Weaned piglets will be used as they are most reproducibly infected with influenza viruses.

Typically, what will be done to an animal used in your project?

Typically, animals used in this project will be immunised by an injection of influenza vaccine candidate into the muscle or by administration into the nose or by aerosols into the lungs, for which the animals may be sedated. The immunisation typically will be conducted twice at an interval of 1 to 8 weeks.

Blood samples will be taken to characterise the immune responses. Immunised and unimmunised animals will typically be inoculated once with influenza virus into the nose. Nasal swabs will be taken daily in the first 7 days to evaluate the shedding of challenge virus. Blood samples will be taken weekly to characterise the immune responses. Animals will then be culled humanely to assess lung pathology and tissues will be collected to

assess virus load and for further analysis of immune responses. The typical duration of an experiment is 21-56 days.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will experience mild and transient pain associated with a blood sample being taken, which includes restraint and insertion of a needle through the skin. Intranasal or aerosol administration of vaccines or therapeutics will be done using mucosal atomisation device or by aerosolisation, to reach the deep lung, using close fitting mask following sedation.

Our extensive experience using H1N1pdm09 and published data indicates that clinical signs of disease are consistently mild in pigs under experimental conditions, moderate being the highest severity ever observed, dependent on the virus strain used. The maximum severity recorded with H1N1pdm09strains is moderate, but in our extensive experience with these viruses the maximum severity is mild. The mild signs consist of intermittent coughing or a mild elevation in body temperature for 1 to 2 days. Rarely, animals infected with influenza viruses may develop moderate clinical sign consisting of laboured breathing, becoming lethargic or anorexic for 1 to 3 days. In this project, any animals which show these more severe signs will be killed if the duration reaches the endpoints in this licence.

In the case of unknown viruses (with unknown severity), pilot experiments will be performed, and challenge virus will be administered at times to ensure, wherever possible, that the peak phase of clinical impact falls within normal working hours, enabling regular observation. However there are provisions for out of hours checks. To allow severity to be monitored and minimised, clinical signs will be serially observed and recorded against systems-based clinical scoring sheets that include clearly defined end-points and intervention criteria. Pigs will be required to be anaesthetised transiently for some procedures and very rarely vomiting has been observed after anaesthesia. Pigs will be monitored throughout the procedure and recovery to avoid any adverse effects associated with the depression of body systems during anaesthesia and / or accidents during recovery

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

According to the cumulative literature and our extensive experience, 85% of animals are expected to show either no or mild clinical signs. Less than 15% are expected to show moderate clinical signs.

However, all animals will be clinically monitored both post-vaccination and post-infection. Assessments and interventions as appropriate will be performed at predefined frequencies in the experimental protocol, including euthanasia on welfare grounds if required.

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due to the complex nature of the immune system, it is not currently possible to study immune responses to immunisation and infection and to determine whether they are protective without the use of animals. It is also impossible to study the lifespan of lymphocytes in vitro because we wish to understand the effect of the local lung environment on their survival and cell division. In vitro experiments will tell us how long lymphocyte can survive in tissue culture conditions but has no bearing on their survival in the lung environment. Therefore in vitro experiments cannot tell us how long immunity to influenza viruses could persist in the lung.

Which non-animal alternatives did you consider for use in this project?

Cell culture and molecular biology techniques will be used to characterise influenza virus in the laboratory before infecting pigs. We will use laboratory techniques to understand the responses of the pigs to infection with influenza viruses using blood samples and tissue samples taken post mortem.

Protection against respiratory diseases is carried out by white blood cells in the lung, called tissue resident memory cells (TRM). After establishing how best to induce TRM we shall perform a series of in vitro experiments to determine what factors influence their maintenance and survival.

We shall also use a primary porcine airway epithelial cell model and tracheal organ cultures to study virus replication, anti-viral therapeutics and vaccines for the control of influenza. We have established for the first time in vitro porcine tonsil, lymph node and spleen organ cultures to dissect antibody and T cell responses. The parallel use of in vitro models and in vivo studies, will validate the predictive value of these in vitro models.

Why were they not suitable?

In line with the objectives of the programme of work a complete biological system is required to study transmission and protective immune responses to influenza virus infection. Therefore, in vivo studies have to be performed to provide critical data and biological materials that correspond to the outcomes and responses to viral infections in the animal itself. Given the nature and localisation of the TRM it is not possible to use an in vitro system to study how these cells are induced following immunisation, nor is it possible to measure immune responses to or protective efficacy of a vaccine without the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers to be used have been estimated using data previously collected from similar studies and in consultation with a statistician.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experiments are designed to ensure the appropriate number of animals are used - numbers are selected that enable robust experimental design compatible with obtaining reliable and meaningful results. The advice of an experienced biostatistician from our establishment will be sought, as well as from other collaborators as appropriate. The animal studies are designed to maximise collection of biological materials/data from each study and enhance the development and use of in vitro and ex vivo methods where appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Using inbred large white pigs (Babraham pigs) in some studies may enable us to obtain significant results with smaller groups of animals since these pigs are 85% identical as assessed by genome-wide SNP analysis and are matched for MHC type I and type II molecules.

- When investigating novel antigens, tissue culture analyses in the laboratory are conducted where possible to refine the number of candidate antigens for evaluation. This allows for a reduction in the number of in vivo studies required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal experiments are designed with close consideration of the likely overall severity and the period of peak severity caused by administration of a defined and consistent dose of virus (for example between 1 x 106 to 5 x 106 pfu per animal for H1N1pmd09) based on previous experience and published information.

We have developed a purpose built mask for aerosol administration which allows maximum exposure in the minimum time.

Sample collection will be carried out within clearly defined limits specified in individual experimental protocols, and repeated sampling will be done at frequencies such that the method of sampling causes no more than momentary pain and suffering and no lasting harm.

Substances administered to animals by injection or intranasal inoculation will be made in the smallest volume commensurate with the aims of the procedure according to good practice guidelines

Because of the rapid air changes in the rooms in the high containment facilities at our establishment, in order to best mimic natural room air, a purpose built Perspex pen (246 cm x 246 cm x 140cm) high is used for the contact challenge which allows the animals to exhibit their natural behaviour.

The severity level after influenza infection is mild in most cases. However, some pigs may develop moderate signs of disease which will not exceed the specified humane endpoints. Symptomatic treatment as agreed with the veterinary surgeon will be provided to alleviate suffering whenever possible.

Pigs housed in the high containment facilities at our establishment are provided with various enrichment items, including a straw bed, hanging toys and a rotation of ground objects to interact with. We have developed an enrichment monitoring program to help define which enrichment items are useful, and how frequently they should be rotated etc.

Why can’t you use animals that are less sentient?

Pigs are natural hosts for influenza viruses and a source for novel zoonotic strains, which may cause epidemics or pandemics in humans. Mice cannot be infected with most strains

of the influenza virus and do not recapitulate signs of illness observed in pigs and humans; guinea pigs do not exhibit overt signs of illness; and ferrets may have different drug pharmacokinetics to pigs and humans. Only in a natural host such as pigs, is it possible to dissect the pathogenesis of disease and identify how to control the virus.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pigs are intelligent animals and so enrichment is particularly important to create a stimulating environment. They are given straw beds which also enables them to express their species-specific behaviour of rooting and investigating. They are supplied with a variety of fruit, vegetables and toys which are frequently rotated.

Where possible, pigs are trained with positive reinforcement to reward desired behaviour e.g. cooperating with procedures which could include swabbing without restraint. This is a refinement in animal handling methods to improve animal welfare and the value of animals in research. Animals are also housed in pairs or groups to allow for normal social interaction.

Highly trained animal technicians will monitor these animals throughout the day, ensuring they are comfortable and to maximise their welfare status. We have 24/7 CCTV surveillance which can be used to monitor the animals' behaviour over time.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Adherence to the ARRIVE guidelines for reporting these studies, as well as reference to the FELASA guidelines for pig health monitoring to help ensure the most robust health assurance for animals used in this study. FELASA guidelines for administration of substances has been used to limit the maximum volumes for each of the routes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will attend appropriate 3Rs conferences, read the relevant scientific literature including the veterinary literature on pain relief, and undertake regular project licence holder training and refresher courses. I will take advantage of news and information provided by the NTCO. I will also use other sources of information such as:

- The NC3Rs
- (AALAS) American Association for Laboratory Animals Science
- (FELASA) Federation of European Laboratory Animal Science Associations
- (ICLAS) International Council for Laboratory Animal Sciences

22. Regulation of the Mammalian Reproductive Axis

Project duration

5 years 0 months

Project purpose

- Basic research

Translational or applied research with one of the following aims:

  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Infertility, Reproduction

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to study how mammalian reproduction and fertility are regulated by the interplay between different genes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Globally, infertility affects around 5% of all couples so the number of individuals with fertility problems is enormous. In many cases, the underlying cause of the infertility is not known reflecting out incomplete understanding of the factors that can cause these problems. A number of infertility problems will be caused by genetic mutations and it is important to study these to try to identify ways in which the infertility can be treated.

What outputs do you think you will see at the end of this project?

The main output from this research will be a contribution to scientific knowledge including data sets and publications in peer reviewed journals and presentations at scientific meetings. Specifically, we will generate novel data and knowledge about the role of specific genes in mammalian fertility. For example, we will define the genes that control the activity of Kiss1 neurons and how these might change during puberty. We will also define the way in which neurons involved in fertility are regulated by hormones (eg sex steroids) or peptides in the brain (neuropeptides). We will also define the function of the Hiat1 gene in controling male fertility.

Who or what will benefit from these outputs, and how?

The immediate short term benefit of this research is that it will provide training to stakeholders that are involved with the project and contribute to our knowledge of the mammalian reproductive axis and how it is controlled. The project will contribute to the research training of undergraduates, PhD students and post-docs. In the longer term, the project will also provide a greater understanding of clinically relevant disorders such as precocious or delayed puberty and may allow the development of treatment regimes. The knowledge from this project might also be of benefit for the development of approaches to treat disorders in women (eg cyst formation in the ovary or post-menopausal hot flushes) or might allow the development of novel male contraceptives by phamaceutical companies.

How will you look to maximise the outputs of this work?

The outputs will be disseminated through peer reviewed publications, reporting findings at scientific meetings, on the departmental web site and via social media. Where possible, we will also try to report negative findings in peer reviewed publications and on my personal web page which is accessible to all.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Genetically modified mice are a powerful resource to understand the function of a gene in a whole animal system as the technology exists to allow the distruption of a specific gene and examine the consequences of this. This project is examining puberty and fertility so it is necessary to use mice at these stages (prepubescent and adult).

Typically, what will be done to an animal used in your project?

The majority of the mice (5000, 90% of total number) are part of the breeding colony to generate a smaller number of mice (750, 15%) for experiments. The genetically modified mice in the breeding colony will not usually have any procedures performed on them, unless a second earclip is required for genotyping, and will not have any detrimental effects. From the breeding colony it is estimated that 350 mice (7% of total number) will only have injections of substances, and a small number (400, 12.5% of total number) will have surgery with recovery.

Most protocols will only take a few weeks to complete although mice undergoing pharmacological treatments will be kept for longer to allow recovery after any surgical procedure. Within the pharmacological treatment protocol, 350 mice will have minor procedures (injection and/or blood sampling). 400 (12.5% of total number) mice will have one surgical procedure (ovary transplantation or gonadectomy or substance delivery into the brain - icv). Up to 50 mice (1% of total number) will have two surgical procedures (gonadectomy and icv delivery). The mice that have undergone surgery may be kept for 12 months to allow long term monitoring of repoductive parameters.

What are the expected impacts and/or adverse effects for the animals during your project?

Breeding of the GA mice is not expected to be associated with any detrimental effects or losses apart from those normally associated with maintaining a breeding colony.

Surgical procedures will be carried out using aseptic techniques. In the uncommon event of postoperative complications, animals will be killed unless, in the opinion of the NVS, such complications can be remedied promptly and successfully using no more than minor interventions. In case of wound dehiscence, an uninfected wound may be re-closed on one occasion within 48 hours of the initial surgery and the NVS informed.

Peri- and post-operative analgesia will be provided in accordance with a regime agreed in advance with the NVS Animals are expected to make a rapid and unremarkable recovery from anaesthesia. In the uncommon event that animals fail to do so, or exhibit signs of pain or distress or of significant ill health, they will be killed by a Schedule 1 method.

Unless otherwise specified, the administration of substances and withdrawal of bodily fluids will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. We have

not observed any adverse effects from administration of hormones, which are normally given in the normal physiological range. Any animals showing any deviation from normal health or well-being will be killed.

A minority of the animals may experience weight loss within 15% (measured against their weight at the beginning of the protocol or compared to age matched controls, as appropriate), mild piloerection, intermittent and moderate hunching, and reduction in their activity within the cage. From the time point of the surgery when these symptoms may be expected to occur, animals will be closely observed every 4 hours during the day to ensure that the symptoms would not last for more than 12hours. If these signs persist for over 12 hours or begin to deteriorate the animals will be killed by Schedule 1 methods. This is not expected to occur in more than 1% of the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild 5100 mice (92% of total number)
Moderate 450 mice (8% of total number)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are no suitable alternative systems that can recapitulate the complex interplay of the different tissues (brain/pituitary/gonads) of the reproductive axis or the hormonal feedback mechanisms involved in its regulation.

Which non-animal alternatives did you consider for use in this project?

The only non-animal alternatives that could be considered are using tissue explants or established cell lines. Established cell lines that could be used to model the physiology of Kiss1 neurons include the mHypoA-50 and mHypoA-55 lines and the KTaV-3 and KTaR-1 lines. While these lines show some responses found in Kiss1 neurons in the mouse such as a response to estrogen, which makes them suitable for some experiments, they cannot model the neuronal circuitry found in the intact brain.

Why were they not suitable?

Tissue explants are not suitable for this project because they cannot be maintained in culture for long periods, they will change as soon as they are removed from the animal, they do not recapitulate the reproductive axis and are not subject to the normal regulatory signals (eg fluctuating hormone levels) that occur in a whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of transgenic mice that will be used over the 5 year duration of this project is based on the number of mice that have been used each year on my previous PPL. Over the course of this licence, we will generate around 5,000 mice (using approximately 170 mice each year for experimentation). Of these, the majority (around 4,150) are used for breeding and these will have no detrimental effects caused by the genetic alteration. As we are studying mutations that affect fertility, the mutant mice are sterile so we have to breed from heterozygous pairs which means that many mice will be wild-type. A further 100 wild-type mice will be used each year for the generation of genetically modified mice and these will not have any surgical procedures performed on them as I reoutinely perform non-surgical embryo transfer. Surgical procedures (mainly removal of testes or ovaries) will be performed on around 400 mice with delivery of substances into the brain performed on around 150 of these.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When appropriate, the NC3R's Experimental Design Assistant (https://www.nc3rs.org.uk/our- portfolio/experimental-design-assistant-eda) and the NC3R's Breeding and Colony Management Resource (https://nc3rs.org.uk/our-portfolio/breeding-and-colony-management) will be used to plan an experiment and to define the minimum number of mice in each treatment group to achieve statistical power. We also have standard operating procedures (SOPs) in the laboratory to help ensure standardisation between different staff.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise the number of surplus mice that are bred and not used in experiments, we routinely keep breeding pairs together for only a couple of months and then stop breeding until we require new offspring. We actively monitor and manage the number of breeding pairs so that we only have the number that is required to generate a cohort of offspring for a specific experimental plan. Pilot studies might be undertaken to get preliminary data on the variability of experimental measurements to allow us to perform Power calculation to determine the minimum number of mice required for statistical integrity. We use surplus wild-type mice from our breeding stocks for control groups rather than buying in additional mice. We also provide surplus mice for tissues to other groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Transgenic mice with disruptions of specific genes involved in fertility (Kiss1, Kiss1R, Hiat1) will be used in this project. Mice are an excellent model to study mammalian reproduction. The main physiological processes are conserved between mice and humans and the hormonal regulation of fertility in particular is almost identical between these species. In addition, the ability to generate transgenic mice, in which a single gene has been altered or removed, provides a very powerful tool for studying the role of a single gene in reproduction. They represent much better and more specific models to study brain function than models involving crude destruction of brain areas. The genetic approaches to generate these models are very well established in the mouse and are efficient enought to allow transgenic mouse generation while keeping the mouse numbers low. In addition, the short gestation period of the mouse allows us to study aspects of reproductive function relatively quickly.

The transgenic modifications carried by the mice do not cause any detrimental effects or pain - the vast majority of the mice will only be killed and used for tissues.

Why can’t you use animals that are less sentient?

It is not possible to use a less sentient model organism (eg nematode worms, Caenorhabditis elegans or fruit flies, Drosophila melanogaster) to study the mammalian reproductive axis. They do not have the appropriate tissues that are found in the mouse or the same hormone systems.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have undertaken a number of refinements in our animal welfare procedures and will strive to continue to do this. For example:

We have developed an ultra-sensitive method for measuring a hormone in the blood, which works with very small volumes of blood (5 ul) so that we can reduce the amount of blood taken from the tail vein.

We will retain existing ear clip tissue taken for identification purposes and use this for identifying the genetic make up of the mice [and thus eliminate the need to re-earclip for genotyping alone.

Transfer of embryos into recipient female mice to generate genetically modified mice will normally be performed using an NSET (non-surgical embryo transfer) device, which is a less invasive method than surgical transfer of embryos.

Where possible, we will use genetically sterile mutant male mice instead of vasectomised males.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the NORECOPA online resource (https://norecopa.no/prepare) for guidance on quality assurance and animal management and as an aide memoire for the topics that should be considered when planning experiments.

We will refer to the various publications on the LASA web site (https://www.lasa.co.uk/current_publications) for information and specific guidance about many aspects of animal research.

We follow the ARRIVE guidelines for publishing our work.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My establishment has a knowledge distribution system (mainly via e-mail and a Biomedical Support web site) to keep all PPL holders informed about advances in the 3Rs. In addition, I frequently check the NC3R's website for advances and subscribe to their Newsletter. I will also have regular discussions with the Named Persons and animal technicians to review current approaches and whether there are any new 3R opportunities. I have also subscribed to the Norwegian NORECOPA Facebook page as this organization provides useful information and resources about the 3Rs. I will also check the LASA web site (https://www.lasa.co.uk/) for information and I have set up an e-toc alert for the ATLA (Alternatives to Laboratory Animals) publication.

23. Xenopus Embryonic Development

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Embryogenesis, Cell Differentiation, Heart Development, Wnt signalling, Cancer

Animal types	Life stages
Xenopus laevis	adult, embryo, neonate, juvenile
Xenopus tropicalis	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims at improving our understanding of embryonic development, that is, how a properly formed body emerges after the fertilisation of an egg by sperm. This project focusses on very fundamental processes, processes that are conserved in backboned animals, which therefore allows us to study these processes in frog embryos as they develop into tadpoles, yet does provide us with valuable information about processes also important for human embryonic development. Studying such fundamental processes is much easier in frogs (compared to human or mammalian development) since fertilisation and subsequent embryonic development of frog tadpoles occur outside the maternal organism and can therefore be observed and experimentally studied without carrying out experiments on the adult organism. Particular fundamental processes that we focus on include Wnt signalling and heart muscle development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

As embryonic cells differentiate (that is: different cells take on different functions and associated shapes, e.g. some cells become neurons while others form muscle) they communicate with each other in the embryo using biochemical cell-to-cell signalling mechanisms, such as particularly Wnt signalling mechanisms. Wnt signalling is not only fundamentally important in frog and human embryonic development, it is also involved in human disease, such as cancer; thus, studying Wnt signalling mechanisms in frog embryos (including how it interacts with other regulatory mechanisms) can provide valuable fundamental scientific understanding that is also potentially relevant for human embryonic development and for congenital birth defects as well as human disease (such as cancer). Because of our research focus on Wnt signalling and on heart development, our findings are likely to be important for understanding Wnt signalling in human cancer and about congenital heart defects; and possibly also for recovery from heart attacks (myocardial infarction).

What outputs do you think you will see at the end of this project?

The fundamental nature of our research probably means that most outputs will be in the form of new information that will be disseminated at scientific meetings and in scientific publications.

Who or what will benefit from these outputs, and how?

The fundamental nature of our research probably means that in the shorter term the immediate beneficiaries will be other researchers and scientific and medical research using other experimental systems. They will benefit from attending the same scientific meetings as us (for instance on Wnt signalling or on Heart development and cardiovascular biology and medicine) and by reading the scientific literature we publish or reviews of our findings by others. However, our fundamental research is very much aimed at providing the kind of new information that will in the longer term benefit human health and health provision. Due to the nature of our major research questions, this is most likely going to be in the area of cancer and heart defects. Beneficiaries could of course also include biotechnology and health industry translating aspects of our findings into products for the health provision or further research in the same specific area or more widely. The end benefits in terms of changes in clinical practice etc. are likely going to be much longer term.

How will you look to maximise the outputs of this work?

We will maximise outputs of our research by collaboration with others, including particularly collaboration within our own research group with researchers using findings

from the accessible frog experimental system to confirm in human and mammalian systems, including in cultured human stem cell differentiation and organoid systems.

Species and numbers of animals expected to be used

- Xenopus laevis: Over five years: 35 adult females (based on reuse), 65 adult males, 250 genetically altered tadpoles.
- Xenopus tropicalis: Over five years: 35 adult females (based on reuse), 65 adult males, 750 genetically altered tadpoles.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The specific research addressing our fundamental scientific questions can be carried out on fertilised frog embryos developing towards tadpoles before they become sentient (before they develop the ability for feeding). These early stages of embryonic development are not regulated since they precede the free feeding stage when it is thought the tadpole or the froglet and then frog developing from it can experience pain or suffering.

However, as part of this research we intend to produce genetically altered animals, while again aiming to study any experimental effects during early embryogenesis, any effects on late-stage tadpoles or the froglets and then adult frogs cannot be ruled out and needs to be carefully monitored.

Typically, what will be done to an animal used in your project?

In order to study frog embryonic development, we need to harvest sperm (from adult male frogs) and eggs (from adult frog females). In order to encourage egg production (and typically also for sperm production) the adult frogs are injected with fertility-promoting hormones (gonadotropin). In order to encourage egg laying the females are typically handled in a particular way so as to mimic what the male would normally do during amplexus. Males are typically culled to dissect and isolate testes used in in-vitro fertilisation.

What are the expected impacts and/or adverse effects for the animals during your project?

These procedures have been highly refined for almost a century for Xenopus laevis and have been improved in the last few decades for Xenopus tropicalis. Normally these procedures therefore only mildly impact the animals.

However, handling (during the hormone injection or during encouraged egg laying) can occasionally cause an adverse effect on the delicate skin of these aquatic amphibians, which can develop (skin sloughing, occasionally as visible abrasion) within 12 hours and normally improves within 24 hours and must essentially be cleared within 72 hours.

However, occasionally in first-manipulation Xenopus tropicalis (and very seldomly in Xenopus laevis and manipulation-experienced Xenopus tropicalis, particularly when not used for several months) following fertility hormone injection, substantive numbers of eggs are not properly laid and can then subsequently develop an egg-bound phenotype (rotting eggs in the abdomen).

Any adverse effects of genetically altered frogs have not actually ever been observed but represents a theoretical concern depending on the particular genetic alteration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity is mild

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The interaction of genes in the embryo is complex because of the three-dimensional structure of the embryo itself. In order to understand these complicated interactions of genes they have to be ultimately confirmed in this three-dimensional landscape of the embryo.

Some aspects of the function of these genes can be studied in isolated tissues (see below), which allows a reduction of whole-animal experiments, however, discoveries from artificially isolated tissues will still need to be verified in the natural three-dimensional setting of the embryo, before they can be relied upon.

Which non-animal alternatives did you consider for use in this project?

Some in our research group are using stem cells in culture to study suitable particular aspects of the relevant biology in this project (such as in-culture cell differentiation of pluripotent embryonic stem cells into functional heart muscle cells).

Why were they not suitable?

Some aspects of the relevant biology can indeed be studied in cell culture, and we use it already to study relevant mechanisms in a more directly medically-relevant mammalian and even human cell culture system. However, often only aspects of the normal biological and genetic mechanisms operate in cultured cells and therefore discoveries from cell culture systems need where possible be verified in the natural three-dimensional setting of the embryo, before they can be relied upon. Cultured cells and tissues lack the three-dimensional complexity of normal tissues and organs and therefore also lack important signalling interactions between different cell lineages that would occur in normal tissues and which are relevant for gene regulation. In heart tissue for example this leads particularly to differentiation of only immature heart muscle compared to differentiation of more normal mature heart tissue in whole embryo systems. However, we are currently exploring ways of improving cultured systems, such as three-dimensional organoid systems to improve them. But currently, a whole embryo system particularly the experimentally accessible Xenopus model system is still indispensable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimation are based on the proposed experiments requiring about 20 weeks' worth of animal experiments per species per year, the interval suitable for re-use of adult females (longer for X. laevis than X. tropicalis), how long isolated sperm is usable (longer for X. laevis than X. tropicalis), the estimated rate tadpoles can successfully metamorphose to adults (based on some experience of our own with wild-type and advice received from Xenopus resource facilities in UK, US, and Japan).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Since the experimental design concerns the number of fertilised embryos, but the number of animals influences the likelihood of getting sufficient embryos to carry out the planned experiments, the experimental design does not in a linear way determine the number of animals used. In practice, many more scientific experiments can be carried out on an

experimental day when a given number of adult frogs are used to produce a lot of embryos for experiments, while the same number of adult frogs on a different day will on occasion only produce few eggs of sufficient quality for scientific experiments. Thus, in practice optimising the quality and reliability of harvested fertilised eggs is therefore more important for the regulated procedures than the number of adult frogs (quantity) used.

However, the number of embryos used will be carefully considered in the experimental design so that the use of animal resources leads to statistically supported results: In the Xenopus field for each experimental condition we ensure we have a sample size of at least 30 embryos, where we analyse the embryos individually (e.g. whole-mount RNA in situ hybridisation or immunocytochemistry). We use at least 15 embryos or 20-30 explants for pooled analysis (e.g. quantitative RT-PCR, Western analysis, RNA-seq, ChIPseq, more if more material is required) to produce continuous values (e.g. ratio of expression to control). Before publication we also repeat the experiment on three different days (involving different males and females to produce sperm and eggs, respectively) and therefore analyse at least three completely independent biological replicates.

Any power calculations of sample size numbers required for a particular experiment is however preliminary until the size of the observed change (effect size) between control and experimental samples is known. More experimental embryos will therefore need to be analysed if a more subtle effect is found and needs to be substantiated. The significance of actually observed effects will be assessed by Student’s t-test (continuous scoring) and Chi-squared test (discrete scoring) or by ANOVA (for more complex multivariate data sets). Professional statisticians at the licensed establishment regularly provide advice on statistical tests.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Optimising the re-use interval for the different species is important, as well as, identifying and recording carefully which animals are more reliable to produce products (mostly eggs from females) so that their re-use is a better use of animal than use of a naive animal. This will ultimately reduce the number of individual animals used, but also since it will be more reliable, this will reduce the number of regulated procedures needed to produce the products (mainly embryos) for scientific experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We propose to use adult Xenopus laevis and Xenopus tropicalis to produce eggs and sperm for scientific research.

The protocol for Xenopus laevis females has been developed for approximately a century and is very refined and should normally only at most cause mild levels of severity. The protocol for Xenopus tropicalis females has been developed for decades, it is also very refined; however, we find (and the wider tropicalis research community finds that first-use of Xenopus tropicalis females can experience severity levels exceeding mild.

It is of course difficult to be sure, but at the moment it appears the difference is inherent to the different species, rather than a lack of sufficient refinement of the protocol for Xenopus tropicalis. The use of Xenopus tropicalis is however justified since the diploid genome (like humans and most other vertebrates) is required for genetic and genomic studies, including those proposed here; which would be much more difficult if not impossible with the allotetrapoid genome of Xenopus laevis.

We have therefore introduced more detailed and more frequent monitoring for signs of ill health during recovery (at least twice per day) in the two days following first-use in regulated procedures for Xenopus females. We will continue to do so throughout this programme for Xenopus tropicalis, and will regularly review whether it is also necessary to continue to do so for Xenopus laevis.

The hormone injections needed for encouraging Xenopus females to mature oocytes and then lay eggs is more reliable when animals are not feed in the two days before the first hormone injection; and the subsequent egg collection (by any method) is more efficient if laid eggs are not intermingled with faeces. Xenopus are cold-blooded (poikilotherm) and therefore do not need to take in food as often as warm-blooded animals (endotherm, such as birds and mammals). However, food will not be withheld for longer than nine days for Xenopus laevis or five days for Xenopus tropicalis. The difference is due to the colder temperature (leading therefore to slower metabolism) at which Xenopus laevis is kept relative to Xenopus tropicalis.

Why can’t you use animals that are less sentient?

The actual scientific experiments are carried out on non-sentient embryos.

Sentient adult Xenopus frogs are required for harvesting eggs and sperm to producing embryos for those scientific experiments. No other stages are available that are less sentient yet can produce eggs or sperm to producing embryos for those scientific experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are now successfully refining an increased monitoring regime for particularly naive first-use Xenopus tropicalis females following the procedure. Information from the UK national Xenopus community also suggests that a more frequent re-use of Xenopus tropicalis females (i.e. more frequent than every three months) is actually beneficial to how the individual females react to the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Xenbase (model system international community web site) e.g.:

<http://www.xenbase.org/common/jsp/showWiki.jsp?Protocols>

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

There is a close network of experts in the UK national (and the international) Xenopus community; particularly for Xenopus tropicalis this provides the most effective and specific source of expert information. We are also regularly briefed by the NIO and by communications by the HO, our current funders and other funding agencies.

24. Bioelectronic Medicines II

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Neuromodulation, Physiology, Autonomic nervous system, Peripheral nerve

Animal types	Life stages
Sheep	adult, juvenile
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this body of work is to provide further evidence that the process of neuromodulation, alteration of an organ’s function by targeted delivery of an electrical stimulation to a specific neurological site or nerve, can be an efficacious alternative, or addition, to pharmacotherapy to treat broad ranging diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Modulating the nervous system (neuromodulation) for the treatment of locomotor, visual, auditory, and genitourinary dysfunction is a well characterised procedure in pre-clinical modelling of disease. This typically involves the implantation of electrodes encapsulated in devices, coupled with a battery power supply, to electrically excite the nervous system, to restore function that was previously lost through trauma or disease. It can also be used to record activity of the nervous system, to detect instability in the system and disease states, as well as block signals that have become pathological. This field of study is now referred to as neuroprosthetics and is now showing great promise as a potential first line therapy in the clinic, for intractable loss of function in patients after injury to the nervous system or with limb amputation.

It is now clear that similar neuromodulation techniques could be applied for the treatment of diseases associated with organs/systems such as diabetes, hypertension, rheumatoid arthritis, and inflammatory bowel disease, medically refractory epilepsy, or myocardial infarction among many others, through modulation of the autonomic nervous system. The autonomic nervous system is a component of the peripheral nervous system that regulates bodily functions, and which may be positively affected with modulation. For example, application of stimulatory devices that modulate the vagus nerve, an autonomic nerve that controls many organ functions, has shown great effect at treating animal models of disease.

The purpose of this work is to provide further evidence that neuromodulation to control organ function can be a viable alternative, or addition, to drug based therapy to treat a broad range of diseases, such as those mentioned above.

We will first ascertain whether novel targeted modulation of the autonomic nervous system can be accomplished in specific organ systems. This will be undertaken in anaesthetised animals. We shall establish an anatomical and physiological understanding, including determining the optimal interrogation point for the nerve to organ. Secondly, in a recovery setting, we will assess the surgical application of the device, the effect on the physiology over multiple applications of the therapy, and the surgical recovery profile .

We need to use large animal models, specifically sheep and pigs, because the size, anatomy, and physiology of these animals is translationally applicable to humans. Our devices are designed for human-scale anatomy, and the farm pig is the most suitable model for this when targeting nerves and organs of the viscera. Pigs are also well characterised with respect to metabolic and inflammatory pathways, and closely resemble

the human physiology. Physiology and anatomy of the sheep will be relevant in cases of implants to the neck, and so these models will be justified and used in those scenarios.

What outputs do you think you will see at the end of this project?

The project aims to test the feasibility of new treatments for patients that suffer progressive diseases (including inflammatory and metabolic disorders), through modulation of the autonomic nervous system. Areas of application include immune-inflammatory, and metabolic disorders. Examples of these disorders include rheumatoid arthritis and type 1 and 2 diabetes, with around 14 and 415 million sufferers worldwide respectively. A common problem with these patients is that they become refractory to pharmacotherapy and the therapies themselves often result in debilitating side effects. The long- term benefit of this work is to provide these patients with a novel and more focussed (patient specific) treatment approach through modulation of the autonomic nervous system. Most of these diseases are life-long and thus substantial benefits accrued by this treatment (over traditional pharmacotherapy and molecular based medicines) are in reducing cumulative suffering, enhancing quality of life and reducing the cost of life-long treatment.

Overall, our efforts in advancing this new treatment modality of neuromodulation will be focused on providing a greater resolution on the mechanism of action of this treatment in the short term. Medium term benefits are to determine efficacious parameters and safety profiles for the surgical implantation of a device and the levels of electrical stimulation of the nerve. This early-stage data will allow predictions to be made on the efficacious levels (strength and duration) of neuromodulation, as well as to support refinement of the device design that could be brought to the clinical market, while refining the surgical approach for implantation. Additionally, immune-modulating and anti-inflammatory therapies through modulation of the autonomic nervous system might be effective treatments for some or all forms of epilepsy. An immediate scientific output resulting from work modulating the autonomic nervous system before and during seizures is to allow further understanding of the pathophysiology of Sudden Unexpected Death in Epilepsy (SUDEP). The longer-term aim for patients is to aid in decreasing seizure frequency and to reduce the risk of premature death in epilepsy patients.

Heart attacks (Myocardial infarctions (MI)) are another area of disease which could benefit from this type of treatment. Current treatments to reperfuse the heart can lead to further rebound injury (reperfusion injury) to the muscle due to inflammation and despite the vast number of treatments for MI there is still a large unmet need and no specific treatment directly affecting reperfusion injury. The goal, and significant benefit to patients, is to develop a targeted therapy to reduce reperfusion injuries and prevent further damage to the heart muscle by the use of autonomic nerve modulation.

The outputs from this study will be publishable data which will be disseminated through peer review journals and meetings (we intend to do this after each set of experiments if appropriate).

Additionally, the output may be data for regulatory studies and patentable products which can be commercialised and offered clinically to patients (once regulated studies have been completed).

Who or what will benefit from these outputs, and how?

Studies in large animals will provide stronger evidence for the translation of these new therapies into humans, providing an anatomically and physiologically relevant platform to validate the implantable device, in both acute and recovery settings. Typically, industry takes about 10 years to successfully take a device from animal to man. Under our previous project licence we have reduced time by 3 years.

In the first instance the data generated from studies will aid the researchers in the selection and characterisation of new surgical implantations which will lead to their further development (e.g. in clinical trials) and could potentially lead to new therapies for immune-inflammatory, and metabolic disorders being introduced to the market.

Long term, these products have the potential to significantly enhance the quality of life for people suffering these chronic diseases or potentially cure them. This will benefit the whole society via reduction in absenteeism from work or school and reduction in demand on health services.

How will you look to maximise the outputs of this work?

Where confidentiality agreements allow, our commercial clients will publish the information via peer- reviewed scientific journals and conference presentations in addition to patent applications.

One of the key goals of our academic clients and collaborators will be the dissemination of results in seminars, conferences, and peer-reviewed articles with open access, in order to promote the general advancement of the fields studied. Negative findings may be published to avoid duplication of work by other groups.

Species and numbers of animals expected to be used

- Sheep: 75
- Pigs: 650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult sheep and pigs will be used because they have a nervous system that is sufficiently anatomically and functionally similar to that of humans and thus enable the final safety and efficacy testing of these devices. These two species are required because the specific target nerves and surrounding anatomy are slightly different between species, and we require the anatomy, physiology and surgical access to be as close to humans as possible in different scenarios. For example, sheep are anatomically & physiologically better suited for upper airway/vagal work while pigs are a better fit for studies involving the abdomen.

The anatomy of the sheep and pig nervous system is well defined, enabling robust application of surgical methods and implantation studies.

Typically, what will be done to an animal used in your project?

After arrival, all animals will be allowed to become acclimatised to the new environment.

Some animals may have blood samples taken and / or receive a pharmacological agent, for example, to modulate the immune system.

The majority of animals will be terminally anesthetised and used in a non-recovery study. Prior to surgery animals may be fasted (but no withdrawal of water) for up to 24 hours. During non-recovery surgery, animals may have implantable devices to allow neuromodulation and nerve recordings, some may undergo imaging (such as CT), samples (such as blood and organ biopsies) may be taken. Just prior to termination, under the anaesthesia, from some animals there may be collection of samples and / or biological materials, to avoid euthanising further animals for this purpose.

A proportion will be anesthetised, undergo a surgical procedure and allowed to recover. Prior to surgery animals may be fasted (but no withdrawal of water) for up to 24 hours. The surgical procedure may involve implantation of a neuromodulation device, imaging, placement of a permanent intravascular catheter. Samples may also be collected. After recovery the animals undergo a series of therapeutic subclinical neuromodulation (levels of nerve stimulation which have been determined in the terminal studies to be efficacious to produce modulation of the target organ but shown to not have off- target side effects). Imaging, such as radiology, may be performed in conscious animals. Pro- inflammatory substances may be given and blood samples may be collected. This may be repeated on a number of occasions over a 12-month period. These animals may undergo a second recovery and / or terminal surgical procedure and if recovered the subclinical neuromodulation and/or pro- inflammatory substances dosing will be repeated. Finally, the animal may undergo a non-recovery terminal procedure or be killed.

What are the expected impacts and/or adverse effects for the animals during your project?

The larger proportion of animals used in these studies will not experience any adverse effects as the studies will be conducted under terminal anaesthesia.

With protocols and procedures that involve animals having recovery anaesthesia, some adverse effects for the animals are expected. Animals may experience discomfort and pain following surgery.

We will monitor this and provide the appropriate level of pain relief and post-operative care. Other effects include weight loss and changes to behaviour and general overall condition. We anticipate these adverse effects being transient and with good monitoring, welfare management, and nutritional supplements these effects can be alleviated. We would expect the animals to show full recovery within 7 days of surgery. If this is not the case the animals will be humanely killed.

With our specialist large animal vets, we have established clearly defined humane endpoints in all our models that minimize discomfort and pain to the animals yet allow us to address our scientific questions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of animals, the studies will be conducted under terminal anaesthesia and the severity level will be non-recovery. However, as stated above, in some studies the animals will be recovered following surgery and may experience some adverse effects, but these would only cause the animal a moderate level of distress.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Computational modelling testing has been done without using animals to give confidence that nerve stimulation may treat disease. The science cannot be advanced further without using animals. Only a whole-body system biology approach will give conclusive evidence and understanding that manipulation of the nervous system can be an effective treatment of disease.

A computer model does not yet exist to test nerve stimulation as a treatment of disease.

Which non-animal alternatives did you consider for use in this project?

Computational modelling is relatively recent in the field of neuromodulation, it has already been successfully utilised in several neural engineering applications. Prior to starting in vivo work, we conducted simulation studies representing approximated nerve behaviour. We used multiple neurostimulation scenarios to determine stimulation current-, charge- and charge-density requirements for nerve recruitment in porcine and human splenic neurovascular bundle (SNVB). We then validated our modelling data by measuring electrophysiological parameters in freshly explanted human splenic neurovascular bundle obtained from organ transplant donors after ethical approval and informed consent. We stimulated the explanted SNVB in an ex vivo electrophysiology preparation using a bipolar cuff electrode and recorded the stimulation-evoked compound action potentials (eCAPs) using downstream hook electrodes. These approaches have enabled the determination of clinically relevant stimulation parameters for implantable device requirements for in vivo work and ultimately to go into humans.

Why were they not suitable?

Computational modelling may one day replace animal modelling in this context, however there is still considerable gap in scientific knowledge around all aspects of the nervous system including anatomy and physiology. Therefore, there comes a point when the computer modelling cannot completely answer the questions and a full intact working nervous system is required. At this point the use of animals for these studies is the only option to test therapeutic efficacy of bioelectronic medicines

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These figures have been calculated on the numbers used under the previous project licence and future plans. Up to the end of 2021 approximately 400 pigs were used under the previous PPL. Predictions for pigs for 2022 mean this number is likely to reach 500 by the end of the current PPL. The number of sheep used was lower than predicted for the previous licence. Because of this the number of sheep for this licence has been reduced.

With the ongoing projects planned for the next 5 years, (expected to increase) and additional projects intended to be started, the predicted number of animals included on this licence is a realistic estimation of the total usage over the 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure we use minimal number of animals required to obtain meaningful and relevant data, we have extensively consulted available literature, attended experimental design and statistical courses, discussed with statisticians and NC3R staff and information provided by the NC3R. All requestors for work under a service contract will be required to justify the number of animals required and if appropriate show how they came to this number. The ARRIVE 2 guidelines have been referred to and followed where appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Definitive studies with sufficient animal numbers to obtain statistically significant results will be performed only after pilot studies have been performed to develop optimal methodology and assess feasibility and outcome measures. Electrophysiology methods are robust and repeatable, with minimal variation between animals. This provides clear results that give us confidence in making decisions even from small sample sizes.

In many cases, the numbers of animals required will be reduced by longitudinal measurement of responses, e.g. by serial blood sampling, multiple stimulations of nerve preps. Tissue samples at the end of studies can be collected to obtain the maximum information from a study. Also, samples taken may be used to inform other studies and provide extra data which will help advance the project or field as a whole.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Pigs and sheep will be used for all experiments because they are the most appropriate species to determine efficacy and safety with respect to the devices tested. Their neuroanatomy and physiology are very similar to that in humans.

We will work with manufacturers and academic experts to ensure a continued refinement approach is adopted for all implantable devices, electrodes and leads. We will work toward fully implantable devices as advancement to external wires and head caps.

Recovery studies will only be performed once surgical technique, application of neuromodulation and treatment parameters have been defined as much as possible using terminally anaesthetised animals.

All methods used for recovery animals will be refined to minimise any pain; these include appropriate provision of analgesia, use of local anaesthetics where possible for blood sampling and close monitoring of animals by large animal veterinarians and advanced trained animal technicians to recognise any adverse effects. All animals will be trained and habituated to the environment, staff and handling techniques prior to study to minimise stress.

Systemic inflammation models are well-characterised and used experimentally in clinical and non- clinical studies to determine the efficacy of medical treatments for immune / inflammatory diseases. Further development of chronic low-level inflammatory models will allow investigation of a range of diseases and the potential benefits of Bioelectronic medicines and therapies in these diseases.

Why can't you use animals that are less sentient?

We need to use large animal models, specifically sheep and pigs, because the size, anatomy, and physiology of these animals is translationally applicable to humans. Our devices are designed for human scale anatomy, and the pig is the most suitable model for this when targeting nerves and organs of the viscera. Pigs are also well characterised with respect to metabolic and inflammatory pathways, and closely resemble the human physiology here. Physiology and anatomy of the sheep will be relevant in cases of implants to the neck, and so these models will be used in those scenarios.

A large part of the project will be performed using terminally anaesthetised animals to define the treatment parameters of neuromodulation. Recovery animals will only be used when these parameters have been defined.

In addition, studies using rats and mice are undertaken as part of this research and help inform these large animal studies; this work is covered by a separate Home Office project licence. Studies involving pigs and sheep are one of the final steps within the project when similarity to human nerves is essential.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise discomfort/harm to the animals, most studies are non-recovery in terminally anaesthetised animals with defined humane endpoints.

All animals will receive appropriate peri-operative care in terms of anaesthesia and pain management both during and after the procedure.

Our in-house large animal vets' expertise further enhances animal welfare by providing close collaboration with dedicated animal care staff and ready access to highly skilled advice. Specific recovery plans have been designed to ensure the best recovery of any animal post-procedure and involve high levels of monitoring.

All animals are habituated to the environment and all recovery animals are trained prior to use for all handling procedures, such as use of a restraining crate.

Least invasive route of substance administration, appropriate needle gauge and local anaesthesia will be used where possible. Negative control groups (baseline groups) will be minimised whenever statistically feasible.

All individual study plans are reviewed including consideration of justification and implementation of refinement and reduction as part of the local protocol review process.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult all the relevant references listed therein, e.g. NC3Rs Blood sampling resource.

(Reference: NC3Rs/BBSRC/Defra/MRC/NERC/Royal Society/Wellcome Trust (2019) Responsibility in the use of animals in bioscience research: expectations of the major research councils and charitable funding bodies. London: NC3Rs.)

For substance administration the LASA substance administration guidelines will be consulted (Reference: Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider. J Am Assoc Lab Anim Sci. 2011 Sep; 50(5): 600–613.)

Animals will continually be monitored for signs of pain and distress, especially post-operative. Post- operative care will be given by specialist large animal technicians and Vets.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continuously monitor publications and the NC3Rs website for new and alternative models that could be implemented as part of this project. In addition, articles on advances in the 3Rs are regularly published on the internal Users News Forum and other relevant information is circulated by AWERB. Whenever possible we will implement these refinements into our studies.

25. Treatment of Short and Long Term Outcomes of Viral Lung Infection

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Lung, Virus, Bacteria, Immunity, Pathology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Lung viral infections cause devastation globally every year as evidenced by the last coronavirus pandemic. We will discover new treatments for lung viral infections and the ongoing complications that arise.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding the role of the immune system in lung viral infection is key to the development of therapies that alleviate severe disease before vaccines are available. Some of our discoveries are being tested in patients already, but not all people respond in the same way. Our aim is to define a suite of treatments that will cover the majority of those severely affected.

What outputs do you think you will see at the end of this project?

Outputs will include:

1. A greater understanding of how the immune system is affected by changes in structure during infection.

2. Publications disseminating our findings to global scientists.

3. Development of concepts with the pharmaceutical industry

4. As demonstrated in our last project license, transfer and testing of our discoveries in relevant patient groups using new products.

5. Dissemination of understanding to the general public via articles in, for example, the public journal The Conversation and interaction with Public and Patient groups

Who or what will benefit from these outputs, and how?

Mid- to long-term the beneficiaries will be the pharmaceutical industry (new targets for development), and particularly the patients who are already benefitting from our discoveries. The health care system will also benefit. For example, our recent trials of new therapeutic reduced the length of hospital stay, reduced the number of patients requiring admittance to the intensive care unit and decreased long term outcomes. This reduces the stress on the NHS and the financial burden of lung infection.

How will you look to maximise the outputs of this work?

We routinely use a Patient and Public involvement group from the British Society of Immunology to capture facets of disease that most concern the patients. This disseminates new knowledge.

My team hold regular REDDIT sessions, which is an online forum for anyone to ask questions on the topic we propose. The last one was on COVID-19 where in two hours we had over 1000 questions to answer. This platform also drives interactions between all participants, even when the session has finished.

I regularly contribute opinion pieces to "The Conversation" that has an online reach to thousands of subscribers. In the last year my pieces have made the top number of interactions in my establishment.

I regularly respond to National and International media interview requests regarding viral infections. I have been inundated during COVID-19.

I have a policy to publish all research, not just those that produce a positive outcome. Negative data is equally as important to prevent others going down the wrong path. Negative data will be published as per other findings in peer reviewed journals and on the Wellcome Trust open access site. The data is also placed onto the group webpages and raw data files shared

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The reason we use standard laboratory mouse strains is because over many decades they have proven to be readily infected with respiratory pathogens via the natural route by intranasal or aerosol administration. As in humans the pathogen replicates in cells lining the airways. Even viral strains that are not mouse pathogens induce a pneumonitis that, similar to humans, is reduced by early treatment with antivirals. The virus divides with similar speed to that in man. Symptoms of disease, like that in man, are dependent on the virus strain and the amount of virus administered. The route of infection, site of replication, replication kinetics and the specific cells recruited to combat that infection are identical to that in man.

We use adult mice, typically over 8 weeks of age as they yield enough cells to perform many experiments per mouse which reduces the need for separate experiments to address different questions. We have tried to replace animal use by using cell lines, but unfortunately a complex system is required to understand long term consequences of lung infection.

Typically, what will be done to an animal used in your project?

In a typical experiment mice will be housed initially in groups of 5. To induce a viral lung infection mice are first anaethetised by inhalation of anaesthetic. Virus solution is applied to the nostrills, which is then inhaled by natural breathing. Mice recover within a few minutes. It takes a maximum of 10 days to recover from the infection. Occasionally, during this 10 day period mice are given treatments by injection. At time points after infection, mice are killed by excess anaesthetic and multiple organs taken to assess pathology and the effect of any interventions. In a few experiments, mice will be left to recover from the viral infection for up to 6 month (typically 3 weeks) and then given a bacterial infection to

see the impact of previous viral infection to general immunity to infection. Other than infection, we may also breed mice that are not available commercially.

What are the expected impacts and/or adverse effects for the animals during your project?

About 50 % of the mice will not have an infection and so will not experience any adverse events. In those mice given a single infection with viruses respiratory inflammation and weight loss may occur. Weight loss appears gradually from day 3, peaks on day 6-10 and full recovery to their original weight occurs by day 10 after infection. Approximately 50 % of animals are likely to experience weight loss. This is because they have been given an intranasal infection that causes inflammation with influenza like symptoms. The remaining 50 % of mice have mild or no symptoms from the infection per se as the infection does not cause weight loss or they have been treated with control substances or therapeutics that reduce inflammation. At the peak of illness mice may show a hunched posture and reduced mobility, but in the main, all mice recover. Transient pain may occur on injection, though in most instances they are anaesthetised when this procedure occurs. Some weight loss may occur in mice given bacteria alone.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This project works to a maximum severity of Moderate. This status is determined by a number of factors including degree of weight loss (maximum of 20 %), mobility, posture and overall condition. Mice are weighed daily and observed. In some cases mice have neared maximal weight loss but are still alert and in good condition. Instead of culling the mouse, we monitor the trajectory of weight loss (the steepness), breathing and general condition, twice daily. This prevents unneccesary termination of the experiment which would require another experiment to be set up. 70 % of mice in our protocols only experience up to 15 % weight loss

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Viral infection causes complex problems, and much of the disabling effects exist long term. The life- threatening illness to infection is caused by the interaction of many body systems. The illness also depends on cross-talk between immune cells and structural components of the lung. During our last project grant we discovered that immune cells are influenced by alterations in tissue structure and have taken this idea into patients and the treatment of those patients. Our discoveries will reduce the need for animal experiments in the future as we focus more on patients. However, we still need to discover more treatment options as one size does not fit all.

Cells cultured in the laboratory do not take into account blood and air flow or the impact of the nervous system. Nor do they show drug distribution. Replacements would be ideal in the current economic climate as animal experimentation is costly and time consuming.

Which non-animal alternatives did you consider for use in this project?

I strongly support the use of non-animal alternatives and have considered the following:

1. Matrigel systems that contain 2-3 different cell types ,
2. Organ on a chip,
3. Tissue slices,
4. Human lung resection, and
5. Human transplant lungs

Why were they not suitable?

Alternatives 1 and 2 still do not represent the lung microenvironment . Nor to they replicate the long term build up of complications over time. Furthermore they do not show how a virus infection leads to bacterial complications in the future, which is a critical medical issue in many patients with underlying lung conditions. Cellular systems also do not allow analysis of repair and the impact of altered repair.

In 3 and 4 we routinely use material collected as part of lung resections in patients with cancer, focussing on "normal" lung 4 cm from the cancer mass. This tissue has effectively reduced the range of experiments performed in mice and we will continue to use this approach. However, the tissue is highly criticised for its suitability and we cannot address bacterial super-infections or the repair process using it.

In an attempt to make the lung resection more representative we initiated discussion with lung transplant teams at our local hospital. Despite long negotiations, transplant material not used in patients is still unavailable. This tissue would still not replicae bacterial super-infections or the repair process well.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

There is an extensive literature using in vivo models of respiratory infectious disease and the applicant has greater than 20 years of experience. The overall number of animals is considerably reduced from the previous license due to the progress made. The estimated numbers in each of the three protocols is based on using 4-5 mice per group, which we have found to provide strong statistical power that reduces the necessity for multiple repeats. Initial therapeutic testing used 5 mice per group which is reduced to 4 mice per group depending on the reproducibility of the effect in the first study. We will not rely on historical precedent however to determine sample sizes as this may lead to serious over- or under-estimation of animals required. Data collected in preliminary experiments will be used to compute the sample size needed in follow up studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The estimated number of animals to be used has reduced dramatically from the last licence since I am no longer supervising the early career academics that used my license for their experiments. The experimental design used for the remaining protocols has reduced animal use in the following ways:

1) Sharing: With correct timing and consultation, we have determined that multiple scientists, asking different questions can use the same mice. Mouse number are based on 2-3 scientists sharing mouse use. In practice we have reached seven sharing.

2) Reducing repeats: It is possible to repeat observations whilst also progressing the research to the next question. Direct repeats are discouraged.

3) Confidence in reproducibility: Over the years of experience the reproducibility of the model has become established. In this license we can therefore be sure of a statistical significance with 4-5 mice per group.

4) Use of NC3R resources: There are online resources available to test null hypotheses (where you take an educated guess that something is true) or the alternative hypothesis (the opposite of the null hypothesis). These resources tell you how many comparisons need to be made within experiments and between experiments. Relevant

resources are also present for randomisation, blinding and allocation. These resources have been used to assess the number of animals in proposed experiments

All personnel using this licence will make optimal use of the experimental design assistant (EDA)and the scientific implications of poor design choice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animal reduction will be facilitated by group members sharing tissue and employing rigorous experiment design developed by our statisticians to calculate the least number of mice needed to address our questions. Where an experimental type is used more than once we will assess performance over time to ensure that it is continuing to perform well. The laboratory has archived specimens that can be used by subsequent researchers. Unfortunately storage processes can affect our results and so these archived tissues have limited use. As proof of principle however, they are adequate.

At our establishment we have instigated a community of researchers for sharing. As an example, we have a germ free mouse colony and when some are used in an experiment the details (age, gender, number per group and time points) are put onto a Teams platform. Members are therefore aware of the experiment and indicate whether they wish to collect additional tissues. This has been incredibly successful and in some experiment lung, gut, skin, bone marrow, kidney, blood and brain have been sampled from the same group of mice, reducing animal use by 7 fold compared to users working individually.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will only use mouse models that have been refined over the years to minimise animal distress and replicate the human scenario better. Procedures involve administration of virus and bacteria by inhalation and injection of immune modulators to reduce disease severity.

Minimisation of animal suffering critically depends on close monitoring of mouse condition (body weight, mobility, the quality of mouse fur, presence of cyanosis and whether they cling onto the cage lid when weighed). Staff perform this inspection daily, or twice daily if

concerned. See scoring criteria below. We try to avoid intraperitoneal injections where possible, using intradermal or subcutaneous where the alternative exists. We will refer to the Joint Working Group on Refinement. The latter, we feel is less intrusive than intraperitoneal. Where appropriate procedures are performed under inhalational anaesthetic that allows recovery within a few minutes. This prevents mice from losing body temperature whilst immobile.

Body weight	No weight loss	0	
	0-5% weight loss	1	
	>5 -10% weight loss	2	
	>10-15% weight loss	3	all experimental animals will be placed on mash
	>15-19% weight loss	4	If weight loss continues for greater than 72 hours, mouse must be sacrificed
	>19% weight loss		Cull Immediate action must be taken.
Ear positioning	Normal	0	
	Slightly retreated	1	
	Retreated completely back	2	
Coat and skin condition	No piloerection	0	
	Slight Piloerection	1	
	Marked piloerection	2	
Social interaction	Normal	0	
	Isolated or withdrawn from group	1	
Posture	Normal	0	
	Abnormal posture (hunched)	1	
Posture and mobility	Normal	0	
	Hypoactive	1	
	Lack or reluctance to move when stimulated	2	
Inactive	Cull		Immediate action must be taken.

Why can't you use animals that are less sentient?

Standard laboratory mouse strains are readily infected with respiratory pathogens via the natural route of the nose. As in humans the pathogen replicates in exactly the same lung cells. Even viral strains that do not usually appear in mice induce an inflammation that, similar to humans, is reduced by early treatment with antiviral medicines such as amantidine and ribavirin. Symptoms of disease, like that in man, are dependent on the influenza strain and the dose of virus administered. The route of infection, site of pathogen growth and the immune cell response are identical to that in man. Unfortunately, none of this can be replicated in less sentient species. Mice of a younger age are technically

difficult to infect and fail to represent the majority of infections that occur in adults and the elderly. Furthermore, early age responses to infection are different to adults.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

An academic at the establishment and the named veterinary surgeon have developed a severity score monitoring system (see above). To minimise animal suffering and recognise when humane end points have been met, they have created an objective scoring system that will be applied to every experimental animal. To generate this scoring system, we have selected welfare indicators that are relevant to this scientific study, are practical to carry out and do not disturb animals during assessment.

Expected adverse effects

- Some animals (5-10%) may experience temporary (less than 24 hours) symptoms (erect fur, respiratory symptoms) following intranasal exposure. Mice are given general anesthetic and there is some risk of pain or death (less than 1%) during the procedure.

- During this time-period animal welfare will be monitored daily

- Weight loss remains the most accurate predictor of mortality, and so body weight will be monitored daily.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow:

Joint Working Group on Refinement

The government animal testing and research: guidance for the regulated community (https://www.gov.uk/guidance/research-and-testing-using-animals)

The NC3Rs webpage https://www.nc3rs.org.uk/

Standard Operating Procedures developed with the University facility and the named veterinary surgeon.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All personnel associated with this project license will routinely interact with the NC3Rs online resource (https://www.nc3rs.org.uk/). Updates from the website will be a standing item on the group agenda where advances will be discussed.

26. Cutaneous Immune Responses in Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

immunity, skin, therapy, inflammation, infection

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify and characterise pathways and mechanisms within, and associated with, the skin that regulate inflammation and immunity during homeostasis and disease. As well as contributing to an understanding of disease pathogenesis, we aim to translate our findings to changes in clinical practice.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The skin frequently represents the first point of contact with pathogens and allergens, yet we still know relatively little of the role of the skin barrier and skin immune system in reacting to such challenges.

The immunopathology of inflammatory skin disorders, including psoriasis and eczema (atopic dermatitis (AD)), combines barrier dysfunction and immune dysregulation. This is exemplified by studies that identified the gene encoding structural barrier protein filaggrin as a key genetic determinant of AD, and the efficacy of currently available drugs that targets proinflammatory immune responses in AD clinical trials to date.

The skin is more than a superficial line of defence and has recently been suggested to have wide reaching systemic influence. Psoriasis is linked to multiple comorbidities including psoriatic arthritis, cardiovascular disease, atherosclerosis, obesity, diabetes, inflammatory bowel disease and psychological disorders. Classically, AD forms the first step of the “atopic march”, the progressive development of non-cutaneous allergic disease, including allergic asthma, rhinitis and food allergy. More recently AD has also been linked to cardiovascular disease. As such work to understand and target skin immune responses is important with wide ranging implications for health and disease.

Commensal bacteria are a part of a healthy skin barrier, which can be dysregulated by disease, as observed with the increased skin density of Staphylococcus aureus in at least 70% of AD cases. Skin colonising bacteria associate with skin infections, inflammatory disorders, more serious systemic infections and non-healing wounds. As such there is a need to understand the interaction of the cutaneous immune system in homeostasis and inflammatory disease with commensal and pathogenic microorganisms and the dysregulation of commensal status, which is key to the development of treatments for skin disorders.

The aim of this project is to investigate fundamental regulation of cutaneous immune responses to further understand the mechanisms of skin inflammation and related diseases, and aid optimisation of approaches to drug and vaccine delivery to this important tissue.

What outputs do you think you will see at the end of this project?

Outputs will include publications describing mechanisms of skin inflammation, pathways of antigen recognition in the skin and draining lymph nodes, and intervention regimen for pathological skin inflammation conditions. Outputs will also include patent applications and candidate compounds with therapeutic application in skin inflammation diseases.

Who or what will benefit from these outputs, and how?

The immediate core benefit of the work will be that we will increase our fundamental understanding of the molecular and cellular pathways that regulate skin infection and

immunity, with particular focus on inflammatory disorders and allergy. With this knowledge we can work towards better prevention of disease (through vaccination, prophylaxis and good practice), improvement in diagnosis at an early stage to increase the benefit of treatment and/or reduce transmission, and development of new therapeutics. These are long-term goals, beyond the 5 year duration of this licence, but the objectives of this project are to provide some of the necessary information, for us and the scientific community, to make this possible.

Our research to date has enabled us to identify new therapeutic targets and develop potential drugs for the treatment of skin allergy and inflammatory disorders, and continuing with these studies under this licence will enable us to support work to take these drugs forward towards clinical trials. In addition, we will continue to pursue the identification of new treatment strategies, for example by using disease models to identify or validate molecules and pathways that can be targeted therapeutically.

The characterisation of recently developed transgenic animals within this programme of work will also be valuable to other scientists aiming to develop therapeutics to these and related diseases by facilitating more rapid progress in their investigations.

Novel findings, delineating pathways in skin inflammation and novel reagents used for modulating these pathways will be published within the 5 year duration of this licence. Patent applications and assessment of products that will be developed for preclinical testing and clinical use may extend beyond the time frame of this licence (beyond 5 years).

Where widely applicable new treatments with public interest will be developed, a wider publication audience will be sought through our funders and local communications advisors.

How will you look to maximise the outputs of this work?

Dissemination of new findings will initially be through lectures, conferences and subsequently in scientific publications, which will be available through an Open Access route. My colleagues and I present our work at national and international conferences where we can discuss work in-progress before publication. This can generate new ideas and lead to collaborations. Indeed, we have a number of collaborations world-wide, with research scientists and clinicians, in which we provide expertise or reagents, and allows us to draw on the experience of colleagues and take advantage of the most advance technology that we can access.

Where possible unsuccessful approaches will be embedded in publication and discussed in meetings.

Species and numbers of animals expected to be used

- Mice: 15,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are currently the "lowest sentience" of mammalian species in which these experiments can be performed robustly and reproducibly. The murine immune and haematopoietic systems closely resemble the human systems and many murine models of human disease have been developed and characterised. The mouse also benefits from well-established and robust technologies for transgenic and gene-targeted genetic alteration. In addition, there is a large body of published scientific evidence that exists to be built upon and referenced to.

The diseases under investigation are normally associated with juvenile to adulthood therefore, this is the choice of life stage in our studies. However, typically mice are 6-8 weeks at the time of experiments.

The diseases that are modelled in mice often differ in some aspects from the equivalent diseases in human (e.g. models of AD are more acute than chronic, as in human disease). Nevertheless, when examining aspects of the diseases such as the response of specific cell types to treatment, there are sufficient similarities to make conclusions that are transferable to human biology and disease.

Typically, what will be done to an animal used in your project?

Our experiments in mice will mimic, in an experimentally controlled fashion, challenges to the cutaneous immune system, including infection, autoimmune disease, allergy and inflammation. We will administer substances by a variety of routes, choosing the most suitable and least invasive route possible. Our models involve creating inflammation or infection in the skin that mimics such conditions as psoriasis, contact/irritant dermatitis, and atopic dermatitis (allergic eczema). These will be generated by for example topical application of irritants or allergens or by injection of such compounds and pathogens, such as bacteria, into the skin (typically to the ear or back of the animal). The symptoms that will develop are inflammation, redness, flaking and thickening of the skin, and skin lesions. Treatments involving novel manipulation of the immune system will then be tested for ability to ameliorate the symptoms of these diseases. The treatments will be delivered either locally by injection/topical administration, or systemically by injection into the blood, or the peritoneal cavity.

Such experiments will typically last one to two weeks and may involve a single injection to induce the disease (or seven daily application of cream to induce the disease), followed by repeated injection (typically two to three times per week) of the treatment. However, a minority of models may extend to 12 weeks to allow for a period of recovery, without

intervention, prior to rechallenge and assessment of treatment efficacy and duration, and assessment of secondary immune responses.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of mice are expected to experience mild to moderate discomfort due to aggravation of the skin, and may experience weight loss during the course of the model. Mice are regularly monitored during studies. The main impact on the animals will be the local symptoms of inflammation. These include redness, flaking and thickening of the skin and possible over grooming. Small areas may also develop lesions of the skin when an **infection model is performed.**

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 5% subthreshold
- 20% mild
- 75% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although we undertake many experiments using ex vivo human cells and immortal cell lines, the existing in vitro assays do not accurately mirror the more complex molecular and cellular interactions that regulate immune and haematopoietic cells in vivo, leaving no practical alternatives to studies in whole animals. Despite the initiation of studies (by others) to perform computer modelling of the immune cytokine network these systems do not currently represent a viable alternative to experimental research. In particular, translational aspects of our research, such as the modulation of the immune system, are only possible in an in vivo context.

Using a mouse model of skin inflammation allows analysis of the complex interaction of the skin with different organs in the animal, including migration of subsets of immune cells from the blood stream, lymphatic system and bone marrow. Mimicking the symptoms of

psoriasis and dermatitis involves restructure of the tissue and formation of features such as flaking skin and inflammatory lesions. This process involves numerous cell types, organs and signalling molecules and as such requires the in- vivo tissue architecture in order to develop.

Which non-animal alternatives did you consider for use in this project?

We perform numerous human in vitro assays to both define the function of factors and cells under investigation, and to refine our experimental approach so as to optimise the information gained and predict how the molecule will act in vivo. We have refined an in vivo human allergen challenge model in which skin blisters can be raised at the site of allergen immunisation to give access to fluid and cellular infiltrate for analysis of the response to those allergens.

We are using several in vitro experimental methods to analyse skin tissue and blood from healthy individuals as well as patients with psoriasis, atopic dermatitis and contact dermatitis.

We use imaging and single cell analysis of gene and protein expression of human tissue samples and use this analysis to predict genes and proteins that play a causative role in the development and susceptibility of the skin conditions.

We isolate T cells from peripheral blood in order to identify cells that can interact with skin cells during inflammatory conditions. We have isolated functionally interesting T cell clones and used these for in- vitro analysis of pro-inflammatory, or anti-inflammatory responses.

We utilise human skin obtained from healthy individuals (from discarded tissue from plastic surgery or biopsies) to recreate in vitro tissue that can retain function for a limited period and to isolate cells for functional and investigative analysis. We use skin tissue derived from patients and healthy donors to isolate several types of skin cells that are involved in development of skin inflammation (e.g., Langerhans cells). We can maintain these cells in a functional state for a limited period during which we can coculture them in vitro with T cells to assess the nature of this intracellular interaction and potential contribution to disease. In this way we have tested and refined a number of potential therapeutics prior to in vivo assessment. For example, we isolated and purified over 100 potentially neutralising antibodies and using a human in vitro antigen presentation model we refined this panel to 5 antibodies for in vivo murine investigation.

Why were they not suitable?

The in vitro and ex-vivo techniques we employ are very useful in generating hypotheses regarding the causes of skin disease and form and refine the theoretical basis for developing treatments, but they do not allow for multi-tissue migration and interaction analysis, and development and testing of therapeutic treatments with multi-factorial analysis of the symptoms of disease. Indeed, temporal and spatial factors are missing

from in vitro and ex vivo analyses. For example, immune cells produced in the bone marrow, may require migration to the thymus for maturation, where upon cells migrate to the site of infection, before subsequent migration and development of immune memory to allow rapid recall upon reinfection. This diversity of microenvironments and time-scale cannot be reproduced in a culture dish or isolated organoid. Reductionist reconstructed cellular in-vitro systems also suffer from bias that we introduce by the choice of cell types co-cultured.

Other limitations, with ethical and practical implications, include the frequency and amount of tissue that can be recovered from human volunteers and patients, the limitation of tissue recovery at early stages of the disease- before symptoms develop, and the limitations on the testing of novel experimental treatments. The use of human cell culture and blister analysis offers tremendous insight, but before we attempt to manipulate the human immune system we need significant amounts of preclinical information that help to inform on the likely efficacy and potential side-effects.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in this project is based on the estimated requirements for experiments in each model as well as the number required to breed and maintain a productive colony.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The group and I have attended courses on experimental design and statistical approaches and will seek further statistical advice from colleagues whenever necessary. We are also aware of online tools such as Experimental Design Assistant (EDA) and G*Power (http://www.gpower.hhu.de/). The web application, Experimental design Assistant (https://eda.nc3rs.org.uk/eda/landing), has been used to rationalise optimal numbers of animals for future experiments. Pilot studies, will be used to test the practicality of experimental design and provide estimates of variability for power analysis to determine future sample sizes.

Shared control groups are used in combined experiments where more than a single question is addressed to reduce the need for repeated control groups. The simplest

example being when using three different blocking antibodies in identical experimental setting, there is only a need for a single isotype control group.

Where appropriate, experiments will exploit a within-sample repeated-measures design to maximise the statistical analysis from fewer animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Best practice is followed for colony management to ensure we minimise breeding of animals that are surplus to our experimental needs. The Establishment has a dedicated colony manager who can advise. There is also a mouse database from which we can source data for our strains that assists in colony management

Pilot studies that determine the parameters for group size calculations will be used to optimise the number of animals used in the experiments.

Collection of multiple tissues at the end of experiments (occasionally storing them for later analysis) will reduce the need to repeat experiments for the purpose of assessing different aspects of the experimental conditions.

Additionally, once characterised, we will make our animals available to the scientific community thereby removing the need to generate multiple animal lines with the same genotype. And we collaborate with labs to provide murine data to their human studies, again reducing the need to regenerate lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using several models of skin disease, which differ in the initial stimulus. These include creams containing an inflammatory compound or allergen, or intradermal injection of an allergen or pathogen that causes skin disease. Where possible in the study of skin inflammation, responses to these substances will be primarily localised rather than systemic in order to reduce the overall suffering. Most experiments will be restricted to one to three weeks in order to limit the duration of skin discomfort.

Topical administration is amenable to control through the daily application of cream where the dose can be reduced or stopped to allow skin healing. Where ever possible allergens and irritants will be administered to the ear in preference to the back to reduce the affected area of skin, but for sensitisation and re-challenge experiments the site of skin administration may differ between the first and second administrations (e.g. ear and back). These models facilitate fine control of skin inflammation, in our experience refined application of inflammation inducing agents allows robust detection of immune responses whilst minimising suffering of the mice.

The severity of inflammation can be scored based on the objective clinical Psoriasis Area and Severity Index (PASI). Evaluated parameters include degree of redness, scaling and thickening of the skin. The level of erythema can be evaluated with the help of an optical red scale, and ear thickness is measured without bias using a micrometer. This will allow robust data collection and careful monitoring of the murine experience.

In a few experiments, mice will undergo bone marrow transplant, which involves irradiation that kills the cells of the mouse's bone marrow to be replaced by new bone marrow that is injected shortly after the irradiation. This treatment causes some illness but it is short term (about a week) and the mice recover with no lasting harm. This type of experiment is an important tool for assessing the role of blood cells, and specific proteins expressed in blood cells, in the progression of the disease.

Batches of bacteria or fungi, or irritants/drugs may vary in pathogenicity or toxicity, whilst different strains of mice may vary in their resistance or susceptibility. To reduce the risk of unanticipated suffering we will first employ a low dose group of two mice, a further two mice may be tested at a higher dose and so on until an appropriate dose level is reached. We use a comprehensive monitoring and scoring system to assess the animals throughout experiments. Where possible we will use the shortest models of disease that will yield satisfactory data.

Why can’t you use animals that are less sentient?

Mice are currently the least sentient mammalian species in which these experiments can be performed robustly and reproducibly. Murine immune and haematopoietic systems closely resemble those of humans and many models of human disease have been developed in mice. The mouse also benefits from well-established and robust technologies for transgenic and gene-targeted genetic alteration.

In particular when investigating skin immunology, animals that are less developed evolutionarily e.g. zebra fish and drosophila flies, do not suitably recapitulate human skin biology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experimental protocols are formulated to minimise stress or harm to the animals and are based on the observations in pilot experiments, repeated past experiments and published observations.

We continually refine our methods, including changing humane end points, assessing and adding new monitoring techniques (e.g., equipment for measuring ear inflammation), and reducing number of procedures to the minimum necessary for the desired effect (e.g., reducing the number of injections of compound once a sufficient effect has been observed).

We regularly inspect animals to determine their welfare (e.g., take ear thickness and weight measurements and observe changes in their social behaviour and appearance). We use comprehensive monitoring and scoring systems where appropriate to assess the animals throughout experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The design of experimental procedure will follow best practices guidance described by ARRIVE guidelines, local guidelines, and PREPARE guidelines as well published guidelines on skin inflammation models. The NC3Rs and the LASA websites provide invaluable information and our Named Information Officer provides further information regarding refinement with regular emails and can be consulted.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review the literature relating to animal models and improvement/refinements of models that relate to our work. We will also discuss ways of improving our models with other groups and with the Named Information Officer, Named Veterinary Surgeon and Name Animal Care and Welfare Officers. We also access specific literature on animal welfare through the NC3Rs web site and regular links sent by the 3Rs Information Officer at the University's Home Office Administration Unit. The group and I attend internal 3R’s meetings and talks to keep us informed of advances in 3Rs that can be implemented.

27. Inducing New Neurons for In Vivo Brain Repair

Project duration

5 years 0 months

Project purpose

Basic research

Key words

brain injury and repair, nervous system regeneration, regenerative medicine, cell-based therapy, epilepsy

Animal types	Life stages
Mice	adult, pregnant, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims at developing strategies of generating new neurons in the brain in order to repair or replace damaged, dysfunctional or diseased neurons and brain circuits.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is a pressing need for effective treatments for a broad spectrum of disease afflicting the brain. This includes neurodegenerative diseases (e.g. Alzheimer's and Parkinson's disease), neurodevelopmental disorders (e.g. autism, schizophrenia, epilepsy) and damage to the brain (e.g. caused by trauma or stroke). In all these diseases neurons have become dysfunctional, damaged or even lost leading to disruption of functional brain

circuits with devastating consequences for affected individuals and society. Our brains have extremely limited ability to generate new neurons and promote self-repair. This project aims to overcome these shortcomings by developing innovative strategies that convert non-neuronal cells in the brain into new neurons that can integrate into brain circuits, with the long-term goal of restoring brain function in human disease.

What outputs do you think you will see at the end of this project?

At the end of this project we will have learnt:

new and more effective ways to convert non-neuronal cells into clinically-relevant neurons; the specific properties of newly converted neurons;

the potential of newly converted neurons to contribute to circuit function and functional restoration.

appreciate differences between non-neuronal human cells and mice cells in their ability to convert into neurons

We will communicate our findings to the scientific community through peer-reviewed publications and presentations at scientific meetings. We will disseminate our research to the general public through non-specialist publications, online material and public outreach events.

Who or what will benefit from these outputs, and how?

In the short term, the main beneficiary will be the scientific community, who will gain valuable knowledge about the mechanisms governing cellular identity, maintenance and plasticity in the brain.

After completion of the project, the translational research community will benefit from protocols and strategies we have developed. These can be used to inform future strategies for cell-base therapies of brain diseases in humans.

In the longer term, we hope that our work will provide a scientific basis for the treatment of currently incurable brain diseases with direct benefits to patients and society.

How will you look to maximise the outputs of this work?

We will maximise our output and impact of our work through:

collaborations with colleagues within our research centre, within the UK and overseas, to complement our own skillset with world-class expertise in the fields of neurodevelopmental sciences and brain disease.

share our expertise and new findings to colleagues to promote complementary research on brain repair.

publish rigorously tested scientific findings that will provide useful information to the scientific community, irrespective of whether they support or falsify our original hypotheses make raw data and protocols widely available to ensure our work can be validated by other research groups.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use mice to study the possibility of generating new neurons in a brain where this does not normally happen spontaneously. Unlike mammals (such as mice and humans), lower vertebrate species, such as fish or amphibians, have a natural ability to regenerate neurons throughout life.

Therefore, to model the challenges of generating new neurons in a brain akin to humans, we need to use animals that lack the ability for natural neuron regeneration, such as mice.

Importantly, mice have similar brains as humans, and like us humans possess a cerebral cortex, which can be afflicted by many devastating human diseases and, for this reason, is a main focus of our project. Furthermore, mice are genetically very similar to humans. This means that the mechanisms of action for the strategies we develop to convert non-neuronal cells into neurons in the brain, are likely to be directly relevant to humans.

Our work needs to be conducted in animals at a time when developmental birth of neurons has come to an end. In mice, this process is complete at the time of birth, therefore it is necessary to conduct our work after birth. Human brain disease occur throughout life. Some disorders are typically diagnosed in early life, including many neurodevelopmental disorders (e.g. autism, childhood epilepsy). Others may manifest in adolescence or early adult life, such as schizophrenia and other mental health disorders. Still others may typically affect us in later life - for example, Alzheimer's disease and stroke. Therefore, it is important that we consider a range of life stages when investigating the potential of our strategies to convert non-neuronal brain cells into new neurons. Additionally, it is important to allow time for our newly induced neurons to mature and integrate into brain circuits. We also need to assess the long- term survival of these new neurons and their therapeutic effects on the organism.

For these reasons, we need to study mice over a range of life stages from birth through to adulthood.

Typically, what will be done to an animal used in your project?

In order to generate new neurons in the brain from non-neuronal cells, we need to deliver certain genes into the non-neuronal cells (e.g. astrocytes). We do this as part of a surgical procedure, where the mice are anaesthetised and we inject vehicles carrying genes into the specific part of the brain we are studying. Almost all mice in this project will have a surgical procedure such as this.

A large minority of mice will also have a second procedure. This can be for one of several reasons. For example, in order to study how the new neurons integrate into the brain, we can place a small glass window in the skull, which allows us to directly observe the new-born neurons as they grow, change shape and become active under a microscope. Alternatively, a second surgical procedure may be required to inject human astrocytes. This allows us to make sure that our research is as applicable to humans as possible. Less commonly, we may perform a surgical procedure to cause a localised and controlled lesion that in some specific way emulates human brain injury or disease (e.g. epilepsy).

Doing this is important to test if generating new neurons might be a useful treatment in brain disease or injury. However, these models of brain disease are typically mild and only account for a small proportion of mice in our project.

Therefore, a typical mouse would undergo either one or two surgical procedures where they are fully anaesthetised. In some cases (i.e. where we fit a glass window to observe the brain) we would place these mice under the microscope several times over a period of a couple of weeks. Sometimes, mice may need a few injections under their skin or in their abdomen to activate genes.

What are the expected impacts and/or adverse effects for the animals during your project?

We have taken care to design our experiments to have the minimal impact/adverse effects on the animals whilst still being able to answer our scientific questions.

Most experiments in this project require mice to have at least one surgery, however, and these do carry risks. Pain, anaesthetic overdose bleeding and infection are the most common side-effects. We work with the veterinary surgeon to make sure we give the correct dose of painkillers and anaesthesia meaning that with good surgical practices these happen only rarely. Mice are reviewed daily, so side- effects are picked up quickly and most can be easily treated with simple interventions (e.g. giving extra painkiller medication) within 24 hours.

A very small number of mice in this project will be used to answer questions about whether creating new neurons can be a treatment for epilepsy. These mice have a specific injury that causes electrical discharges in a part of their brain. They do not have convulsive seizures but sometimes they might show some abnormal behaviours (such as stopping

mid-activity). These aren't harmful or painful for the mice, but they can occur throughout life.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 50% of animals in our project will experience mild severity (mostly related to general husbandry and breeding of the animals, some of which have an injection(s)).

The other half of animals will be those who have at least on surgical procedure, and these would be classed as experiencing moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The brain is the most complex organ in the body, a fact that can be attributed to the plethora of different types of cells and their multiple, highly specific interactions with one another. These include exquisitely specific communications between neurons within a given brain area, as well as those across brain areas. Moreover, these are complemented by interactions with various kinds of non- neuronal support cells, such as astrocytes, oligodendrocytes and their progenitors, microglia and other immune cells, and cells of the vascular system (e.g. pericytes and endothelial cells). To make matters even more complex, these interactions undergo change throughout development of the organism and depend on the health and life experience of the organism. In previous and ongoing work in our laboratory, we have successfully developed strategies to reprogramme non-neuronal brain cells into neurons using cells in a culture dish, revealing many important aspects of the underlying biology.

However, we have also learnt that the complex environment of the brain poses additional barriers to the conversion that can not be recreated in a dish. Furthermore, we are now trying to understand whether new neurons that we generate are capable of integrating with other neurons in the brain and become recruited into functional brain circuits. Finally, we want to determine if these new neurons can provide beneficial effects to malfunctioning brain circuits, such as those we see in human brain disorders. This requires us to conduct

experiments in suitably complex animal models of healthy and disordered brain function and measure the functional consequences of induced neurons on neural circuit activity.

Which non-animal alternatives did you consider for use in this project?

1. Cell Culture - growing human or non-human cells in a laboratory dish

2. Brain organoids - 3-dimensional cell aggregates derived from pluripotent stem cells

3. Computational models

4. Human volunteers/patients

Why were they not suitable?

1. Cells in culture have differences in gene expression and states of maturity and, therefore, do not present the same barriers to cell-fate conversion strategies encountered in living mammals. They also do not mimic the degree of complexity needed to study the importance of the local cellular environment or integration of new neurons into brain circuits.

2. Brain organoids are a new technology, which we work on in the lab as well as using animal models. They succeed to mimic a bit more of the cellular complexity that exists in the brain. However, many cell types and structures are missing and the overall architecture remains immature. They are also very restricted with respect of modelling complex human diseases or behaviours. We closely follow this advancing field and wherever possible would prefer to work this system over animals. Currently, this system is not suitably advanced to meet the aims of the project proposed here.

3. There are no suitable computational models that capture the dynamics of gene regulatory networks and their perturbation during cell conversion and across several cell types within the complex context of functioning brain tissue.

4. At this stage, glia (non-neuronal cells in the brain) to neuron conversion is at a very early stage of exploring its feasibility in the live brain. Our studies are an absolute prerequisite for any potential clinical translation in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have experience working with mice for research and can look at the exact number of animals that we have bred during a year. If we breed similar numbers per year over the next 5 years of this project, we estimate we will breed between 5500 and 7500 mice. However, since our research team is likely to

expand during the next 5 years, it may be the case that there may be more mice bred in the next years than years that have passed. Therefore, we estimate that this project will require around 8,500 mice to be bred during next 5 years, however, not all of these will be subjected to scientific experiments, many are used in breeding and colony maintenance.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We design our experiments in such a way to keep animal numbers used to a minimum that still provide robust statistically valid answers to our scientific questions. We request that all members of the lab visit the NC3R's website (https://www.nc3rs.org.uk/the-3rs) and use this and other appropriate tools to calculate appropriate sample sizes when designing their experiments.

We also take steps to maximise the amount of information gained by each animal. Examples of this include the use of some imaging modalities which allow data to be collected over time in the same animal to be taken (rather than, for example, culling cohorts of animals at specific time points). Our work is increasingly trying to invest in and develop tools and training that will help us to collect this sort of data so we can reduce overall animal numbers. We have built this into our experimental designs. In these scenarios, however, it is important to ensure that reducing the number of animals used is balanced against any additional suffering that might be caused by repeated data collection on a single animal. Once animals are humanely killed and tissues collected, we can also perform multiple different types of analysis on a single mouse brain. This allows us to collect lots of information from one mouse, rather than needing to use a separate mouse for each type of analysis.

Sharing data and resources (e.g. animals, tissues and data) between research groups and organisations can also contribute to reduction. We use genetically altered mice lines that have established protocols (e.g. drug dosing protocols) to avoid needing to use animals to create our protocols from scratch.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever we are trying a new viral tool in the lab or a new technique, we conduct pilot studies on a very small number of mice to ensure protocols are working well. This allows us to avoid subjecting larger numbers of animals to a treatment before knowing if the tools and techniques are working.

Very often, we use genetically modified mice to study specific cell types in the brain. If an animal has only one copy of a gene, then there is only a 50% chance of their offspring having the gene we need for conducting our scientific experiments. This means that around 50% born may not be suitable for particular experiments. It is usually more efficient to have mice that have two copies of the gene (homozygous). That way, 100% of the litter have the gene of interest and avoids breeding additional mice. We use this wherever possible, however, there are many situations where it is still necessary to maintain mice that have only a single copy of the gene. Although we often need genetically altered animals to perform experiments, some of our work can be done in 'wild type' (non-genetically altered) mice. We can often, therefore, use the siblings of the genetically altered mice to conduct experiments - saving on the unnecessary breeding of additional mice.

We encourage researchers to share brain tissue or other samples that they have in surplus so that information gathered from a single mouse can be maximised.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Work on this project is exploring strategies to generate new neurons in the brain, which may one day help develop treatment for human brain diseases. To do this we deliver genes to specific cells in specific parts of the brain. We mostly do this by using viruses that have been genetically modified to remove harmful viral genes and prevent their replication but can still express the genes we want to study in the cells that they infect. Delivering these genes involves an injection into the brain as part of a surgical procedure. To be able to directly visualise new-born neurons in the brain and explore how they integrate into local brain circuits, we make use of techniques to implant small transparent windows and other devices that can help to measure neural activity. These procedures are well-established and are performed under anaesthesia and with attention to making sure mice receive appropriate doses of painkillers and general post-operative care when the wake from any operation. Wherever possible, we try to only perform one operation on any one mouse. Although there are several situations where two, or at most three, operations are required for scientific reasons. We make sure mice are allowed to fully recover between operations.

Since we are trying to develop strategies that may one day be used to treat human disease, it is important to study the role of injury and disease on our reprogramming and

vice versa. To do this, we use two approaches. One is to make a small cut in the cortex of the mice during a surgical operation. Because this cut is very small, localised and controlled the mice do not show any abnormal behaviour or signs after this injury but still allows us to get crucial scientific information. Our other approach is to study whether newly reprogrammed neurons could be beneficial in treatment resistant epilepsy. We use a well-established model where a chemical is injected into the hippocampus of mice, which causes some neurons to degenerate, causing a form of epilepsy called mesial temporal lobe epilepsy (MTLE). Because the damage in MTLE is restricted to the hippocampus, it is called a focal epilepsy. The advantage of using this model is that the mice do not have convulsive seizures as the seizure activity is 'focal' at the hippocampus and surrounding tissue and does not spread throughout the brain. This means that the mice can live almost behaviourally normal lives (although they can have some behavioural pauses and repetitive movements) while still allowing us to study the benefit of reprogrammed neurons in the context of epilepsy. The MTLE and brain injury mouse models account for only a small part of our work.

Why can’t you use animals that are less sentient?

Many non-mammalian animals such fish and amphibians show a much greater ability to regenerate their nervous system than mammals. Since we are ultimately interested in developing treatments to repair damaged or dysfunctional human brains, to have any relevance, we need to study this in a scientifically appropriate (mammalian) species. Although all our surgical procedures are performed under anaesthesia, regenerating neurons from glia in the brain takes time (weeks to months).

Therefore, we can't study conversion of glia to neurons in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We regularly review and update our protocols for anaesthesia, analgesia and any drugs that we may administer to animals with the veterinary surgeon to ensure that the route and dose of any treatments are optimised to keep any pain or suffering to a minimum during the experiments that we do. We ensure that mice are kept warm, observed and generally cared for after any surgical procedure and that they make a full recovery before being returned to their home cage. During operations mice have their temperature maintained, breathing monitored and pain reflexes checked regularly to make sure that they are well and pain free during all procedures. New researchers are trained under supervision by experienced researchers to make sure they are competent with any new procedure before being allowed to work independently. Mice are visually checked by animal staff daily in our animal unit to make sure they are well. After a procedure, researchers perform additional checks to ensure recovery is complete, administer any necessary post-operative pain relief and that any implanted surgical devices are not causing discomfort to the animal.

When awake animals are used during imaging or data collection, we ensure that the mice are gradually habituated to the experimental/microscopy environment (usually in brief sessions over several days) before any real data is collected. This reduces any stress the mice may experience by the act of collecting data and they are usually very quick to relax when well habituated.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Researchers will be familiar with and expected to meet the criteria laid out in the latest published ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines.

We follow best practice advice laid out by NC3Rs at: https://www.nc3rs.org.uk/3rs-resources/anaesthesia and expect new and experienced researchers to complete the e-learning resources and implement these practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will work with our Named Training and Competency Officer on our Establishment licence to ensure that information about advances in 3Rs (and training opportunities) are being communicated and disseminated to researchers working on animals. We are setting up regular scheduled meetings with researchers performing animal work to come together to discuss local issues with animal work and foster a culture best practice in refinement techniques. These will be a forum for discussion on the practical implementation of any advances in 3Rs in our project. As well as completing all mandatory training, any new researchers in the group are expected to set aside time to visit the NC3Rs website to read/watch all aspects relevant to our protocols, as well as general best practice in husbandry, experimental design, euthanasia and surgical procedures.

28. The Developmental and Heritable Basis of Adaptive Variation in Fishes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

adaptive divergence, climate change, phenotypic plasticity, genetic mutation, development

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, adult, juvenile, aged, pregnant
Gasterosteus aculeatus	embryo, juvenile, neonate, adult, aged, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will use fish to understand the genetic basis and developmental factors responsible for adaptations. A range of species will be used to address different aspects of adaptation including changes in metabolism and bone development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Natural selection can't work without variation in traits (morphology/anatomy, behaviour, physiology) to sort. Therefore, we address a number of important questions including how the environment contributes to trait variation, and how development and genetics contribute to trait variation. This has broad importance for research on the effects of climate change on natural populations, and the use of fish as model systems for m medical topics such as metabolic research (including diabetes and obesity), as well as common birth defects such as cleft palate (i.e. craniofacial research). The science involved will bring forward an understanding of how variation arises before selection in a way that is unique in the field.

What outputs do you think you will see at the end of this project?

The projects will result mainly in a number of publications focused on the genetic and developmental basis of trait variation in fish. We expect no commericial products to arise. We hope that we will open new doors to the study of human diseases and the effects of climate change on natural populations and start to get a handle on the genetics and environmental factors involved.

Who or what will benefit from these outputs, and how?

This will benefit fish biologists and evolutionary biologists. In the short-term the research will be of interest to other academic scientists but over the longer term we think the findings will be relevant to medicine as well to biologists interested in how populations of cold-blooded ectotherms will respond to warmer habitats as a result of climate change. This will include research on facial variation and bone development, as well as metabolism. The work will develop fish as a model system for these human syndromes and potentially shift research towards them over time.

How will you look to maximise the outputs of this work?

The work will be published in journals, and presented at national and international conferences. Press releases will be provided for some outputs to enable news organizations to pick up on our findings.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 2500 Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Fish are an extremely variable group, both within and between species which makes them applicable to a wide range of questions. Natural populations of fish are well known to exhibit adaptive variation in head and body shape, behaviour, and physiology. This occurs naturally as adaptations, but it is also the case that populations are facing new challenges in a changing world and will likely need to change. Fish also share a surprisingly strong genetic identity with humans (many traits have the same genetic basis in both humans and fish) making them relevant to human health conditions and are highly suitable to experiments. Many species are also well studied in terms of developmental stages and the events that occur as they grow (i.e. they possess a published ‘developmental series’) making assessments of change straightforward. This lets us use fish to target many key stages such as when the jaw first forms, or metabolism and growth slows.

Typically, what will be done to an animal used in your project?

Most fish would be reared under stable conditions with mild experimental procedures being applied such as changes in diet, feeding, flow, or temperature. However, some focal individuals would undergo injections of compounds to aid in individual identification, or for experiments involving assessments of physiology. Some fish would also be provided with exposure to pharmacological compounds (at larval stages) in the water, targeted at testing the effects of molecular pathways. Finally, we would occasionally perform genetic editing techniques and rear fish to examine the phenotypic effects. These genetic edits would be targeted at genes involved with adaptation and thus are unlikely to have negative effects on fish.

What are the expected impacts and/or adverse effects for the animals during your project?

Our experimental procedures involving injections would involve momentary pain under anaesthesia lasting seconds to minutes.

In some cases we would also need to reduce feeding levels for periods of 6-8 weeks to induce metabolic effects.

Blood and fluid extractions would also be a potential source of temporary stress lasting on the order of minutes to hours.

The use of anaesthesia for some procedures, while reducing stress in many cases, is likely to have effects on behaviour (unbalanced swimming, laboured breathing) lasting a few hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild (~80% of subjects) - Moderate (~ 20% of subjects)-

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of live fish is the only way to experimentally test and understand the basis of adaptive trait variation. Many fish species are new study systems for experimental approaches and therefore important insights about their specific adaptations have yet to examined. A non-animal alternative would not provide a means to make discoveries about the developmental and genetic basis of adaptation.

Which non-animal alternatives did you consider for use in this project?

We could not consider non-animal alternatives for this project. This is because we are interested in adaptive traits are within fish and need to be assessed them directly. These are not well understood in general, especially for fish, and thus in silico approaches would not be feasible.

Why were they not suitable?

Non-animal alternatives could not provide information about how specific populations respond to environmental change. As we are interested in whole animal responses and the genetic factors involved, our project requires animal subjects.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated our numbers on the basis of current practises in the field. For example, for G. aculeatus a recent study (https://onlinelibrary.wiley.com/doi/pdf/10.1111/mec.13965) shows that for fish an experiment to relate genetic variation to trait variation the typical experiment uses 300 individuals.

However, in our case we will use two independent populations and ages which each double our needs to 1200 individuals for this part of the project. Similarly, we have investigated traits previously and found that a sample size of 10-40 individuals is required (10 for molecular measures, 40 for outward morphological traits). This approach will make the work acceptable to the field, making the use of these animals worthwhile.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have planned a set of novel experiments on understudied traits. For statistical analysis this precludes knowing the levels of variation for each trait we plan to examine making it difficult to provide precise numbers. However, the power of our experiments to detect statistical differences due to temperature, population, dietary, and age effects will be enhanced through the implementation of a randomized block design including factors such as population, rearing temperature, and species/ecotype as fixed blocked effects. We will also regularly employ the use of generalized linear mixed-models to limit the potential effects of pseudoreplication using individuals as a random effect (some fish will need to be raised within the same experimental unit). Overall, this will enhance statistical power, as observations will be made at the individual rather than group level. This means that individuals could be measured more than once without any statistical compromise being made.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Reduction will also occur through the measurement of multiple traits on the same individual when sampled (e.g. fat level, body composition, appetite level, morphological shape). Also, some of the methods we use to assess body composition (micro-CT scanning) will enable morphological variation to be assessed in 3D for future projects. The scanning will take place locally with a collaborator who is in possession of a micro-CT scanner.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The fish species we intend to use are ideal models for a range of questions. This includes questions surrounding evolution and development, but extends to clinically relevant variation, and the impact of climate change on natural populations. What is occurring in fish is that some adaptations from nature can actually mimic traits found in human disease whereby ‘screening’ has been done by natural selection instead of lab researchers. So, while clinicians usually focus on mutant lines screened for traits of interest, and which may suffer from inbreeding, or generally poor health our fish are robust. This is because the traits of interest are part of an adaptive process that limit the negative effects associated with a 'disease' phenotype. This is a special aspect of adaptations that standard lab models may never offer. Ultimately, this should lead to a more powerful way of studying disease and require fewer animals overall, and the study of traits that do not compromise the health of the animals. This will provide a better approach relative to the use of highly inbred lines with large, often lethal, mutations.

We will use standard lab assays for the measurement of metabolic traits (Western blots, qPCR) and standard techniques for the measurement of morphology. The fact that fish of a single species can also live and reproduce in a range of temperatures is making them increasingly relevant for understanding the impacts that climate change could cause. The populations of sticklebacks we have identified living in warmed waters fish this very well and can help us look into a potential future situation of how adaptations occur in a warmed world.

Why can’t you use animals that are less sentient?

We will use adult fish mostly, but also their larvae prior to independent feeding to understand development. Thus, we will use these species at less sentient stages. However, when studying the effects of advanced aging, or traits that emerge at later life stages it is simply impractical to consider a less sentient set of species within the vertebrates. The fish that we rear will largely be kept for morphological/anatomical analysis and will allow them to serve as study subjects in the current and future projects.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have existing bespoke protocols for anaesthesia for each of the species that we will continue to monitor and adjust. The aquaria we use will also be equipped with enrichment materials such as rocks, structures, plants as appropriate to the species. We have found that this leads to seemingly calmer fish. Given the variety of cichlid species we rely on, a

set of references regarding their preferred diet, with the ability to provide herbivorous or carnivorous foods. We will even provide these foods at different depths in accordance with the ecology of a given species. Temperatures and water parameters are also to be kept in line with those found in nature. Together these aspects should reduce stress and recovery times from any potential impacts of procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Westerfield, M. (2000). The zebrafish book. A guide for the laboratory use of zebrafish (Danio rerio). 4th ed., Univ. of Oregon Press, Eugene.

Ribbink, and B. J. Sharp. (1983). A preliminary survey of the cichlid fishes of rocky habitats in Lake Malawi. South African Journal of Zoology.

Schultz E. (2014) Juvenile Threespine Stickleback Husbandry: Standard Operating Procedures of the Schultz Lab

https://production.wordpress.uconn.edu/fishlab/wp-content/uploads/sites/116/2014/07/CompleteSTBKhandbook_31jul.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will be in regular contact with our local NACWO as the fish are kept under experiment. I will also be in regular contact with our local vet and belong to a mailing list of project licence holders that will continually inform us of changes to legislation. Regular checks of NC3Rs and Norecopa websites will be made for confirmation and updates to possible refinements.

29. Pathological Calcium Leak and Abnormal Heart Rhythm

Project duration

5 years 0 months

Project purpose

Basic research

Translational or applied research with one of the following aims:

- Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cardiac, arrhythmias, sudden death, catecholaminergic polymorphic ventricular tachycardia, heart disease

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Patients with heart disease are at greater risk of dying suddenly due to abnormal heart rhythm. This project seeks to understand the mechanisms linking "leaky" calcium channels in the heart and arrhythmias and work towards developing new treatments to prevent sudden death.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sudden cardiac death is a major global healthcare problem, estimated to account for up to 20% of deaths in Western societies, or more than ~7 million deaths globally per year. It is not fully understood how arrhythmias start in the heart, however loss of control over cellular calcium levels is thought to be an important contributor. This project will firstly generate scientific knowledge of the mechanisms linking calcium and arrhythmias in heart disease. By better understanding the mechanisms of disease, this could influence the current clinical management of patients by opening up new opportunities using already available treatments. This improved understanding will guide the development of new therapies for heart disease. In the longer term this research could improve the quality of life and reduce premature mortality in a large and growing section of the global population.

What outputs do you think you will see at the end of this project?

This project will generate new scientific insights into the cellular origins of arrhythmias in the heart. This will improve our understanding of how arrhythmias begin and reveal new opportunities for intervening. We will develop new experimental treatments and validate their efficacy at preventing arrhythmias in a small animal model of heart disease. The findings will be published in peer-reviewed journals and presented at conferences. Eventually this work could lead to new drugs and treatments for patients with heart disease.

Who or what will benefit from these outputs, and how?

In the short term, clinicians and basic scientists will benefit from the improved understanding of the cellular events leading to arrhythmias in the heart (1-2 years). This could encourage a re-thinking and re-evaluation of the treatments currently offered to patients with heart disease, and prompt trials of existing drugs that are not currently used for this purpose but which may have a positive effect preventing arrhythmic events. Therefore, in the medium term (3-5 years) this could benefit patients that currently have heart disease by improving the way their condition is managed. In the long term (5-10 years), the anti-arrhythmic treatments developed here could lead to clinical trials and new treatments for a broad range of patients with heart disease.

How will you look to maximise the outputs of this work?

We will work closely with national and international collaborators with expertise in different areas of the project. These collaborators will provide technical facilities, materials and knowhow to ensure the project success and the ability to complete all objectives during the project timeframe. In addition, we will establish connections with clinical cardiologists to hone the clinical aspects and maximise the potential for this research to translate into patient benefit. Our results will be submitted for publication in esteemed peer-reviewed journals with high readership to maximise its visibility.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse is the species of choice when genetic manipulation is required to mimic human disease and is the only mammalian model used so far to replicate the inherited human hearts disease catecholaminergic polymorphic ventricular tachycardia (CPVT). No larger animal models of CPVT such as rat, rabbit or pig are available. This project requires regular access to fresh isolated heart muscle cells (myocytes). Mouse cardiac myocytes share the excitation-contraction coupling processes of human myocytes that make them a suitable model species for this investigation. There are no non- animal sources of adult myocytes. Non-animal alternatives such as stem cell derived cardiac myocytes and zebrafish cardiac myocytes do not have the same structure and function as adult mammalian cells and so cannot be used for this purpose. The mutation being studied results in a "leaky" calcium channel which is characteristic of CPVT caused by other mutations and common pathologies, such as heart failure. A main advantage of using this model is that it does not require surgical intervention and mice do not experience a detrimental phenotype. Therefore these results should be applicable across a wide range of human disease, without inflicting unnecessary suffering. CPVT is typically diagnosed in childhood and with the best currently available treatment patients can live into adulthood. Therefore mice will be used at approximately 4 months old, representing the equivalent of early adulthood in mice.

Typically, what will be done to an animal used in your project?

Procedure 1: Genetically altered mice with a mutation in a cardiac calcium channel will be bred and maintained for experiments. The majority of mice will undergo no further procedures and will be killed at approximately 4 months old for collection of heart tissue to generate single heart muscle cells.

Procedure 2: A small number of mice will have radio transmitters surgically implanted under the skin to record and transmit electrical heart signals (ECGs). The ECG will be recorded wirelessly during anobservation period of up to 4 weeks in conscious, freely moving mice, to detect the incidence of irregular heart rhythm. Arrhythmias in CPVT patients typically occur during periods of increased emotional or physical stress when levels of adrenaline increase. To simulate emotional stress in mice, we will briefly and intermittently blow warm air on the mice using a hairdryer under close supervision. Once the observation period is complete, some mice will further undergo a cardiac stress test

(injection of adrenaline and caffeine) under terminal general anaesthesia to establish their susceptibility to arrhythmia.

Procedure 3: We will investigate whether modified proteins can prevent arrhythmias in CPVT mice and provide therapeutic value. To do this, some mice will be injected via the tail vein with a non-replicating and non-pathogenic genetically engineered virus that will deliver the genetic material required to make therapeutic protein the heart. We will investigate whether regulatory proteins are protective against arrhythmias by recording the ECG during normal living and during the cardiac stress tests described in Procedure 2, and by isolating cells from the heart to measure their function (as above).

What are the expected impacts and/or adverse effects for the animals during your project?

Mice with the mutation under investigation do not experience a harmful phenotype in normal housing conditions therefore genetic manipulation alone (as is the case for the majority of mice used) is not expected to produce adverse effects. Surgical implantation of miniature ECG transmitters may cause localised trauma and discomfort that will be mitigated by post-operative analgesics. Surgery carries a risk of wound infection that will be mitigated by surgeries being performed by a skilled surgeon, maintaining sterile conditions during surgery and administering post-operative antibiotics. There is a risk of disrupted wound healing due to rodents chewing their sutures; if this occurs new sutures will be placed. Mice are expected to recover completely within 7-10 days post surgery as shown by a recovery of post-operative weight loss and full recovery of mobility. The virus used to express therapeutic proteins in the heart evokes minimal immune response and should not cause adverse effects. At the end of experiment mice will be killed humanely using an appropriate approved method by qualified and skilled practitioners.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold - breeding of genetically altered animals - 50%

Moderate - ECG and protein expression studies - 50%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse is the only mammalian species available as a model of the human disease CPVT. Mouse cardiac muscle cells are structurally and functionally similar to human cells which is necessary for this research. These similarities make mouse a suitable model species for this investigation. Non-animal alternatives such as stem cell derived cardiac myocytes do not have the same cellular structures and lack important ion channels compared to mammalian cells and therefore cannot be used for this work.

Which non-animal alternatives did you consider for use in this project?

Induced pluripotent stem cell derived cardiac myocytes (iPSC-CM), human endothelial kidney (HEK) cells

Why were they not suitable?

Although CPVT research has been conducted in iPSC-CM and transgenic zebrafish models these cells have major dissimilarities compared to human heart muscle cells that are incompatible with achieving the aims of this project. Mammalian myocytes possess membrane structures, called t-tubules, that create a localised environment near the calcium channel that strongly influences its behaviour. iPSC- CM and zebrafish myocytes are completely absent of t-tubules and therefore lack this important aspect of calcium regulation. The amplitude and timecourse of calcium released during each contraction is very different in iPSC-CM and zebrafish to human and mouse myocytes, due to different expression levels of calcium regulating proteins and ion channels, and therefore the relationship between calcium and membrane voltage and the relative importance of different arrhythmia mechanisms will be different in these species. Another main difference is that human or mouse ventricular myocytes do not contract unless electrically stimulated or are exhibiting spontaneous activity (the cellular equivalent of arrhythmias in the heart), whereas iPSC-CM do spontaneously contract.

Where possible, e.g. for biochemistry studies, non-animal HEK cells expressing CPVT mutant protein will be used as a suitable alternative to animals because cell structure is not a concern for these experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal usage numbers are based on extensive prior experience in this type of research. This includes estimates of the volume of data that can be collected from each animal, the variability in data, and the number of replicates needed from each animal to detect statistical differences between groups. The numbers account for the fact that a single animal can generate data for multiple experiments (because the heart is dissociated into millions of individual cells).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There is no difference in the prevalence of CPVT between men and women, therefore both male and female mice will be used for this study reducing the number of mice needing to be bred. A principal technique this project will employ involves separating the heart into millions of isolated muscle cells (myocytes) that can be experimented upon separately. This greatly reduces the number of animals used because a single heart can generate data for multiple experiments. Myocytes are normally viable for up to 9h after cell isolation however, for some experiments myocytes will be maintained in special cell culture conditions for up to 48h allowing data collection over multiple days. Where surgery is involved, the experiments are designed to extract the maximum data from each animal e.g. in addition to recording ECG during normal activity in conscious freely moving mice, the arrhythmia susceptibility will be measured in the same mice under terminal anaesthesia. The hearts from these mice will then be used for cell isolation, histological analysis, or protein analysis. For protein biochemistry experiments, human endothelial kidney (HEK) cells will be used as a non-animal source of RYR2 protein. Frozen tissue and cells will be stored for use at a later date. The experimental data obtained from these distinct lines of inquiry will be incorporated into computer simulations of cardiac myocytes to improve their accuracy and predictive power, which will in turn reduce the need to use animals in future.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

I will use the expertise of the Biological Services team to ensure an efficient breeding strategy is used, due to their experiences with breeding transgenic animals. Data gathered during pilot studies were used to estimate the number of animals needed to detect statistically significant differences between experimental conditions and these estimates will be continuously monitored and updated if needed.

We have tissue sharing agreements in place that mean tissue and organs that would otherwise be disposed of can be used by other research groups wishing to use them.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The primary aim of this project is to identify new treatment approaches to reduce arrhythmias and sudden cardiac death triggered by abnormal intracellular calcium. We will use a transgenic mouse model of the human arrhythmia syndrome CPVT to investigate the efficacy of new possible therapies. The most conspicuous difference in CPVT cells is an increase in spontaneous calcium release, which also occurs in highly prevalent heart failure and other cardiomyopathies. A major advantage of using this model compared to other models of heart disease/failure is that no surgical intervention is required to produce a pathological calcium phenotype because the causative mutation is present from birth. The mice do not experience a harmful phenotype during normal living therefore this reduces the pain, suffering and distress experienced by animals. It also reduces the variability between animals thus reducing the number of independent observations needed to detect differences in experiments. We will use wireless ECG transmitter implants allowing recordings to be made in conscious freely moving mice, without the need for restraint. We will use a modified adenoassociated virus (AAV) to express regulatory proteins in the heart of living mice. This causes less immune response in animals and preferentially expresses protein in the heart. The use of AAV is therefore a refinement compared to older virus technologies. Using intermittent warm air from a hairdryer as an unfamiliar stimulus is a painless way to elicit mild emotional stress and increased heart rate in mice.

Why can’t you use animals that are less sentient?

This project requires a source of mature cardiac myocytes that possess similar calcium handling and electrical properties to human. Mice at a more immature stage and less sentient species such as zebrafish have less developed cellular structures and different calcium and electrical properties making them unsuitable. ECG telemetry implants, although small, do require a minimum size of mouse be used therefore younger animals are not suitable. Anaesthesia affects cardiac parameters, such as heart rate, which will affect arrhythmia susceptibility, therefore conscious recordings are the preferred method.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice with ECG transmitters will be housed with non-instrumented companions to minimise stress due to loneliness. Mice will be closely monitored during recovery from surgery to ensure they are eating and their wounds are healing properly. Welfare assessment score sheets will be completed for each operated animal and record any signs of adverse effects

or suffering allowing action to be taken accordingly, such as adjusting pain medication or humane termination. Cardiac-specific expression of proteins can be achieved by intrathoracic injection of adenoassociated virus carrying a transgene, but this is traumatic and carries the risk of lung puncture or cardiac rupture. Instead, we will used a refined approach by using a virus that specifically targets the heart and that is injected via the tail vein using single-use needles. This will improve the efficiency of infection of the heart (because the virus will circulate around the entire heart, not just the peripheral surface) and reduce trauma, pain and risk of transmitting disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs Refinement resource hub for updated procedures we could implement

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date with news posted by the NC3Rs on their website, subscribe to the newsletter and regularly check the resource hub for advances in relevant techniques. We will stay in regular communication with Named Persons and animal technicians to stay up to date with developments and improvements we could make to improve animal welfare. We will receive emails from the NC3Rs regional programme manager and participate in seminars and symposia.

30. Enhancing the Effectiveness of Oncolytic Virus-Induced Cancer Immunotherapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, cancer immunotherapy, oncolytic viruses, metastatic disease, relapsed disease

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to test the efficacy of oncolytic virus based anti-cancer therapies and gain a better understanding of the regulatory systems that exist to prevent cancer therapies from working. An improved understanding of the cancer environment will allow us to design novel treatments to eradicate cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have developed novel oncolytic virus-based therapies for the treatment of cancer using human in vitro systems. However, before clinical translation can be considered it is important to validate the efficacy of these approaches using animal models that recapitulate the complexity of the tumour microenvironment and provide host cellular interactions that could influence anti-cancer responses.

Different types of cancer, or indeed cancers of the same tissue origin, have developed a range of strategies to prevent chemotherapy and/or immunotherapies from working. Moreover, the challenges that exist for the successful elimination of cancer at different stages of disease (e.g. primary cancers, metastatic cancer or relapsed cancers that have re-occurred after initially successful therapy) may also be different. Gaining a better understanding of the strategies used by cancer cells to survive will help us develop combination treatments that are effective against disease. This is important as many forms of cancer remain incurable and novel and effective therapies, that are safe and well-tolerated, are urgently required.

What outputs do you think you will see at the end of this project?

We expect multiple outputs to be obtained by the end of this project. For example, we will identify mechanisms that are used by different types of cancers to prevent therapies from working and develop novel treatments that can be translated into clinical trials to improve patient outcomes. Throughout this project, we will disseminate our findings by publishing data in peer-reviewed scientific journals and by presenting our work at scientific meetings, including local seminars and national and international conferences.

Who or what will benefit from these outputs, and how?

In the short term (within 3 years), researchers working in the field of cancer research or cancer immunology will benefit from these findings through knowledge gain. In the longer term (5-10years), we hope that the results obtained from animal models will be translated to cancer patients and that patients will benefit from the novel therapies identified (e.g., through increased patient survival and/or the development of safer and better tolerated treatments). The clinical application of safe and well- tolerated treatments will ultimately increase the quality of life for patients undergoing treatment.

How will you look to maximise the outputs of this work?

We will publish our research in high-quality peer-reviewed journals and work collaboratively with academic and clinical colleagues at a local, national and international level, to share our experience and expertise. We will also maximise outputs through the dissemination of results at relevant scientific meetings and by the delivery of seminars locally or at other universities.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use established mouse models of a range of cancers (including ovarian cancer, colorectal cancer and multiple myeloma, amongst others) to characterise the cancer microenvironment and test the efficacy of novel treatments. Mouse models will be used because laboratory studies using cancer cell lines or patient samples do not (i) recapitulate the full repertoire of complex interactions that occur within the cancer environment or (ii) provide information about optimal drug scheduling and delivery routes.

We will use both juvenile (5-10 weeks) or adult mice (>12 weeks) to test anti-cancer agents. This will allow us to determine whether there are differential responses to treatment depending on the age of the animals used. The age of mice at the start of each study will be dependent on the specific cancer model and aim of the experiment.

Typically, what will be done to an animal used in your project?

Animals will be injected with tumour cells at the start of each study and then treated with therapeutic agents. Therapeutic agents could be delivered by injection into the bloodstream, the tumour or the peritoneum. Additionally, therapeutic agents may be delivered orally, either by oral gavage or in food and water. To assess the effectiveness of treatments, tumour burden will be monitored using imaging software, blood sampling, calliper measurements (tumour size) or at the end of the study, after the animals have been killed. The method of tumour monitoring will depend on the tumour model being used. During therapeutic interventions, it is possible that mice will be subjected to multiple procedures (up to 5 times/week). The duration of established cancer models is usually between 1-4 months; however, is also dependent on the cancer model. All animals will be killed humanely at the end of each experiment and mice may be killed at specific time points depending on the research question being addressed.

What are the expected impacts and/or adverse effects for the animals during your project?

General signs of ill health will be assessed throughout each study.

Injection of tumour cells, and the resulting tumour mass, may cause some pain and discomfort. However, in our experience tumour growth is extremely well tolerated. Hind limb paralysis/weakness is a common adverse event in some cancer models (e.g., multiple

myeloma), however, with daily monitoring this symptom is observed early, and animals are humanely killed at the first sign of hind limb paralysis/weakness. Potential, but unlikely adverse effects for tumour growth and metastasis could include weight loss, hunching, tremors or convulsions or altered breathing; however, we have not experienced any of these adverse events to date. All animals will be humanely killed if they display any sign of discomfort or deterioration of health.

The administration of therapeutic agents by different routes may also cause pain and discomfort; however, pain associated with therapeutic intervention will be short lived. No adverse events are expected as a result of therapeutic intervention, except short-lived discomfort at injectable sites, during oral gavage, or following repeated dosing. It is possible that mice may develop a fever after treatment with some biological agents, although to date, we have not experienced this in any of our studies. If this was an anticipated possible side effect, mice would be monitored carefully for signs of discomfort and humanely killed if symptoms did not subside within a couple of hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals will be killed humanely at the end of the experiment and are expected to suffer no more than moderate suffering during the entire experiment. Moderate suffering is expected because of the cumulative effects of repeated procedures, although the treatment itself is unlikely to cause any adverse events except short-lived discomfort during treatment administration. Mice may also develop a fever after treatment with some biological agents, however, in our experience this is unlikely (<5% animals).

Moderate adverse events associated with injection of tumour cells, and the resulting tumour mass, may cause some pain and discomfort. However, in our experience tumour growth is extremely well tolerated. Hind limb paralysis/weakness is also a common adverse event in some cancer models (e.g., multiple myeloma). Potential, but unlikely (<5% animals) adverse effects for tumour growth and metastasis could include weight loss, hunching, tremors or convulsions or altered breathing; however, we have not experienced any of these adverse events to date.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to better understand the regulatory systems that exist within the tumour and identifying novel treatment strategies which make cancers more amenable to therapeutic intervention. Although we conduct many experiments in the laboratory to investigate the effectiveness of anti-cancer therapies, these models are not fully representative of what may happen in patients. This is because:

(i) cancer cells do not exist in isolation but co-exist alongside other cell populations which support cancer growth and development; and (ii) the response to therapy involves a complex set of interactions between different cell types and at different locations within the body. Therefore, to identify treatments that have the best chance of success when translated to cancer patients, they need to be tested in animals that model the full complexity of cancer environment and that have a fully functioning immune system.

Unfortunately, it is only possible to model simple interactions between different cell populations in the laboratory. However, this will be done as much as possible to replace and reduce animal experimentation.

Which non-animal alternatives did you consider for use in this project?

We use a range of non-animal alternatives to characterise cancer cells, the cancer microenvironment and the effectiveness of treatments. These include human cancer cell lines, human immune cells isolated from health donor blood, and cancer tissue and blood from cancer patients. We use these routinely in the laboratory, either cultured alone or in co-culture model systems to mimic cell-to-cell interactions that occur within the cancer environment. Animal work is only carried out when laboratory studies have been performed and data has confirmed that therapeutic strategies are effective against disease.

Why were they not suitable?

Cancer is a complex disease with multiple cell-to-cell interactions occurring within the tumour and unfortunately, these cannot be accurately recapitulated in the laboratory. Therefore, animal models are required to fully characterise the cancer environment and test the effectiveness of novel treatments.

Moreover, laboratory-based studies do not allow us to: 1) determine whether therapeutic agents can reach tumour sites after different routes of delivery, 2) establish the best route of delivery, 3) identify off-target effects to non-tumour tissue, or 4) optimise treatment schedules in a complete living system capable of inactivating and/or clearing drugs from the body. Taking this into account, we rely on data obtained from well-designed animal experiments to determine the true efficacy of drugs before translation into patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This animal number has been estimated based on current and planned research activity. Protocols are based on previous work where statistical differences in tumour burden or survival have been demonstrated. Typically, group sizes require 6-10 animals (dependent on mouse model/therapy) to provide sufficient power to detect statistically significant differences. In vivo passaging of cells is required for some tumour models, where this is required animal numbers are low and determined depending on the downstream experiment; typically, tumour cells obtained from one animal is enough to seed tumours in 4 recipient animals.

Where possible, we will use imaging and blood sampling to monitor tumour burden longitudinally in the same animal to avoid unnecessary killing. This will reduce the number of animals used.

As part of good laboratory practice, we will write standardised protocols for each experiment including the study objective(s), experimental plan (animal numbers/groups and schedules) and methods that will be used for downstream analyses of results. While the overall numbers of animals may appear large, 2500 animals over 5 years equates to 500 animals/year to cover a range of different research projects, carried out by multiple staff. The estimated use for protocol 2 and 3 (therapeutic intervention protocols) is 1000 (protocol 2) and 1300 (protocol 3) animals over 5 years. An additional 200 animals are expected to be required for protocol 1 (in vivo passage of cells). In total, this is the equivalent of 500 animals/year for the project.

A typical study would have a minimum of 6-10 animals/treatment group, simply testing one agent vs controls would be 12-20 animals for one small experiment, and 3 biological repeats of the same experiment would require 36-60 animals. Moreover, more complex testing of combination therapies, which requires testing of single agents as well as the drug combination, means that these numbers rise rapidly. The maximum estimated number of animals required for this project were therefore calculated are based on the last 5 years' experience of working with different cancer models, alongside current and predicted research activity.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Protocols are based on previous studies where efficient statistical differences have been demonstrated. In therapeutic studies (protocol 2 and 3) typically 6-10 animals are required

per treatment group (dependent on mouse model) to provide at least 80% power to detect differences using analysis of variance. Routine passaging of cells (protocol 1) will be decided based upon the number of animals required to generate sufficient cells for subsequent downstream studies. Normally tumour cells from one animal will be passaged into 4 recipients, with some cells remaining for the generation of frozen stocks to be used at a later date.

We will continue to re-evaluate animal numbers in line with new developments and technology. In particular, we would like to improve in vivo tumour imaging which will enable us to carry out longitudinal experiments (with repeated measurements) in the same animal, rather than having to kill cohorts to obtain the same endpoints (i.e. tumour burden) ex vivo. Advances in these areas will improve experimental design and group randomisation prior to therapeutic intervention

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continually review animal numbers throughout the course of this project license and try to establish more sensitive methods for monitoring tumour burden (e.g. imaging technology). For each experiment, we will ensure that tissue from each animal is fully utilised, this will allow us to thoroughly assess biological changes and maximise the output from each study. For example, we will endeavour to share tissue that is not needed for our study with other researchers, so all tissue is fully utilised.

For new studies, where data on therapeutic efficacy is not available, pilot studies and power calculations will be carried out to estimate the size of the likely therapeutic benefit before group sizes are finalised. Statistical advice will also be sought throughout the programme to take into account any new developments and reduce animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse tumour models

Mouse models will be used because these are the lowest form of mammal recognised as relevant for human cancer. Mice do not develop spontaneous cancer at a rate compatible

with experimentation, therefore tumour cells will be implanted into the mice. In general, we will use two types of mouse models to study cancer and the effects of new or existing cancer therapies. The first model uses mouse tumours implanted into mice with a fully functioning immune system. This is important as the therapeutic agents we test are act on immune cells (e.g. termed immunotherapies) and harness the immune system for their anti-cancer effects. Tumour models will depend on the study but will encompass models of both haematological malignancies and solid malignancies. A second model uses human tumour cells implanted into mice that lack part of their immune system or mice that have been engineered to develop parts of the human immune system. These models will be used less frequently but are important when mouse models of cancer do not closely resemble the characteristics of human disease. As tumours grow in each of these models, the health of all animals will be closely monitored to avoid pain and discomfort associated with tumour growth. If necessary, animals will be humanely killed.

Methods

Throughout this project, we will use practices that minimise stress, harm and pain to animals. For example, we will only use single-use needles for injections to avoid pain from dulled needles. For tumour cell injection we will do this via the tail vein (for models of haematological malignancies), intraperitoneally to model ovarian cancer or subcutaneously for other cancer types (e.g. colorectal cancer). After tumour cell implantation, we will monitor tumour burden using various methods depending on the tumour model, these include bioluminescence (IVIS) imaging, blood sampling, assessment of animal grith/weight, calliper measurements, and/or monitoring of disease-related symptoms. These studies will be done with and without therapeutic intervention.

All procedures are mild, and it is not anticipated these will have adverse effects. However, mice will be monitored daily for symptoms of disease or adverse events associated with treatment. Our work is based on the humane treatment of animals and all work will be carried out by fully trained staff to ensure the highest standards. Discomfort will be limited to unavoidable procedures that are required to conduct valid research. If at any time any animal is showing signs of ill health or continued distress they will be killed humanely.

Why can’t you use animals that are less sentient?

A whole organism is required to establish the effectiveness of novel anti-cancer treatments. As such, mouse models are extensively used in the study of cancer, cancer immunology and to test cancer immunotherapies. There is a wealth of information available on mouse models and they are reliable and reproducible models of the disease. Mice are also very similar to humans genetically, and the process of cancer development is conserved between mouse and humans. Mice that lack a fully competent immune system also allow the growth of human tumours and also allow us to study human disease in a living organism.

Less-sentient species (e.g., zebrafish) can be used to study tumour development; however, restricted tumour size means that are unlikely to develop the full repertoire of immune evasion strategies that prevent the immune system from eradicating the tumour. Thus, this makes it difficult to establish the true effectiveness of novel immunotherapy strategies. For our studies, which are aimed at examining the efficacy of treatments against primary tumours and/or metastatic disease, mice are the most reliable to model tumour progression and treatment delivery.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

General signs of ill health and discomfort will be assessed using the principles of the grimace scale for mice. Moreover, mice will be monitored regularly for other signs of discomfort, including any changes in behaviour, weight loss and movement. We will also attempt to identify earlier endpoints for our studies, to minimise harm and potential discomfort. To minimise harm to animals, we will strive to use refined mouse models of cancer which identify earlier endpoints that do not rely on the animals showing signs of being unwell, suffering and pain to mice. Where possible, we will use specialised non-invasive imaging techniques (carried out under anaesthesia) that can detect the disease at much earlier stages. We will make sure that each cancer model is reliable and reproducible, this will also allow earlier endpoints to be used. For example, increased monitoring around the expected study endpoints (e.g., via imaging, blood sampling, calliper measurements or detailed visual inspection for early disease- related symptoms) will allow mice to be humanely killed before significant disease-related symptoms develop. Some of these refinements will also allow reduce the number of mice required and tumour burden and biological readouts can be observed and monitored in living animals.

Only animals that are in good health will be use and animals which lack a fully functioning immune system will be housed in ventilated cages to minimise their risk of infection. Any procedures that could lead to pain or discomfort will be performed with anaesthesia or appropriate pain relief. All animals will be regularly monitored for possible adverse effects that may occur in response to the tumour growth, procedures or treatments. If required, we will seek advice from the Named Veterinary Surgeon (NVS) and Named Animal Care & Welfare Officer (NACWO) (e.g. for administration of antibiotics if an infection is suspected). Small pilot studies will be used to identify optimal treatment regimens including drug dosing, timing of therapeutic intervention and route of administration before proceeding to larger scale studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Procedures for establishment and monitoring of tumour growth, metastasis and animal welfare will follow best practice guidelines (e.g. NCRI Guidelines for the welfare and use of animals in cancer research, Workman et al. 2010 Br. J. Cancer). We will also consult the

NC3Rs website for information on the 3Rs. Published guidelines (Guidance on the Operation of the Animals (Scientific Procedures) Act 1886) which highlights recommended volumes for blood sampling and number of procedures will be followed.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I regularly receive NC3Rs online resources and updates and am a member of our local HO licence holder committee which meets regularly to discuss animal welfare and important developments. I also attend local, national and international conferences and read peer-reviewed literature to remain up to date with new advances. Importantly, animal experimentation will not be carried out until we have generated a significant amount of in vitro data demonstrating the effectiveness of novel therapies against human disease, and the appropriateness of selected mouse models.

31. Investigating the Role Of Platelets in Haemostasis, Thrombosis and Immune Response

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Platelets, Immune cells, inflammation, Haemostasis, Cancer

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the roles of blood cells, mainly platelets, in stopping bleed, heart disease and regulation of the immune system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Identifying the role of newly identified proteins/receptors in the regulation of platelet function contribute to research data that can be used in the development of effective new therapies, such as drugs that prevent strokes or excessive bleeding, and/or repurposing of clinically approved drugs that may be beneficial in other disease conditions.

The assessment of platelet function from mice whose proteins of interest have either been deleted or mutated provides a practical understanding of their involvement in diseases. Furthermore, a particular protein that may have a minor or substantial effect in isolated cells may have a greater or lesser role in the complex in the body environment where other factors may influence its actions. Thus, the true potential contribution of key platelet proteins/receptors needs to be assessed in a physiological context to understand their real-world function.

What outputs do you think you will see at the end of this project?

Our proposed programme aims to establish novel and previously unexplored (and underappreciated) roles for platelets and platelet proteins/receptors in the regulation and modulation of haemostasis, thrombosis, and the immune system, thus contributing to knowledge of genes and proteins that are candidates for cardiovascular disease. As such, our research is of relevance to and has the potential to have impact upon (i) clinical research scientists, who will use our data to screen patients for biomarkers and to inform and guide future clinical studies/trials; (ii) pharmaceutical industry researchers who could develop our disease models and transgenic animals for drug screens; (iii) Appropriate data/findings will be shared via high impact, peer-reviewed publications and we anticipate that data from this project will initiate several follow-on studies. The applicant is also very active with public outreach activities and on Twitter and it is expected that our data/findings will be of interest to online and print scientific magazines as well as charities (e.g., the British Heart Foundation and the Medical Research Council).

Our studies of the mechanisms of CVD have led us to address links between oxidised low-density lipoproteins and platelet dysfunction. Our current area of interest and expertise lies in crosstalk between the immune and cardiovascular system. Understanding these intricate systems is complex. For our research, we are using mice to make models for disease (such as sepsis and dyslipidaemia) we see in humans to examine the role(s) platelets play in the development of these disease. We are using tests to identify new drug targets and find new genes/proteins that lead to/aggravate disease symptoms. We hope that we will identify biological markers and molecules that may lead to the identification of drugs that are more effective for treatment in humans.

Who or what will benefit from these outputs, and how?

Pathological thrombosis is a major component of the pathology that underlies cardiovascular diseases (CVD) and other chronic diseases. In the UK, CVD accounts for 28% of annual deaths and is the greatest cause of mortality, killing approximately 161 000 people in 2012 (www.heartstats.org - British Heart Foundation). Furthermore, these

numbers do not take into account the thrombosis related deaths associated with diseases such as cancer and diabetes. Thus, thrombotic disease inflicts significant health and financial burden on the UK. More recently, platelets are understood to modulate the immune response to inflammation and cancer, but the mechanisms remain unclear.

In the short term, the data generated in this project will establish the role of platelet proteins/receptors in CVDs and immune response to infection, thus providing further opportunities to drive academic excellence. In the absence of key data on the role of platelet receptors, such as PD-L1, it is currently not possible to assess the effect of anti-PD-L1 drugs in the prism of platelets. Therefore, using a platelet-specific PD-L1 KO mouse model will clearly define the role of this receptor in thrombosis and inflammation. This will inform the direction of future research that we disseminate to scientists and medical doctors through conference presentations, and publication of the data in scientific journals using the ARRIVE guidelines on animal experiment reporting. As standard with good academic practice all models developed in our laboratory would be shared with the wider scientific community, both directly within our institute and wider afield. Should our work lead to refinements in laboratory practice for example as improved surgical, imaging, or experimental procedures these would be made available for other researchers to utilise.

On the long term, based on the results, selective drugs targeting platelets can be administrated, in particular drugs available on the market that can be re purposed to use in patients with CVDs and/or sepsis. Identifying a target that can reduce thrombosis and inflammation is crucial to justify a clinical trial that can reduce pain in patients, decrease organ damage and increase survival in these patients. There are also potential advantages for the pharmaceutical industry, which remain highly interested in developing agents to control unwanted platelet activation.

Our work programme, therefore, not only facilitates correct understanding of CVD and inflammation, but may also provide an avenue for effective treatment.

How will you look to maximise the outputs of this work?

We will publicise our findings to the wider scientific community, industry and the public through annual conference presentations, publications and other media.

Our work is presented on a regular basis within our institute, through research seminars, and often disseminated through academic conferences. These are used to discuss the work in progress and provides a forum with which we can discuss experimental issues (including animal welfare and phenotypes) informally with other experts in order to refine techniques and help develop best practice. The publication of our work is another major form of dissemination, where we report the findings in a more formal manner. In our recent work, we used a similar approach to that outlined in this application to identify a new mechanism of thrombosis.

We aim to publish at least two high impact publications, which build on our previous work. Upon publishing our research results in scientific journals, we will prepare press releases in collaboration with the press offices of the University. This transparency of approach to sharing data will maximise our outputs, ensure that our research activities are complementary rather than competitive and that the field moves forward as quickly as possible.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We plan to use adult mice as a model for human platelet function. Well-established and standardised tests allow our data to be compared with a large body of scientific literature. While there are subtle differences between mouse and human platelets, in most cases mice model normal and diseased processes in humans well. Through the use of genetically modified mouse models, this project also allows us to overcome the limitations that are caused by an inability to perform molecular biology on platelets, due to lack of nucleus.

Typically, what will be done to an animal used in your project?

In this project, blood will be taken from adult mice, some of which are genetically modified, and blood cells isolated to be examined in the laboratory. Some mice will be subjected to haemostatic or thrombotic in vivo assays under general anaesthesia. Under some protocols, adult mice might be fed a special high fat diet that mimics Western-styled food, for up to 4 months, to examine the effect of such diet on blood cells. In other protocols, adult mice might be injected with agent(s) to provoke an immune response to investigate the complex relationship between platelets and the immune system.

What are the expected impacts and/or adverse effects for the animals during your project?

None of the mouse strains that we currently hold or are interested in bringing in under our project licence have an overt or adverse phenotype under normal conditions. However, there are three areas where adverse effects may be anticipated.

1. Dietary manipulation - on rare occasions some mice find high-calorie diets unpalatable and begin to lose weight. Mice will be monitored daily for their general well-being and weighed on a weekly basis. Should an animal show signs of distress, it will be

removed from the study and returned to a normal diet. If the distress continues, the animal will be culled by a schedule 1 procedure.

2. Administration of substance - There could also be potential impacts of administration of substances designed to influence the recruitment and/or function of circulating platelets and/or immune cells. Substances will be administered where dosing and potential toxicity data are available in the mouse or similar species. If adverse effects are suspected or reached the maximum allowed score (protocol 5), the animals will be withdrawn from the study. If the adverse reactions persist, the animals will be killed by a Schedule 1 or other method stated in the protocol immediately. As data is collected, we will review the protocol to ensure that the severity limits are appropriate.

3. Recovery during anaesthesia - The severity of this procedure will be controlled through the use and careful monitoring of general anaesthesia throughout. There is a possibility the animal recovers prematurely from anaesthesia, although this would be a relatively rare occurrence. To prevent premature recovery from anaesthesia there will be continuous monitoring of the depth of anaesthesia by testing the limb flexion/withdrawal reflex and/or the corneal reflex, which will be supported by continual monitoring of heart rate and body temperature. Should there be suspicion that the animal is recovering prematurely additional anaesthetic will be administered by inhalation. However, it is noteworthy that this has not occurred during the procedures performed in the last five years and therefore we do not anticipate this to be a common occurrence.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of our procedures is categorised as non-recovery, mild or moderate. The majority of our procedures (>80%) are carried out under non-recovery, while the remaining procedures (<20%) will be either mild or moderate.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although we are committed to using non-animal methods wherever possible, it is difficult to mimic integrated physiological processes and behaviour in in vitro systems, in addition to ethical limits on human experiments. Often using animals is the only means of achieving the objectives of experiments. Moreover, the study of blood platelets is dictated by three limiting factors.

1. We minimise the use of animals by using platelets from human volunteers. However, the experimental approaches that we can use with human platelets are limited. This is because platelets do not contain genetic material (i.e. DNA). This means that they cannot be grown in culture and cannot be modified through standard genetic techniques used in other cell types. Mouse gene knockouts provide a powerful approach to understand the role of a specific gene in platelet function. This cannot be replicated with human platelets.

2. Complete replacement of immune-challenged animal models is difficult. The conglomerate of immune responses associated with infection or cancer is too complicated to model in cell culture systems. This is coupled with the inability to culture platelets ex vivo.

Therefore, the use of genetically altered knockout mice to identify and delineate the pathways involved in platelet activation is required. Our laboratory is committed to performing work with animals only when the potential biomedical advances warrant this. We are interested in developing new approaches that would reduce the use or generation of genetically altered mice to study platelet function, and we are closely monitoring studies in other laboratories that have begun to examine ways to produce genetically modified platelets (using siRNA technology) in vitro from bone marrow culture. Should this technology become available, we will look to adapting it for our own studies.

Which non-animal alternatives did you consider for use in this project? Pharmacological inhibitors that target specific proteins/receptors using human platelets. Why were they not suitable?

In vitro studies using human platelets and pharmacological inhibitors are showing a great deal of promise to study platelet function. However, this model remains imperfect and fail to capture the complexities of human body, which involve complex interactions between many different cell types, and in many cases communication between the vascular and immune system

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In the types of studies we perform, the anticipated response is usually “all or nothing", that is the genetically modified mice fail to respond to stimuli when compared to the wild type. Therefore, the numbers for in vitro studies of our programme are calculated based on the number of samples we can prepare per mouse. For example, the blood from each animal provides approximately 1 ml of washed platelets which is sufficient to prepare for four samples. With this knowledge, we can extrapolate the appropriate number of mice required by determining how many samples are required for each series of experiments within our project. Under these controlled conditions we aim to use approximately 6 mice per strain per assay (and 6 control animals) since platelet responses are generally very reproducible.

In general, we use between 10 and 15 assays during our functional evaluation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design is driven by studies performed on human platelets, which act as a guide to the potential importance of key proteins in the function of platelets. Careful analysis of the data emerging from these experiments will determine the need for experiments in animals. It is noteworthy that the experiments performed under this licence are discovery science and so very little information is available to guide our calculation of numbers. However, based on your experience of performing similar studies in mice in the past, we can reasonably estimate the lowest number of animals to gain meaningful results and whether extensive experiments using multiple in-depth assays are required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have a number of strategies for optimising animal numbers.

1. The key step is the generation of pilot data from in vitro functional assays. Lack of phenotype in these assays (usually between 10 and 15 assays) prevents mice from being used in experiments that require dietary manipulation and reduces the breeding of mice.

2. All other tissues (e.g; muscles) from mice sacrificed under any of the protocols are available for other researchers within our institute.

3. Tissue (e.g; kidneys, heart, liver) and whole blood analysis will be performed following schedule one of our immune-challenged animal model (protocol 5). This will greatly reduce the number of animals sacrificed and provide more meaningful data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project, we will use mice (wildtype and genetically modified) mainly bred on a C57/BL6 background. Initial animal health will be verified prior to importation to ensure the welfare of the animals. No experiments are performed on newly imported animals for at least 7 days. Mice will be bred and maintained in our facility at the University of Hull. Our breeding facility is meticulously maintained by qualified staff that implements rigorous health checks on mouse colonies, minimizing the risk of infection. Experiments will be performed to investigate the role of blood cells in haemostasis and immune response. Currently, the mouse haemostatic and immune systems are considered a strong model for that found in humans and has the advantage of genetic manipulation. However, there are a number of areas where we have refined our programme of work.

Protocol 1. We have now established ear punching for biopsy collection. We use ear punch for identification purposes and the resulting sample is used for genotyping. This is kept to a minimum if modified strains we use are bred as homozygous coupling meaning that only the initial parentage requires identification and genotyping and beyond this, it is performed in a random fashion. Hair samples might be used for genotyping should we find the data reliable and accurate. Our genotyping data will be verified by determining the absence of the deleted protein(s) from platelets using Immunoblotting. Animals are kept under supervision following biopsy until the bleeding has ceased. If bleeding does not cease within 15 minutes without intervention, or if the application of pressure to the wound does not cease bleeding, the animal will be culled by an approved schedule 1 method. Should excessive bleeding occur during ear punching for biopsy, the affected strain of mice would not be subjected to tail bleeding assays (protocol 2) to avoid any excess suffering.

Protocol 2. This procedure is performed under terminal anaesthesia as a non-recovery protocol in order to avoid subjecting the mice to a painful procedure. To avoid excessive bleeding and stress for the animal, we restricted the procedure to 20 minutes or 15% blood loss- based on a circulating blood volume of 1.5-2.5mL (whichever happens first). At which point the experiment is stopped and the animal is humanely culled (Schedule 1 method). We will also adopt other methods to quantify bleeding time measurement (e.g. OD and HB measurement following bleeding- time measurement). Cross- validation of our data will result in less variation and thus fewer animals will be used.

Protocol 3. As part of refining our procedures and reducing animal usage, we have moved over to using tail vein injections for the delivery of antibodies for the labelling of platelets. This refinement is much quicker and less invasive than other methods (give examples), minimizing any pain the animal might encounter. Moreover, this allows us to use both carotid vessels for thrombosis assays and will therefore reduce the number of animals required.

Advice will be sought from the NVS and NACWO about new advances and developments in surgery procedures and/or anaesthesia that might lessen the pain for mice. In all cases, at the end of Protocol 2 and 3 animals will be swiftly and humanely killed to minimize the severity of the procedure.

Protocol 4. High-fat diets can induce severe phenotypes in genetically modified mice designed to provoke extreme hyperlipidaemia. We have avoided specifically these “diet-sensitive” mice and used a very short-term feeding regime. This approach, if successful, will allow us to develop models of disease that more accurately represent the human disease condition without having to keep mice under long feeding regimes in which serious health issues are known to occur.

Protocol 5. For our model, we will use established protocols that invoke immune challenge in mice. Animals will be routinely monitored and checked against a comprehensive list of clinical signs and symptoms. Animals that cross our severity threshold will be culled immediately using a Schedule 1 protocol. To minimise unnecessary suffering, strains that are known to tolerate immune-challenge will be used. Clinically relevant signs will be used to assess animals as an endpoint instead of death.

Sublethal doses of LPS will be used (see protocol 5).

Why can’t you use animals that are less sentient?

Less sentient animals such as fish or frogs are not appropriate for our research as these differ in their haemostatic and immune response.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The major refinement to our protocols is in the area of in vivo thrombus formation. We have now moved away from cannulating the carotid artery to inject antibodies to label cells (platelets), and we are now using tail vein injection instead. The success rate of cannulating the tail vein is significantly higher and more reproducible, thereby reducing the number of mice required for experiments.

Furthermore, since this procedure is performed under terminal anaesthesia, it minimises suffering in the mice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Major guidance through the project is taken from the NC3Rs, whose website (hubs and microsites) provides a vast array of resources on the general principles underlying the experiments highlighted in this project; this includes anaesthesia, breeding strategy and numbers, and experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use regular literature searching and the NC3Rs website to gather up to date information about advances in animal research. This information will be disseminated to anyone involved with this licence including the project licence holder (PPLH), personal licence holders working under the licence (PILs) and named animal care and welfare officers (NACWOs) and implemented where appropriate.

Rabbits	juvenile, adult
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The major aim of this work is to increase our understanding of atherosclerosis, a disease characterised by the accumulation of fat (especially cholesterol) within the arterial wall. Subsidiary aims are to improve ultrasound-based methods for measuring details of blood flow near the arterial wall, since the development of the disease depends on such details, and to improve the similar, ultrasound-based methods for measuring pulse waves in arteries, since these can be used to assess risk factors for the disease and also consequences of the disease such as heart failure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Atherosclerosis is the main underlying cause of heart attacks, strokes and peripheral artery disease and is thereby one of the largest causes of morbidity and mortality in Western countries, and increasingly important in developing countries, despite the availability of drugs that lower classical risk factors such as high blood pressure and high cholesterol levels in blood. We need more information about how the disease develops in order to design new ways of intervening in the process. The information we need includes details of blood flow, and we are developing new techniques for their measurement. These techniques have other uses, including in diagnostics. Concerning the simple, low-cost detection of heart failure, there is a clear unmet clinical need for this. For example, 75% of patients with heart failure in the UK are diagnosed as a result of an acute hospital admission, even though 50% had been to their GP with symptoms in the previous 5 years.

What outputs do you think you will see at the end of this project?

If all the projects receive funding , outputs would be: (i) identification of new pathways that control the rate at which cholesterol enters the arterial wall from blood, (ii) identification of possible points or molecules that could be used to modify such pathways, (iii) determination of whether the data obtained in the aorta are also relevant to the more clinically relevant coronary arteries, (iv) algorithms for measuring the stresses imposed on the arterial wall by the flow of blood, and for measuring properties of pulse waves in arteries, by ultrasound, and (v) data on such stresses and pulse waves. We aim to publish all our data as full papers in refereed scientific journals.

Who or what will benefit from these outputs, and how?

In the short-term, our data will benefit other research groups investigating how arterial disease develops, or attempting to measure arterial blood flow or pulse waves. In the long-term, the pathways may lead to new therapies for reducing atherosclerosis, and the methods may lead to new techniques for diagnosing disease.

How will you look to maximise the outputs of this work?

Our work is highly collaborative, including other principle investigators in this Department with expertise in cell signalling or ultrasound, and with collaborators in Aeronautics who are experts in flow. Knowledge is disseminated through publication in scientific papers (I have published >100) and, more rapidly, by attending conferences. Unsuccessful approaches are discussed in our papers.

Species and numbers of animals expected to be used

- Mice: 150
- Rabbits: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

When we examine fundamental processes that should apply to the same cell type in any mammalian species, then we use mice. For example, mice are used when examining the fundamentals of the transport of cholesterol across the cells that line the inner surface of our vessels, forming a barrier between blood and the underlying wall. (Cholesterol and other fats do not dissolve well in blood, and they are therefore transported bound to proteins, as part of particles call lipoproteins.) We use rabbits when we examine specific pathways the might form a link between blood flow characteristics and arterial disease. That is because the characteristics of blood flow scale with body weight; stresses in rabbits are much closer to the stresses occurring in people and indeed we have validated that they are sufficiently similar for this purpose. Mice are not. Finally, we use rabbits for the ultrasound methods simply because their larger size gives us better resolution compared to the dimensions of the arteries.

Typically, what will be done to an animal used in your project?

There is a range of procedures. (i) In the simplest, an animal might receive an intravenous injection of a blood thinning agent so that arterial tissue can be harvested after death without blood clots forming.

(ii) For the measurement of flow and pulse waves, the animal would be terminally anaesthetised and then ventilated, allowing imaging to take place without animal movement. Drugs are sometimes given under terminal anaesthesia (i.e. anaesthesia without recovery) to modify the properties being imaged.

(iii) A very common procedure is the give an injection into a vein of a naturally occurring molecule with a dye attached to it. This is allowed to circulate for times up to a few hours, and then the animal is given the blood thinner, anaesthetised, and its blood vessels chemically "fixed" at the same time that the animal is killed, so that we can measure how much of the tracer was transported into the wall. ("Tracer" means a small fraction of molecules of one type that are labelled so that they can be followed

- for example by attaching a dye to some of the lipoproteins mentioned in the preceding section.) In some of these experiments, the animal might additionally be given a non-harmful drug orally or intravenously in an attempt to modify movement of the tracer. (iv)

Less commonly, vessels are perfused with tracers, and sometimes drugs, after cannulation in situ under terminal anaesthesia. (v) The most complex experiments involve feeding an animal a cholesterol-enhanced diet for several weeks in order to induce mild atherosclerosis. Again, drugs might also be given to modify the disease, either orally or through the implantation of small pumps under the skin. The latter involves recovery surgery, but the pumps (which resemble capsules) are small and recovery is rapid. Again, drugs are non-harmful.

What are the expected impacts and/or adverse effects for the animals during your project?

Almost no adverse effect is expected from any of these procedures since they involve only oral or intravenous administration of non-harmful substances, procedures under terminal anaesthesia, or administering diets that induce only the early stage of arterial disease, withoutu symptoms. Mature rabbits are sometimes reluctant to switch diets and this may result in weight loss - methods for stimulating appetite will be used in such cases. Administering drugs during the induction of disease involves recovery surgery if the dugs require the insertion of pumps under the skin - this is a standard procedure and adverse effects can be alleviated by simple pain-reduction routines.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rabbits 27% mild, 40% moderate, 33% non-recovery

Mice 47% mild, 20% moderate, 33% non-recovery

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Arterial disease and the processes on which it depends, including subtle features of blood flow or transport properties of the arterial wall, can only be conducted in vivo; the circulation, and indeed the fat metabolism of the animal, need to be intact. The same applies for determining whether imaging methods can be useful for measuring blood flow

or arterial waves in vivo - blood needs to flow, pulse waves need to propagate, and overlying tissue needs to move and generate noise for this to be assessed.

Which non-animal alternatives did you consider for use in this project?

The animal-based work is supported by other types of work. Cell culture is used to study mechanisms at the molecular and cellular level. For example, FSTL1 was indentified as a target through such experiments. We have applied for funding to continue such work e.g. to identify other targets. We use in silico methods (computational fluid dynamics) to simulate blood flow, but such simulations require acurately defined inflow, outflow and geometric "boundary conditions" that can only be obtained in vivo. We are already testing early versions of our heart failure diagnostic methods in patients, but animal work is required to further refine the methods and to compare the results with "gold standard" data obtained using invasive techniques such as arterial catheterisation. Finally, we aim to submit a grant proposal for a study examining aortic geometry and disease location in cadaveric human specimens with abnormal spinal curvature, such as scoliosis; this would be expected alter the pattern of blood flow (which we can compute) and, if our theory is correct, disease location should change in a corresponding fashion.

Thus we have considered using computers to simulate blood flow, measuring permeability of the cells lining the arterial wall in culture, and testing imaging methods in models such as latex tubes with artifical blood flowing through them. These are all excellent methods and we routinely and extensively employ them in our work but they cannot fully replace the use of animals, especially in studies of the effects of mechanical stresses and drugs on transport and disease, for which an intact organisms is required. The early stages of the disease, which is the focus of our research on arterial disease, are unfortunately too mild to be imaged non-invasively in people, e.g. by MRI scans.

Why were they not suitable?

These systems only give preliminary answers; the insights obtained from such methods are essentially hypotheses that need to be tested in vivo because the models do not completely replicate the complexities of intact physiological systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have submitted a grant application to study arterial disease which proposed the use of 62 rabbits. This typifies the numbers used per grant. We have several more proposals in preparation but it is not possible to say how many will get funded. As an estimate, therefore, 50 animals of each species have been included in each protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Effects of each drug tend to be tested separately, due to the nature of the funding stream, and are therefore tested simply as experimental versus control. (Controls will be shared for two or more drug groups when this is feasible.) The size of each group is calculated according to the minimum useful size of the effect, the variation between animals and the statistical power that is required. (Effect sizes are taken as 20% since smaller effects would be hard to detect in clinical trials if translated to human subjects.) In some cases this produces very low numbers (e.g. 2 or 3), which causes great difficulty when attempting to publish the work; in such cases we use the minimum number that is acceptable to journal editors and referees.

The ultrasound trials are exploratory and cannot be quantified in this way: the minimum number is used to develop the technologies. No further animals would be used when, say, the device produces measurements with sufficient discriminatory power for the results to be useful, or when this has not been achieved but there are no practicable methods for further improvement.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Tissue is stored for future use (e.g. for staining of molecules to identify future drug targets). Tissue from other organs is shared with groups within our Department. Pilot studies are conducted when administering drugs of unknown efficacy.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Models are: mice and rabbits, vessels cannulated and perfused in rabbits under terminal anaesthesia, genetically modified mice that develop arterial disease, and rabbits fed a

cholesterol-enhanced diet. All drugs administered to conscious animals are non-harmful and all diets are administered for durations that induce only asymptomatic disease ("fatty streaks"). There is very slight pain due to intravenous injections. Pain arising from an aseptic implantation of osmotic minipumps under the skin that is effectively controlled by the administration of suitable pain relief as recommended by the establishment vet.

Why can't you use animals that are less sentient?

Most procedures do not involve any pain or harm, or are conducted under terminal anaesthesia, so these considerations do not apply. Animals have to be sufficiently old for diets that induce arterial disease to be administered. Species are the least sentient that are known to develop atherosclerosis with the spatial distribution that we require: only rabbits are known to show the age related distribution of lesions around branches that are seen in human aortas. For studies where these distributions are not important (e.g. when investigating fundamentals of transport across the layer of cells lining blood vessels), mice will be used. We would not wish to use cold-blooded species since their lower temperatures will affect the physics of transport. For example, diffusion of molecules through the gaps between cells is highly dependent on temperature.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals undergoing implantation of pumps under the skin are given pre-emptive analgesia. For animals that are administered diets to induce arterial disease, dietary supplements are increased gradually. If there are signs of adverse effects despite these precautions, alleviation will be provided,

e.g. temporary return to a normal diet, or an increase in analgesics after osmotic minipump insertion, and appropriate humane end points applied if necessary.

During the course of regulated procedures, animals may be transferred to other sites within the primary Licensed Establishment. Such transfers will only be undertaken where scientifically justified (e.g. where tissues or cadavers will not suffice); only if the animals have been inspected by a competent person and deemed to be in a suitable condition to be transferred; the transfer is conducted in a manner to minimise distress and there is no reason to believe the animals will suffer as a consequence of the transfer. The Home Office will be promptly notified of any unexpected welfare problems associated with transferring animals. In order to ensure that any additional harms to the animals associated with transport, and any potential effects on the quality of the science are both minimised, the following post-procedural recovery and acclimatization guidelines will apply. Normally, medically and surgically prepared animals will be allowed a minimum procedural or post-operative recovery period of 7 days prior to transfer and all animals will be allowed a minimum acclimatisation period of 7 days at the destination campus, prior to any subsequent use in regulated procedures. These periods may be varied, subject to the prior written approval of the NVS, in cases where there is a clear justification for this.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult guidelines of the Laboratory Animal Science Association for dosing volumes and resources of the National Centre for the Replacement, Reduction and Refinement of Animals in Research for techniques. Since many procedures are conducted under anaesthesia, the correct administration of anaesthesia is critical. For this, we follow standard textbooks and information for vets/veterinary nurses in small animal anaestheia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through reading of the scientific literature and through information and courses promoted by the institution, and by signing up to the NC3Rs newsletter. Note also that I have lectured to undergraduates on animal models and on animal welfare whilst at a previous University.

33. Genetic and Environmental Regulation of Adiposity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Diet, Adipose tissue, Genetics, Zebrafish

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to utilise zebrafish as a model organism to better understand how genetics and environment interact to regulate fat tissue traits such as (i) body fat levels (such as in obesity), (ii) distribution of fat accumulation in different areas of the body and (iii) function of the body fat in the context of obesity and associated disease. This work will help us to understand genetic predictors of disease risk, how they interact with the environment (e.g., diet) and identify new potential therapeutic targets to treat obesity-related disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The majority of adults in the UK are either overweight or obese (67% of men, 60% of women, NHS statistics 2021). Obesity is a primary risk factor for many 'cardiometabolic' diseases including cardiovascular disease and diabetes, along with cancer and neurodegeneration. However, we currently do not have sufficient knowledge on how the genetic makeup (or genotype) of an individual can cause obesity and how an individual's genotype interacts with an obesogenic environment characterised by high-calorie diets and low levels of physical activity. This limitation hinders our ability to predict obesity-related disease and design new therapeutics to alleviate obesity-related disorders. Obesity is characterised by increased body fat (adipose), and it is the quantity, composition and regional distribution of body fat which are primary drivers of disease risk in obesity. Body fat levels, distribution and composition are heritable and have a strong genetic basis. Therefore, it is important to identify and understand the genetic factors that regulate body fat levels and distribution. The zebrafish model system has many similarities to human and can be used to model the cellular, molecular and genetic mechanisms underlying obesity-related diseases in humans. Importantly, using zebrafish has several experimental advantages for studying body fat and obesity-related diseases. Undertaking this work will provide new understanding of genetic risk for obesity-related diseases and will therefore benefit a large section of the general public.

What outputs do you think you will see at the end of this project?

This project will teach us how genetics can contribute to obesity and cause obesity-related disease. We will identify specific genetic mutations (which we are born with and inherit from our parents) which

(i) influence an individual's propensity to become obese, (ii) influence how body fat is regionally distributed and (iii) how body fat functions. Collectively, these determine an individual's susceptibility to suffering from obesity-related disease. In particular, we will understand how body fat responds to an obesogenic environment (in the form of high-calorie diets and increased eating). For example, we will identify if a specific gene mutation causes more belly or leg fat to expand in obesity. It is these differences in body fat distribution which can exacerbate obesity-related disease. We will publish our findings and experimental insights in scientific journals which will be open access to the public. We will present our research findings at scientific conferences to disseminate information to the scientific community, and we will also undertake public engagement activities to disseminate our research to the general public. We will work with academic and industrial collaborators to help progress obesity-related drug development projects. Our long-term

goal is to understand obesity and associated disease and identify new treatments to predict and ameliorate obesity-related disease.

Who or what will benefit from these outputs, and how?

This project will benefit numerous groups including, the scientific community who will benefit by obtaining new information relevant to obesity and obesity-related disease which will augment their own research findings. This knowledge exchange will accelerate the development of obesity-related treatments. Pharmaceutical companies will also benefit in a similar way to this knowledge exchange which will further accelerate the development of obesity-related treatments. This project will utilize genetic data from humans. As such, our results will be directly relevant for patients and the wider population, and also provide new therapeutic targets to modulate disease risk. With the dawn of personalized medicine, the identification of important disease-associated genetic elements by this project will enable prediction of obesity-related disease risk in patients prior to actual disease onset.

The general public will also benefit from knowledge garnered during this project which will contribute to better understanding of risk for obesity and disease.

How will you look to maximise the outputs of this work?

We will maximise the output of our work by collaborating extensively with research groups bringing experience of human clinical genetics. This interaction will enhance our ability to identify genetic mutations that are associated with obesity. It will be this clinically relevant information which we use to develop models in zebrafish. We will make our findings publicly available through open access publications, and will present our work at local, national and international scientific meetings. We will work closely with funders (including the MRC and also medical charities) to disseminate our research findings to the general public.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 35,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using zebrafish as a model system to understand how genetics and environment contribute to obesity and obesity-related disease. Zebrafish are an excellent model for studying obesity and related disease and have extensive genetic and physiological similarities to humans. These similarities mean that disease causing mechanisms are often shared between zebrafish and humans and so the information we uncover will be

relevant for human disease processes. This high level of conservation also means that any drugs identified to treat disease processes in zebrafish might also be applicable to humans. In addition to similar disease processes, zebrafish are also a good model system because they offer a robust and tractable model to test the function of obesity genes – it is relatively straightforward to genetically alter zebrafish and test very specific obesity gene mutations. Further, zebrafish are highly amenable to imaging tissues that are implicated in obesity. For example, we can see into body fat to understand how it responds to obesity, and we can see into the brain to understand how they might influence appetite and obesity susceptibility. We mainly use young zebrafish at the larval and juvenile post-embryonic stages which provide a simple model and allow us to test our specific ideas in a relatively simple system. Together, these advantages of the zebrafish model allow us to obtain useful information on obesity genes and susceptibility to obesity-associated diseases.

Typically, what will be done to an animal used in your project?

One of the main advantages of using the zebrafish model is that we can conduct non-invasive imaging of tissues implicated in obesity and obesity-related disease. With this in mind, the majority of animals in this project will be genetically altered to encode fluorescent proteins in their genomes which allow us to visualise specific cells and tissues that are relevant to obesity and associated disease (e.g., fat cells or neurons that control appetite). Zebrafish will also be genetically altered to carry potential obesity- causing mutations that have been identified from human clinical and genetic studies. By using these two types of genetic alteration we will be able to test whether a specific mutation/genotype affects obesity or disease and visualise the process in cells and tissues. This methodology will allow us to gain new information on these obesity genes. In addition, we will also perform diet manipulations to test whether for example exposure to a high-fat diet or over-feeding will modify the function of the obesity genes.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of our experiments will be non-invasive and without any signs of adverse effects for the zebrafish. With a small proportion of the diet manipulations, we will be inducing a mild form of pre- diabetes characterised by increased blood sugar levels. It is important that we induce these very early signs of diabetes and obesity-related disease as we wish to understand the physiological response to this diet. However, these are very early signs of disease without any strong adverse effects and experiments will be halted prior to any strong adverse effects within a few weeks of the onset of symptoms. For some of the diet manipulations we may induce weight loss by food restriction. However, zebrafish are remarkably resilient to food restriction and no adverse effects are observed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not study animals with severe adverse effects. However, prolonged administration of a high-fat diet can induce increased blood glucose and insulin resistance which we would classify as moderate adverse effects. Even though we are inducing these symptoms, we would study these animals over a relatively short period of time so that any damage to organs or tissues would not manifest and disease severity would not progress. We expect that less than 1% of animals which are part of this project would experience moderate adverse effects. We study animals with mild adverse effects, such as mild stress or physical restraint to facilitate imaging. However, a relatively low percentage of animals would experience mild adverse effects (less than 5%). The vast majority of animals will not experience any detectable adverse effects (greater than 90%) and most are kept for breeding and maintenance with no evidence for suffering or adverse effects.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Obesity is a complex physiological trait involving cross-talk between multiple organ systems. For example, mutations that influence the function of neurons within the brain may control our appetite and how much we eat. Whereas, mutations which function within fat cells may govern how the fat cells respond to obesity. The cross-talk between these systems determines our susceptibility and response to obesity. As such, it is difficult to effectively model these responses in vitro in a culture dish. However, in zebrafish we use a relatively simple model to understand these interactions but which faithfully recapitulate interactions that occur in obesity.

Which non-animal alternatives did you consider for use in this project?

In this project, we will also utilize culture of human and mammalian cell lines wherever possible. Cell culture systems are very useful for studying responses in single cell types and autonomous responses. However, to properly understand obesity and body fat levels, composition and distribution, laboratory animals must be used that recapitulate the interactions that occur in the physiological context of a highly complex living system.

Why were they not suitable?

To properly understand how genotype and diet interact to regulate body fat levels and distribution it is necessary to conduct in vivo experiments and model systems that recapitulate the interactions that occur in the physiological context of a highly complex living system. For example, for studying fat distribution it is not possible to culture multiple fat types together and assess interactions leading to fat distribution differences in obesity – this must be done in a living physiological system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have calculated the number of animals that we are likely to use based on our current use of zebrafish as a model system. Of the animals we project to use, the majority are for breeding and maintenance purposes (PROTOCOL 1). We have calculated the projected number of fish, based on our current use of approximately 150 tanks of zebrafish per week, in which we keep an average of 20 fish. We aim to refresh stocks once per year, meaning that we will use 5 separate generations of each stock over the course of the project, giving a total of 15,000 animals.

For PROTOCOL 2 we project use of up to 6,000 zebrafish for the generation of new genetically altered animals. This number largely reflects the new ability to target gene function at scale using new tools, including CRISPR/Cas9 gene editing. We plan to test the effects of 250 genes over the course of this project using an average of 20 animals per assay – this will require 5,000 animals. We will also generate stable mutant lines from genes that exhibit particularly important functions when assessed by acute gene editing, and expect to generate up to 20 such lines, with current estimations that we need to grow up 50 animals to successfully do so (1000 animals). Thus, we estimate that we may use up to 6,000 animals in total for PROTOCOL 2 .

In addition, we predict using a further 8,000 animals for our experimental analyses (PROTOCOL 3). We plan to use 8,000 animals for live imaging, photostimulation and induction studies as part of PROTOCOL 3 and this estimate is calculated based on current usage of analysing ~80 experimental groups of ~20 animals over the course of this 5-year project.

For PROTOCOL 4 (diet manipulations), we plan to use 6,000 animals based on current usage. Of these 6,000 animals, we estimate that 3,000 will be used for immersion in a high-fat diet solution (25 experiments using 25 animals per group), and 1,000 animals used each for the food restriction, overfeeding and high-fat powder diet manipulations (8

experiments using 25 animals per experimental group). We carry out very careful calculations to define how many animals are needed to find statistically meaningful effects in our experiments, and will continue to do so for new studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Firstly, wherever possible we will utilize zebrafish at unprotected stages (5 days old and younger) to reduce the number of animals on experimental protocols. For example, we can visualise the neurons in the brain that influence appetite at 4-5 days old and we have shown that manipulation at these stages can influence feeding almost immediately. Secondly, we will control experimental variability by utilising precisely stage-matched individuals for experimental comparisons. We have established criteria for these stages previously and these are now standard for the field. We will also control fixed effects such as housing, diets and husbandry by consulting with professional husbandry staff and using well characterised inbred zebrafish strains. Thirdly, in the diet manipulation we make use of randomisation to distribute inescapable differences between individuals randomly across the groups. Fourth, we will make use of non-invasive longitudinal imaging of zebrafish which allows us to perform a repeated measures experimental design. By taking two or more measurements for each animal over time we can effectively control for inter-individual variation, improve experimental efficiency and reduce animal numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will work closely with other research groups to ensure the efficiency of our transgenesis and mutagenesis is optimal. By doing so, we will keep up-to-speed with the latest technological developments and improvements in efficiency which will ultimately reduce animal usage. We will also work closely with professional husbandry staff who are optimising diet and other husbandry procedures to minimise variability across fish stocks and ultimately reduce the need to raise large numbers of fish for experiments. Where possible we will conduct pilot experiments to ascertain exact experimental conditions and sizes of effects which will enable us to more accurately predict sample sizes needed and will ultimately reduce use of zebrafish.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using the zebrafish model to understand how genetics and environment interact to regulate obesity and associated disease. Zebrafish are an ideal model system to study obesity and related disease owing to a high degree of conservation to mammalian disease processes, coupled the ability to non-invasively image relevant fat cell types in living animals without perturbing the endogenous physiological context. This experimental advantage represents a significant refinement of methodology as equivalent techniques in mammalian models requires surgical implantation of an imaging window which not only causes suffering and distress to the animal but also initiates an inflammatory response. Owing to zebrafish transparency and their small size, the imaging method we employ is entirely non- invasive. An additional refinement is the simplicity and high efficiency of genetic manipulation in zebrafish. These methodologies allow us to generate transgenic lines that enable to visualisation of specific cell and tissue types, and also allow us to engineer specific mutations into the zebrafish genome that allow us to model human obesity mutations. These methods are non-invasive and can be conducted in the externally fertilised eggs, with any potential adverse effects owing to the methodology ascertained prior to reaching protected stages. To aid further refinement we will continue to research new methodologies and work together with husbandry staff to develop and implement new practices that bring refinement to existing techniques.

Why can’t you use animals that are less sentient?

Body fat and regional adiposity is a bony fish innovation (ie, it evolved along with a bony skeleton). Therefore, zebrafish are one of the simplest and less sentient organisms which possess regional body fat. Further, we use zebrafish at the earliest stages where body fat appears and so are arguably less sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The vast majority of our experiments are non-invasive and do not cause any adverse effects. However, we implement a robust monitoring system to record and monitor any potential adverse reactions. For example, when conducting diet manipulations we keep a daily monitoring record along with multiple checks throughout the day on the welfare of the animals on the special diet. This allows us to respond quickly and effectively to any adverse effects. We will continue to revise and improve on the monitoring.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow and implement the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines issued by the NC3Rs. Further, we will keep abreast of developments

in the scientific literature which will be the best source to identify refinements to existing methods.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We follow news from the National Centre for the Replacement Refinement & Reduction of Animals in Research (NC3Rs), and also discuss with local vets and named animal care and welfare officers.

Importantly, we stay informed of the relevant scientific literature for methodology development and refinements.

Domestic fowl (Gallus gallus domesticus)	adult, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Infectious bronchitis virus (IBV) causes a respiratory disease in chickens. It causes economic losses and is a risk to food security as infected chickens do not gain as much weight or produce as many good quality eggs as uninfected chickens. IBV is prevalent throughout the world and there are many different strains of the virus circulating. Currently available live attenuated vaccines are not able to protect chickens against all of these strains and have the potential to revert to a more virulent form.

The aim of this project is to produce a rationally attenuated IBV vaccine vector that can be modified for the production of effective vaccines against a variety of IBV strains belonging to different serotypes. In order to achieve this aim, we have three objectives:

1. To identify pathogenic determinants present in the IBV genome.

2. To identify immunogenic determinants present in the IBV genome.

3. To determine the protective efficacy of IBV vaccine candidates.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The avian coronavirus, infectious bronchitis virus (IBV), is a highly contagious poultry pathogen prevalent in all types of poultry flocks worldwide and is responsible for economic losses, welfare problems in chickens and a potential risk to food security. IBV preferentially causes respiratory disease, but can also infect other organs such as the kidneys (resulting in kidney disease) or the reproductive tract (resulting in loss of egg production and/or egg quality).

IBV is the aietological agent of infectious bronchitis; an economically important infectious disease affecting chickens in the UK. It is estimated that IBV affects 22 million chickens and costs the UK poultry industry £23 million every year. Poultry is an important food source worldwide; with an estimated 55 billion chickens produced worldwide per annum, including 5 billion for egg production.

What outputs do you think you will see at the end of this project?

Outputs of this work will include new information regarding pathogenic and immunogenic determinants within the IBV genome. Outputs may include the generation of genetically modified IBVs that have potential to act as live attenuated vaccines against multiple serotypes. We always aims to publish our work in scientific journals in a time appropriate manner therefore outputs will also include publications. This ensures the scientific community remains up to date with the results that we produce. We will also file patents for any results that may have commercial potential/impact.

Who or what will benefit from these outputs, and how?

Our work uses the host species that IBV affects and therefore is of direct benefit for the development of IBV vaccines to protect chickens against this disease. All commercial chickens are vaccinated against IBV. Vaccine breakdown has a major effect on the UK poultry industry, not only financially, costing £23 million every year, but also affecting bird

welfare and risking food security. This work will establish whether our novel approach to vaccine design through rational attenuation and modification of vaccine serotype is capable of producing safe and efficacious vaccines for the control of IBV that are less likely to revert to virulence. The development of safer vaccines will reduce the amount of antibiotics used to treat secondary bacterial infections associated with infectious bronchitis, which would have positive environmental impact. Results of these studies may reveal correlates of protection against IBV, informing the design of future studies.

In a shorter time scale, this project will allow for the identification of pathogenic and immunogenic determinants within the IBV genome. This is not only specific for the IBV field of research but will also prove information for the wider coronavirus field, and therefore may aid in vaccine research and design for other coronaviruses. The coronavirus family consists of a large number of viruses that infect a diverse range of species including swine, bovine and humans. The outputs of this project will therefore feed into the One Health initiative. The results of this project will be of direct benefit to the poultry industry and vaccine developers.

How will you look to maximise the outputs of this work?

This study will inform the wider academic community including other researchers working in the fields of molecular virology, livestock health and coronavirus research, particularly IBV, and will inform approaches to development of other veterinary and human vaccines. Knowledge generated by this project will be widely disseminated to the research community through peer-reviewed publications and presentations at national and international virology conferences and interactions with members of the poultry industry and veterinarians. We will aim to set up collaborations with both academic partners and industry partner when appropriate. We will openly discuss and aim to publish “negative” data which in the regard of this project involves the identification of genome factors which are not pathogenic or immunogenic determinants.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 1750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using the natural host of IBV, the domestic chicken for which we wish to contribute to better IB disease control. Only the chicken can be used for propagating most strains of IBV, assessment of pathogenicity and analysing potential vaccines; we are developing vaccines for protecting chickens against IBV.

Typically, what will be done to an animal used in your project?

This project will include two main types of experiments. The first, to determine pathogenicity will involve birds being inoculated/vaccinated via the intraocular (eye drop) and/or intranasal route with IBV. Chickens will be monitored twice daily. Clinical signs including snicking (sneeze) and rales (tracheal vibrations) will be assessed in a non invasive way for up to 10 days post infection. Swabs of the oral cavity, oesophagus and trachea maybe taken daily. Typically, at either 4 or 6 days post inoculation randomly selected birds will be euthanised. The second type of experiment to assess immunogenicity or vaccine efficacy will begin as described for the first experiment. This experiment will differ as chickens will typically be challenged three weeks post vaccination. The challenge virus will be a pathogenic IBV and will also be administered via the intraocular (eye drop) and/or intranasal route.

Chickens will be monitored both post vaccination and post challenge for up to 10 days. Blood samples will typically be taken from a superficial vein (e.g. wing vein) two days pre vaccination and two days pre challenge. Typically, at either 4 or 6 days post challenge randomly selected birds will be euthanised. All birds will be culled at the end of both experiments as described; the end of the experiment will be 14 days post the last inoculation.

What are the expected impacts and/or adverse effects for the animals during your project?

All our experiments using chickens involve the development of vaccines ultimately for the benefit and protection of chickens against disease and are carried out in environmentally controlled experimental animal facilities. We keep animals under regular observation and use non-invasive measurement of clinical signs of infection. IBV mainly causes clinical signs very similar to the common cold in humans; a few days of snicking (akin to sneezing), watery eyes and wheezing. Chickens are expected to recover from respiratory disease within ten days and will experience a maximum of moderate disease severity, most will only experience mild disease. As we need to analyse virus growth and disease pathology in different organs, all chickens will be humanely euthanised at the end of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Chickens are expected to recover from respiratory disease within ten days and will experience a maximum of moderate disease severity, most will only experience mild disease. It is estimated that 60% of chickens will experience mild severity and 40% moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Pathogenicity and vaccine efficacy can only be assessed using the natural host of IBV, chickens; there is no in vitro or ex vivo alternative model. Embryos cannot be used as alternatives to chickens as even strains non-pathogenic for hatched birds can cause morbidity in embryos. Also, although the non- pathogenic Beaudette strain does cause ciliostasis when inoculated onto ex vivo tracheal organ cultures (TOCs) in the laboratory, it does not cause tracheal ciliostasis following eyedrop/nasal inoculation of chickens. In vitro assessment of immunogenicity, for example virus neutralization assays will be carried out where ever possible, however the identification of virus neutralizing antibodies in vitro has been shown not to correlate with protection in vivo.

Which non-animal alternatives did you consider for use in this project?

Tissue culture, including primary chicken kidney cells and ex vivo tracheal organ cultures (TOCs) will be used whenever possible. The growth and titration of IBV isolates that cannot be grown in cell culture or TOCs will be carried out using embryonated eggs.

Why were they not suitable?

Pathogenicity, immunogenicity and vaccine efficacy can only be assessed using the natural host of IBV, chickens; there is no in vitro or ex vivo alternative model. As stated above, although the non- pathogenic Beaudette strain does cause ciliostasis when inoculated onto ex vivo TOCs in the laboratory suggesting that it may be pathogenic, it does not cause tracheal ciliostasis following intraocular (eye drop) and intranasal inoculation of chickens. Additionally the H120 and Beaudette strains of IBV which are both attenuated in vivo, are pathogenic in embryos.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A statistician is consulted prior to each study to ensure that an appropriate number of chickens is used to generate meaningful results. The number of birds per group at each time point is selected to guarantee statistically relevant results for the assessment of protection and pathogenicity based on many years of experimental work on IBV and the recently published meta-analysis of the required sample size in vaccination-challenge experiments with IBV.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted the publication on the meta-analysis of the required sample size in vaccination- challenge experiments with IBV and we have taken into account the results from the many years of IBV in vivo studies that have been carried out.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continually review the published literature with a statistician to ensure optimal number of chickens are being used. We will also keep up to date with the standards set for IBV vaccination by the European Pharmacoepia. Post-mortem tissues will be shared with other researchers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using the natural host of IBV, the domestic chicken for which we wish to contribute to better IB disease control. Only the chicken can be used for the assessment of pathogenicity and analysing potential vaccines; we are developing vaccines for protecting chickens against IBV. Most of the chicks that we infect develop mild respiratory disease from which they recover within a few days. Chickens will be observed twice daily following inoculation with IBV to ensure that clinical signs and welfare of the chickens are closely monitored. Inoculation of the chickens via the intraocular (eye drop) and intranasal route mimics both spray vaccination practices and natural infection via the aerosol route.

Chickens inoculated in this manner only experience mild momentarily discomfort.

Why can’t you use animals that are less sentient?

Embryonated eggs will be used for the growth of IBV isolates that cannot be grown in cell culture. Cell culture and TOCs will be used where possible to minimise the use of embryonated eggs.

Pathogenicity and vaccine efficacy can only be assessed using the natural host of IBV, chickens; there is no in vitro or ex vivo alternative model. Embryos cannot be used as alternatives to chickens as even strains non-pathogenic for hatched birds including Beaudette and H120, can cause morbidity in embryos. Tracheal ciliary activity in ex vivo tracheal organ cultures is also not an appropriate model for pathogenesis in vivo as IBV strains such as Beaudette can cause ciliostasis when inoculated onto ex vivo TOCs in the laboratory but cannot not cause tracheal ciliostasis following intraocular (eyedrop) and intranasal inoculation of chickens.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedure for determining pathogenicity and vaccine efficacy has been used for many years by us and others, and has been published. We inoculate the chickens via the intraocular (eye drop) and intranasal route, mimicking spray vaccination and aerosol transmission but in a more controlled way.

Chickens will be monitored twice daily following inoculation with IBV to ensure that clinical signs and welfare of the chickens are closely observed. The chickens used in this research will be housed in open raised floor pens with solid floors which were specifically designed in consultation with our Animal Technicians and NACWOs. Flexibility was an important feature of the design to ensure pen sizes can be increased as the birds grow. Chickens will be provided with enrichment including perches, pecking blocks and live feed. Foraging, scratching and pecking are all important behaviours to birds and so enrichment provided will enable them to express their species specific behaviour.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to the ARRIVE guidelines for reporting of in vivo studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep updated with published literature regarding animal experimentation in poultry and will regularly consult the NC3Rs website. We will maintain an open dialogue with the animal technicians and NACWOs in relation to enrichment that can be provided.

35. Developing New Multivalent Recombinant Vaccines Platforms Against Infectious Diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Vaccine, Infection, Prevention, Immunology

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the research is to develop new and improved vaccines. These will be low cost vaccines that can protect against several disease that affect children and adults in Low-Middle-Income countries (LMIC) and in the Western world.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is an urgent need for improved vaccines against infectious diseases. New vaccines need to be safe, well tolerated, effective and offer broad coverage against many pathogens. In fact, multiple pathogens often coexist in the same geographical areas and a single vaccine able to control these diseases would be a desirable asset.

There is also an urgent need to make vaccines that are easy to develop and produce at low cost, to benefit poorer countries via increased affordability.

It is important to develop vaccines that are based on simple construction and therefore suitable to move from early experimentation to production in the shortest possible time. The design and realisation of new vaccines should be simple enough to allow modifications that increase protection against multiple pathogens in response to epidemiological changes and also to allow preparedness for the potential emergence of new and unknown diseases with pandemic potential.

What outputs do you think you will see at the end of this project?

The main output of the project will be the generation of new, safe, effective, versatile, vaccines against bacteria that cause grave infections worldwide in adults and children. The vaccines will protect simultaneously against many variants of each bacterial pathogen, given that these variants often coexist in the same geographical area or circulate between different areas, emerging suddenly and unpredictably. The project will yield vaccines mainly, but not exclusively, against bacteria that cause acute infections for which antibiotic treatment often fails. The project will target mainly bacterial meningitis, gonorrhoea, salmonellosis and can be extended to other infections caused by bacteria, virus and parasites.

The information produced by the project will be divulged in due course for the benefit of the scientific community. This will happen in the form of scientific publications and presentations at meetings.

The work will produce intellectual property that will support in the future grant and patent application and clinical trials.

We will also engage with the general public, via the University press office, the engagement channels of our industrial collaborators, via science festivals and informal public engagement talks and via appropriate contacts with the press and the media.

Who or what will benefit from these outputs, and how?

The project will primarily benefit adults and children at risk of acute and chronic infections caused by meningococcus, gonococcus and Salmonella. These diseases are widespread globally with an unpredictable epidemiology and devastating epidemic potential especially in Low and Middle Income countries of Africa and East Asia. These diseases have a very high level of resistance to antibiotics and therefore their prevention through large-scale vaccination programmes remains the best option at a global level.

The short-term output (3-5 years from commencement of the work) will be the construction, development and testing at the preclinical level (to the end of animal experimentation and ready to enter studies in humans) of candidate vaccines able to protect against multiple variants of each one of these pathogens.

This will be followed by the necessary steps for the production of clinical batches of the vaccines, licensure and organisation of clinical trials in humans (5-6 years from commencement of the work). Trials in humans will follow and will be completed within 6-10 years from commencement of the work.

Given the recent global experience with vaccines against COVID-19, and the current collaborations that we have with industrial partners, these timelines may be shortened to deliver the vaccines.

How will you look to maximise the outputs of this work?

We collaborate with other academic institutions and with industrial partners. This will allow us to expedite the research phases of our work and also to perform the essential steps required by the future development, testing and production of the vaccines. Therefore, the outputs of this research will be impactful. We will divulge our work via open access publications and talks at conferences subject to prior protection of intellectual property if required. We will engage with the public to share and explain our research via open days, interaction with the media and suitable press releases from the University.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We shall use adult mice to test the immunogenicity of the vaccines. The mouse model is a reliable and broadly used small animal model for the initial evaluation of immune responses and protection induced by vaccines against many bacterial pathogens. Results

obtained in mice have informed vaccine development against many pathogens of humans and other domestic animals for decades.

Typically, what will be done to an animal used in your project?

Vaccines will be injected into animals. They may be injected intravenously (i.e. into a vein), intraperitoneally (i.e. into a body cavity), subcutaneously (i.e. under the skin), intranasally (i.e. instillation of small volumes into the nostrils), orally (i.e. into the mouth or stomach). Booster doses may be given at 2-4 weeks intervals, usually for a maximum of 4 doses, to mimic the number of doses that will be given to humans if the vaccines were successful in the later clinical phases.

Blood samples will be taken after each vaccination to test for the induction of immune responses.

In some cases, animals will also be injected with drugs that act on the bacteria (e.g. antibiotics) or that increase immunity (e.g. antibodies).

In some cases, vaccinated animals and a small number of unvaccinated control animals will be infected for a short time with low, subclinical, doses of live bacteria.

At the end of the experiments the animals will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

The vaccines will consist mainly of inactive preparations and therefore cannot cause infections. In some cases we may use live bacteria that are genetically impaired in their ability to grow in a mammalian host. The vaccines will have been constructed and previously tested in non-animal models (e.g. cell culture, chemical tests etc.) to make sure that they are likely to have the lowest possible level of side effects.

Our experience on immunity to bacteria and vaccine development, acquired during several decades of fundamental research, allows us to predict correlations between the type of immune responses induced by vaccines and the presence or absence of protection. In the case of Neisseria vaccines, serological tests (i.e. serum bactericidal activity, SBA) can be taken as predictors of vaccine efficacy.

Therefore, only in rare cases we will need to re-infect vaccinated animals with virulent pathogens to conclusively determine vaccine efficacy. This will happen, within this project, in the case of Salmonella infections where a firm and conclusive immunological correlate of protection is not available. When this is done, the infection experiments with live bacteria will be performed at low doses and their duration will be short, thus minimising clinical signs, should the vaccine prove not to be sufficiently efficacious.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

- Mild=96%
- Moderate=4%
- Severe= 0%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed to test the quantity and types of immune responses induced by the vaccines that we are currently constructing. In some cases, we also need to infect animals with low doses of live bacteria to ensure that vaccines can protect animals against disease. This is the necessary prelude to human testing in clinical trials.

Which non-animal alternatives did you consider for use in this project?

There are no non-animal alternatives to conclusively test the immunogenicity and protection of vaccines. These need to be ultimately tested within the complexity of the immune system of a whole mammalian organism.

We routinely use non-animal alternatives to test the side effects of our vaccine preparations, to determine their chemical composition, measure the presence and quantity protective components within the vaccine. This is done before any animal experimentation takes place.

We use cells in culture, chemical tests that measure the composition of the vaccine and immunological tests that predict the efficacy immune responses to the vaccine. For example, in the case of Neisseria vaccines, we measure the ability of animal sera to kill bacteria as an indirect measure of vaccine activity and protection.

Why were they not suitable?

Because it is impossible to evaluate if a vaccine stimulates immune responses unless a whole animal is injected with a vaccine. Non-animal tests (see above) can in some cases be used to measure the presence of immune responses induced by the vaccine in the animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have 30 years of experience in designing animal experiments with the aim of testing vaccines against bacterial infections.

We estimated the numbers of animals according to the expected number of vaccines that we shall test, considering groups sizes and experimental protocols. The numbers of animals within each experimental group and the size of each experimental group are decided as indicated in the sections below. Briefly, throughout the project we estimate to test approximately 200 possible candidate vaccines in small-scale experiments involving 10 mice per candidate on average. We expect to take forwards about 10% of these (20 candidates) for further immunogenicity and functional studies that will involve approximately 150 mice per candidate vaccine.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We design experiments to include as many experimental groups in parallel as possible, with the smallest number of animals per group (as determined by statistics, pilot experiments and mathematical modelling); we associate one control group to as many experimental groups as possible so to reduce the number of control animals used in our experiments. We plan to make the best possible use of experimental design assistants including the NC3R one (Experimental Design Assistant, NC3R) whenever appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We carry out pilot studies using small numbers of animals, but making sure that these group sizes can support power calculations for larger scale experiments and/or yield statistically significant results able to provide a definitive answer on whether to take forward or dismiss a particular vaccine candidate. In our work we plan to take forwards to larger animal studies only those vaccines that in pilot experiments show real promise.

Based on pilot studies and on similar work performed by us in the past, we perform statistical calculations to determine the minimal group sizes and number of repeats without compromising scientific accuracy.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We shall use the mouse model of vaccination and reinfection. Animals will be immunised either with non-living bacterial vaccines or with live attenuated bacteria. The reactogenicity (side effects) of the vaccines will be extensively reduced by genetic manipulation of their DNA and is ascertained by extensive biochemical characterization and in vitro testing on cell lines. We have adopted the use of commercially available reporter cell lines to ascertain and measure the reduction in toxicity of the vaccines prior to inoculation into animals. We use cells lines created specifically to investigate TLR4 activation. Whenever possible, we use antibody levels and the presence of cellular responses as correlates of vaccine-induced protection (e.g. in the case of meningococcal and gonococcal vaccines); this abrogates the need for re-challenge with virulent bacteria. In the case of other bacterial pathogens, such as Salmonella, it is necessary to infect the animals with live bacteria to conclusively ascertain vaccine efficacy. In this case we only perform reinfections in those animals immunised with vaccines that have proven immunogenic in in vitro tests (i.e. measurements of antibodies and/or cellular immunity). When reinfection is required, we use low doses of live bacteria and we allow the infection to progress only for the time necessary to detect differences in bacterial numbers between vaccinated animals and non-vaccinated controls. We precisely know the grow rates of our challenge Salmonella strains and therefore we can be sure that the infection would not proceed faster than expected even in the event the vaccines proved to be ineffective and/or in non-immunised controls. Therefore, the challenge infections largely remain within the mild band of severity.

Why can’t you use animals that are less sentient?

Vaccine testing requires adult animals with a mature immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We provide the best possible husbandry care for our animals. This includes regular cleaning, health checks, within-cage enrichment tools and the use of female animals as much as possible to minimise the chances of in-cage fighting and therefore allowing group housing. We acclimatise our animals for at least 7 days before the start of any experiments. We regularly inspect the animals before and during the experimentation to ascertain that they stay in within the severity of the ascribed protocol.

Experimental procedures are performed by skilled PIL (Personal Licence) holders, according to tried and tested protocols that have evolved during several decades to reduce stress and suffering to the animals. Refinements include optimisation of volumes, use individual needles for each animal, optimisation of needle size, improvement of techniques for gavage through the use of light anesthesia

that allows more accurate dosing and reproducibility of results. We reduce the potential toxicity of our candidate vaccines by removing from the bacterial DNA specific genes (e.g. lpxL1, msbB) that encode for parts of their membrane that have inflammatory activity. When we infect animals with live bacteria we always use low numbers that do not cause disease and we do not allow the experimental infections to progress to numbers of bacteria in the body that can cause, at worst, mild clinical symptoms. The numbers of bacteria to be injected are precisely measured in the inoculum by optical density and then confirmed by counting viable bacteria on bacteriological growth media. Gavage procedures performed under light anaesthesia (with rapid recovery) ensure reproducibility of experiments, reduced variability (thus need to use less animals per group) and reduced stress/harm to the animal due minimal chances of surface damage of the aesophagous (potential consequence of an animal resisting or struggling during the gavage procedure). Welfare assessment protocols will be considered when appropriate, as these can be useful tools to monitor adverse effects and determine when humane endpoints have been reached. The experience of the Named Persons and animal technicians will be useful to create welfare scores by recording relevant adverse effects and incorporating the earliest humane endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the PREPARE (https://norecopa.no/prepare) and ARRIVE (https://arriveguidelines.org) guidelines as a routine of good practice and as a requirement for scientific publications. In addition to these, when appropriate and required we shall also benefit from papers from the Laboratory Animal Science Association, (LASA) https://www.lasa.co.uk/current_publications/. The details of each experiment (e.g. dosing regimens) will be based, whenever possible, on peer reviewed publications that have used similar vaccines in the past. Many of these papers are from members of our research group.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our establishment provides regular updates on the 3Rs. The PPL holder is the Chairman of the Animal User's committee at his establishment and a member of the establishment Management Committee.

These committee meetings include a dedicated section where improvements of the 3Rs are discussed. The PPL holder and his group attend NC3R events and workshops and subscribe to the NC3Rs e- newsletter. Regular consideration and reflection of the latest practical guidance from Laboratory Animal Science Association (LASA) will provide additional sources of new recommendations and advances in animal techniques.

36. Improved Induction and Identification of Tinnitus in Mice Prior to Treatment with Drugs or Genetic Alteration

Project duration

5 years 0 months

Project purpose

Basic research

Translational or applied research with one of the following aims:

- Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

tinnitus, salicylate injections, noise exposure, genetic manipulation, behavioural test

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to use refined models of tinnitus in mice to identify receptors and test drugs that might produce a significant reduction in the tinnitus percept.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is estimated that over four million prescriptions a year (in the USA and Europe) are for drugs to treat symptoms associated with tinnitus such as stress or problems sleeping. There is currently no drug available to abolish the perception of tinnitus directly and this represents a potentially huge market.

The current healthcare bill for treating tinnitus on the NHS is estimated to be 750 million pounds per year. There have been many attempts to find a pharmacologically effective treatment for tinnitus, in the last 10 years, but so far no drug has been approved for its treatment. Tinnitus is a symptom in a wide variety of clinical histories and there is clear evidence that more than one mechanism underlies tinnitus. Fundamentally we do not fully understand tinnitus and have no broadly effective way to treat it. Tinnitus has similarities to the chronic pain associated with phantom sensations experienced after limb removal and a new drug class has recently been shown to be effective against this type of neuropathic pain. We are hoping to develop reliable models of tinnitus in mice that can then be used to show that this same drug class is effective against various subtypes of tinnitus, especially those that are linked to hearing impairment. Mice are important in this research because genetic knockouts have been produced that will allow investigation of the mechanisms underlying tinnitus.

What outputs do you think you will see at the end of this project?

The drugs we are proposing to use were designed for treating heart problems or neuropathic pain and we hope to obtain reliable evidence that this type of drug is also effective in alleviating the symptoms of tinnitus, once we have refined our mouse models of tinnitus. On the basis of our initial methodological work we expect to be able to produce one peer reviewed paper on the use of characteristic body movements associated with the acoustic startle reflex as the basis of a reliable method for detecting tinnitus in mice. We will then test the most promising examples of the drugs in our mouse models. As some of the drugs are nearing the end of their patent protection, then we would not expect any delay being placed on the publication of a second paper aiming to show that this type of drug is effective in reducing the symptoms of tinnitus.

Who or what will benefit from these outputs, and how?

There is a clear need for a pharmacological treatment for tinnitus and if we can establish a reliable model for testing drugs in mice then this should be generally useful for the initial testing of drugs with therapeutic potential. Our commercial partner wants us to test drugs that they have developed for treating conditions such as neuropathic pain. They are now interested in repurposing the drugs as a potential treatment for tinnitus. Before initiating expensive clinical trials they need convincing evidence of efficacy in animal models. Other

drug development programmes would also benefit from having a reliable mouse model for tinnitus.

How will you look to maximise the outputs of this work?

This work involves collaboration with a large drug company. Once we have established an improved tinnitus model in mice we would encourage the company to repurpose these existing drugs as a treatment for tinnitus. They have the resources to initiate clinical trials and this would be the next step.

Species and numbers of animals expected to be used

- Mice: 300 wildtype and 50 genetically altered (GA)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Tinnitus does occur in children, but it is more common in adults and its incidence peaks in the population group aged from 60 - 70 years old. There is no known direct genetic cause and in many people the exact causative factors are unknown. Thus the most appropriate animal model for drug testing is a mature mammal. The strain of mice to be used in this study (C57BL/6J) shows early onset hearing loss which is already present by six months and is equivalent to the age-related hearing loss (presbycusis) found in humans of over 60 years old. Thus, in order to have time to induce tinnitus and treat it with various drugs, before the onset of hearing loss, we will start the baseline behavioural training while they are still juveniles. Mice have a brain that has the same structures and neurochemicals as all other mammals and are a suitable model of the human auditory system. The main advantage of mice is the availability of technology designed to abolish the expression of specific genes in particular parts of the body, such as the ear. This allows us to test the role of particular gene products (such as ion channels involved in the activity of the auditory nerve). We, along with other scientists, aim to develop a behavioural test for tinnitus in mice that is relatively quick and easy to implement. This behavioural test is designed to allow us to test the effects of deleting certain gene products that may be essential to the development of tinnitus. We will also test drugs that may alleviate the symptoms of tinnitus by blocking the gene product without any genetic manipulation.

Typically, what will be done to an animal used in your project?

We have two models of tinnitus:

1) The salicylate model is a rapid onset, reversible form of acute tinnitus that involves the injection of a high dose of sodium salicylate (the active form of aspirin). This form of

tinnitus occurs in human patients who receive high doses of oral aspirin to treat certain types of advanced cancer. At high doses salicylate (aspirin) is an effective pain-killer and anti-inflammatory agent. The main side effects of these high doses of salicylate are mild hearing loss and tinnitus along with thinning of the blood (anti- coagulant function) and possibly irritation of the stomach/intestine. Salicylate reliably produces tinnitus in 95% of animals and its effect peaks after about two hours. We can then compare the evidence for tinnitus in the wildtype mice with those that have had the gene for a specific membrane channel (HCN2) deleted. This testing involves presenting a series of brief startling clicks to the animal and measuring small body movements using a system of infrared cameras that track the relative ear and trunk, neck or tail movements in 3D space as the animal moves freely around the chamber. After 60 min. of testing we have sufficient data to determine if the animal has developed evidence of tinnitus and the experiment is concluded. We would not expect any of the GA mice to show evidence of tinnitus. We have not used salicylate to induce tinnitus in mice before but it is a standard model in mice. The first experiments will gather pilot data to check the safety of our protocol for administering the salicylate and the ivabradine and experimental drugs used to treat the tinnitus symptoms. Only one injection of salicylate will be made per mouse and the experiment will end within 5 hours.

2) The noise exposure model is a chronic model of tinnitus that takes about 6 weeks to develop in mice and involves two, 1 hour long periods of moderate noise exposure applied two weeks apart. The sound is presented to one ear using a loudspeaker connected by a tube to the animal's left ear while it is deeply anaesthetised. During the period of anaesthesia, we record auditory brainstem responses (ABRs) using subcutaneous needles. These needles pick up tiny brain potentials that we can use to measure hearing thresholds, before and after the noise exposure, to confirm the degree of hearing loss. Anaesthesia is usually induced by an intraperitoneal injection of a liquid anaesthetic mixture followed by supplementary injections to maintain anaesthesia at a constant deep level. Gaseous anaesthetic gives greater control over anaesthetic depth and would be used if it were possible to supply it safely without interfering with the experiment. Currently we are unable to safely extract it from the sealed acoustic chamber without introducing noise into the chamber during the ABRs, but if it becomes possible to do so in future then we would use an anaesthetic such as isoflurane under the direction of the NVS. Animals are anaesthetised for about two hours and then recover over the following two hours after one or two sessions of noise exposure. The animals may demonstrate hearing loss in one ear and are left for the next six weeks before behavioural testing is started. About 40-50% of the noise exposed animals should develop tinnitus in the wildtype population but we would expect that none of the GA mice would develop tinnitus if our hypothesis is correct. As it is chronic tinnitus a range of drug doses will be used to test drugs that block the channels that have been deleted in the GA mice. All the tinnitus animals and some of the GA mice would also be given sham drug injections (no drug just the vehicle that they are dissolved in) to act as controls and check for tolerability issues. These animals would then be tested with the GPIAS (gap-induced pre-pulse inhibition of the acoustic startle)

behavioural test to confirm whether or not the sham drug injection (vehicle only) had any effect on behaviour. The experiment would then be concluded.

What are the expected impacts and/or adverse effects for the animals during your project?

High concentrations of salicylate cause tissue breakdown around the site where they are injected. In a relatively short experiment (5 h) this should not cause more than mild distress because the salicylate is also a very effective pain-killer and anti-inflammatory agent at these high concentrations. Over the first two hours the localised injection of salicylate is dispersed and distributed throughout the body via the blood circulation. We will conclude all our experiments within five hours of administering salicylate while its therapeutic actions are still near maximum.

The unilateral noise exposure used to induce chronic tinnitus is a non-invasive procedure , under general anaesthesia, that does not seem to be associated with any appreciable pain subsequently. During the period of general anaesthesia the animal will have reduced control over its breathing, blood pressure and temperature but external measures will be taken to compensate for this. Initially there will be a mild temporary hearing loss, but the procedure is designed to avoid producing any permanent hearing loss. Although tinnitus will develop in some of the animals, they should not find it distressing because the sound percept in tinnitus is relatively quiet (about 20 dB above hearing level) and the percept will sound like an externally generated background noise.

The behavioural testing necessary for determining the presence of tinnitus will be mildly distressing for the mice because 1) they feel threatened by having reflective markers placed on sensitive parts of the head (such as the ears), 2) they are in isolation during the testing, and 3) the presented noise pulses are designed to startle them. We hope to identify a startle movement in mice such as neck extension or tail flick that avoids sticking markers to the ears. However, during the initial experiments to compare marker position we may need up to 15 periods of sedation/anaesthesia while placing ear markers. The cumulative effect of these periods of sedation and testing may move the procedure into the moderate category. After noise exposure some animals may develop a hypersensitivity to loud sounds (hyperacusis) that is moderately distressing and can lead to flight behaviour from the startle sounds.

These animals become calm again when returned to their home cage, but they may have to be withdrawn from the study and are killed by a Schedule 1 method. This is expected to apply to less than 10% of the animals.

The subcutaneous injections of experimental drugs may cause mild and transient discomfort but compound and doses are fully characterised and no systemic effects are expected other than mild bradycardia or muscle trembling at the highest doses.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

With the salicylate animals, less than 10% are expected to enter the moderate category and none will remain in this state for more than five hours.

With the noise exposed animals no more than 10% would be expected to show moderate symptoms of distress and the rest should only be in the mild category.

With the initial studies to find the most effective position for reflective marker placement six of the mice (less than 20%) may require multiple periods of sedation that may be classed as moderate but the other mice should not exceed the mild category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are trying to identify drugs that would be effective in alleviating tinnitus, but before beginning clinical trials we need to obtain preliminary evidence of their efficacy using animal models. As tinnitus is a conscious phenomenon and its neural basis is not properly understood we cannot currently use in vitro or computer modelling methods to test the effects of these drugs. Previous research on humans has been able to demonstrate pre-pulse inhibition (PPI) using the small muscle potentials associated with the vestigial pinna reflex and have found similar changes in tinnitus patients as we expect to see in our mice. We also know that tinnitus is a good measure of salicylate toxicity in the clinic. This reassures us that our mice models are closely analogous to human tinnitus. Currently there are still no drugs that have been approved for specifically treating tinnitus in either America or Europe and the clinical trials to date have still not found any drug that is broadly effective.

Which non-animal alternatives did you consider for use in this project?

Computer modelling of the effects of the drugs on the firing rates of nerve fibres in the cochlear nerve.

Why were they not suitable?

The cause of tinnitus is still not properly understood and the mechanisms that cause its development have still not been worked out. We do not know enough about the neural mechanisms producing tinnitus in order to model the effect of altered neuronal firing rates on its development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Developing a behavioural test to identify tinnitus in mice using the ear-flick or other head, body or tail reflex movements

Before starting the tinnitus experiments we want to optimise the behavioural method for identifying tinnitus in Protocol 1. This will involve studying the acoustic startle response, so that we identify the method that is the most refined and reliable. We don't want to risk having to change our analysis method half way through the study as this could involve repetition of experiments or the need for larger group sizes initially. The acoustic startle involves many groups of muscles and these are recruited at different sound levels (Pantoni et al. 2020, Quantifying the acoustic startle response in mice using standard digital video. https://doi.org/10.3389/fnbeh.2020.00083). Thus, we will need to optimise the position of pairs of reflective markers that are tracked by our three cameras in 3D space. This Optitracks tracking system has not been used with the acoustic startle in mice before and we will need to try out different positions of pairs of markers to find the optimal positions that involve the mice in the least discomfort and give the most reliable indication of the startle reflex at the lowest sound levels. We will need to try attaching markers to different points on the 1) cheek, 2) pinna, 3) head at midline, 4) lateral thorax, 5) abdomen, 6) spinal column and 7) the tail. Measurements will be made of the movements of two markers relative to each other. Our aim will be to find positions for the minimum number of markers causing the least distress to the mice but that will also give a reliable measure of the reflex. Mice do not like being touched near their head and placing markers on the pinna may require transient sedation. No more than six markers would be placed on a mouse at any one time and no session would last more than 50 min. but they may be shorter than that if the mouse appears distressed. We will also need to try different marker sizes (3 or 4 mm) and different types of bedding in the chamber to minimise reflections. Because of these 9 variables and the need for quantitative data using groups of up to 6 mice (3 of each sex) we expect these initial experiments may involve up to 9 X 6 = 54 mice. Each mouse would have multiple periods (on average 10) of behavioural testing where we altered the stimulation and recording parameters. At the end of this initial testing

we would conclude the experiments (Schedule 1 method) as we would not want to expose them to tinnitus induction and testing in addition.

Once the recording parameters have been optimised, subsequent mice will go through a refined period of baseline testing in protocols 2 and 3 to determine which are suitable for attempting tinnitus induction. Mice vary in their ability to perform in this behavioural test of their initial GPIAS response and we have estimated that as many as 20% of the mice may not be suitable for behavioural testing and will fail to complete the baseline testing. This is based on our experience with guinea pigs where over 20% have been found unsuitable for making behavioural measurements. Thus, we have estimated that we will start with 246 wildtype mice even although we only expect to use 200 in producing tinnitus models. Similarly with the GA mice we expect to use 50 for preliminary testing even although we only need 40 for tinnitus models. The calculations that lead to the total of 300 animals is shown in the Action Plan Section and described below.

Development of tinnitus following salicylate

In protocol 2 we will administer salicylate alone to 4 wildtype mice (plus 2 sham injections as controls) and 20 GA mice to compare the two groups. We expect that none of the GA mice will develop tinnitus but even if a few do, the use of a group of 20 should be sufficient to show a significant effect unless the effect size is quite small (less than 10%).

Development of tinnitus following noise exposure

The numbers required for the noise exposure model are estimated based upon the incidence of tinnitus generated by noise exposure. In the mice 40 - 50% of animals are expected to develop tinnitus following noise exposure. None of the knockout mice should develop tinnitus and if any do then this would support the null hypothesis that HCN2 channels are not involved in the production of tinnitus.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We plan to carry out pilot studies to improve the reliability of the GPIAS method using wildtype mice. This preliminary work should reduce the number of mice needed in the main tinnitus experiments as there should be improved reliability for the GPIAS method when using the ear/tail flick and neck/thoracic reflexes instead of the whole body startle that has been used previously in mice.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Using externally bred animals (either commercial wildtype or from our collaborator), rather than having our own breeding colony of GA mice will greatly reduce the number of GA animals needed overall. By using mice of both sexes we will reduce the numbers of unwanted mice in our collaborator’s colony of GA mice.

We will use a vehicle and drug doses that have already been shown to be safe and effective in studies by our collaborator and the drug company.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of animal

Mice are, by far, the most commonly used laboratory species and they thrive in safe, well-maintained animal units. The mouse has been the preferred species for large-scale genetic studies and there are now highly advanced methods for altering their genetic expression and changing their molecular biology that are not available in any other mammalian species. Thus, we will be using the C57Bl/6J mouse as our collaborator has developed a cre/lox knockout of the HCN2 channel in the peripheral auditory system in this strain. This strain is the most commonly used strain for genetic manipulation and our results should be widely relevant to many other laboratories. The thin skulls of mice, which have relatively little calcification, means they have an easily accessible cochlea and they have been a preferred model for studying the genetics of the auditory system for more than 30 years. Additionally, there is a large literature on the mouse auditory system and the genes controlling its function, much of which might have to be replicated if a different animal were used (contradicting reduction).

Methods for inducing tinnitus

Tinnitus can be induced rapidly and reliably by injecting a single high dose of sodium salicylate (300 or 350 mg/kg). This is a standard method for inducing tinnitus in mice and has been used with the strain that we will be using. A single injection of salicylate should cause less overall distress to the animal than noise exposure as it avoids the periods of anaesthesia and subsequent recovery as well as the gradual onset of tinnitus over six weeks. In the past we injected salicylate i.p. and this was associated with irritation and potential damage to the wall of the gut in our herbivorous guinea pigs whose digestive process is easily disturbed. The gut of the omnivorous mice should be less sensitive to the salicylate and either i.p. or s.c. injections will be made depending on which produces the least distress. Injections via the i.p. route are simpler than s.c. in small active mice that have been scruffed, but following consultation with the NVS, he recommends that we start with s.c. injections as they should be less painful. We aim to minimise any irritation to the

gut or subcutaneous tissue and lessen the risk of any distress. We will administer the HCN2 channel blocker two hours after the salicylate and then perform all the behavioural testing within the next two hours. The HCN2 channel blockers have an analgesic effect and should reduce any discomfort. This The rapid testing means that the animal can be sacrificed within five hours of the salicylate being administered and any local inflammation is minimised. Salicylate injection in mice by the s.c. route may be safer than by i.p. injection as the LD50 for i.p. injections is 500 mg/kg but for s.c. injections it is 550 mg/kg. Salicylate is absorbed by passive diffusion and rapidly distributed to most body tissues and so both routes have been shown to be effective at increasing the levels within the inner ear that we are interested in studying.

For most of the experiments, we induce chronic tinnitus via noise exposure and although this is performed under a GA the animals are allowed to recover so that we can study the behavioural changes that occur subsequently. Previous studies have used very high sound levels during the noise exposure (120 dB SPL) that causes permanent hearing loss. However, recent work in the guinea pig has shown that two consecutive periods of more moderate noise exposure a few weeks apart may be equally effective at inducing tinnitus and does not produce any significant permanent hearing loss in the audiogram. We will initially try two periods of moderate noise exposure in the mice to determine if we can induce tinnitus in about 50% of the mice without any associated hearing loss. Reducing the amount of hearing loss should also reduce subsequent stress in the animal.

Method for identifying tinnitus

The most widely used test for identifying tinnitus in rodents is the gap-induced prepulse inhibition of the acoustic startle (GPIAS). We have been successfully using a version of GPIAS, based on the ear flick reflex, in our guinea pigs for the last eight years. The ear flick reflex has a lower threshold for production than the whole body startle and so we can used lower sound levels for producing the startle that are less distressing than those used traditionally (90 dB instead of 110 dB). Groups working with mice have mainly used the whole body startle but this response habituates very quickly and after 5 repetitions is much smaller. We now want to use more robust components of the acoustic startle, based on more localised muscle twitches such as the ear flick or neck extension, that should show less habituation. We also want to measure other small body movements such as thoracic expansion and the tail flick which are part of the startle response and show little evidence of habituation. We have recently measured the sharp intake of breath that is produced by a startling pulse at the same time as the ear flick by placing an additional pair of reflective markers on either side of the thorax in guinea pigs. Our sensitive video cameras should be able to measure thoracic and tail movements in the same way in mice. Mice are naturally active and continually explore their surroundings especially if they are outside their home cage. However, this should not be a problem for us because during the analysis of the reflex movements we measure the relative position of the two pairs of markers. During the reflex response the ears move towards each other while the walls of the thorax move away from each other. In our analysis we only extract these relative movements of each pair of

markers and discard the data about absolute position. Pilot experiments performed by our previous PhD student, who is now in America have indicated that the ear flick response is a possible method for tinnitus estimation in mice but he did not use the thoracic, neck or tail markers and they may be more suitable. The reflective markers are self-adhesive and will not produce any skin irritation.

Why can't you use animals that are less sentient?

Tinnitus is a conscious perception and by definition can only be experienced while conscious. A number of mammalian models of tinnitus have been developed but although it is possible that tinnitus exists naturally in some non-mammals there is no experimental model available. The mechanisms underlying tinnitus are not fully understood and so it is not yet possible to use in vitro or computer models to adequately test the effect of drugs on tinnitus.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Induction of tinnitus by salicylate injection

High doses of salicylate can lead to irritation of the stomach or gut wall and we will be particularly careful to avoid this problem. Salicylic acid has a pH of 2.4 but we will use the sodium salt as this has a pH that is close to neutral. Part of the problem with salicylate is that it is normally injected as a hypertonic solution and this may cause transient oedema. We will initially use the sub cutaneous (s.c.) route for injections and will apply local anaesthesia ointment (e.g. Marcain, EMLA cream) to the skin beforehand if we find any evidence of swelling. Alternatively, we may use direct injections into the peritoneum as that is the standard method in mice. Animals will be carefully restrained and injections performed by trained and competent staff in accordance with LASA guidelines. We will always seek to minimise any distress to the mice during the injection of substances and will seek the advice of the NACWO or NVS. The condition of the animals will be checked frequently, typically every half hour immediately after the injection for up to two hours to check for any signs of ill-health e.g. changes in home cage behaviour or activity.

Recovery anaesthesia for noise exposure

The main risk of adverse effects are related to the anaesthesia, including remote management and monitoring required to record the auditory brainstem responses (ABRs) and for exposure to noise in one ear. By careful observation using for example a pulse oximeter and camera with monitor it is possible to check for changes in blood oxygenation or breathing rate and this should allow remedial action. Oxygen will be available both before and during anaesthesia. The duration of ABR recordings will be kept to a minimum (15 min) by only recording at a small sample of selected frequencies. After recording the post-deafening ABR a reversing agent such as atipamezole may be injected (i.m.) if appropriate and as recommended by the NVS to aid recovery. Administering a general

anaesthetic may lead to transient, mild distress due to the physical restraint or injection [or insertion of a hypodermic] needle. This will be minimised by making sure staff are fully trained and monitored for competence before making injections. We will ensure smooth and swift recovery by placing the animal in a warmed recovery cage and ensuring a good posture conducive to easy breathing and offering accessible and palatable diet.

Behavioural testing

One of the conditions sometimes associated with noise-induced tinnitus is hyperacusis which is an increased sensitivity and decreased tolerance to loud sounds. If animals experience hyperacusis then they may become very restless and repeatedly attempt to climb out of the chamber in the sound booth during testing. The first time this happens testing will be stopped and the animal returned to its home cage. If it happens three times in a row the animal will be removed from the experimental group and either used to collect brain tissue following perfusion with fixative or killed by a Schedule 1 method.

Animals are never restrained during behavioural testing and will not experience more than a mild level of stress from being placed in the test booth. They will never be left in the booth for more than an hour in any one day. While in the booth they will be kept under constant observation using three infrared cameras. The mice are briefly restrained during the placement of markers but initial experiments will try to identify a placement method and positions for the markers that will minimise this stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All recovery experiments involving a general anaesthetic involve a risk of injury to the animal and the risks increase with the duration of the anaesthesia. Advice will be taken from the NVS and BSU Director about recent refinements that may useful. We will keep abreast of the literature for developments in animal models and will follow guidance on the NC3Rs website (https://www.nc3rs.org.uk/) as well as the Norecopa website.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will rely on guidance about improved methods from the Named persons who will provide detailed oversight and assistance with all aspects of the work. They have already been working with us over the last few years to help us improve our experimental methods using guinea pigs and this will continue with the mice. We will also consult the NC3Rs website, the website of Norecopa (https://norecopa.no/more-resources/culture-of-care), attend their meetings or training sessions where appropriate and keep informed by searching the relevant literature as well as consulting with our collaborator in Kings College London.

37. Genetic and Chemical Validation of Drug Targets in Leishmania

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

leishmaniasis, parasite, Leishmania, virulence, drugs and vaccines

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to characterize the key biological processes of Leishmania parasites that are required for infection and virulence. This will inform novel strategies for drug and vaccine development for leishmaniasis

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Parasitic disease of humans remains a major worldwide problem. Leishmaniasis is caused by the single-cell protozoan parasite Leishmania and is categorized as a Neglected Tropical Diseases (NTD) by the World Health Organization (WHO). This disease is prevalent in tropical and subtropical areas of the world. It causes significant morbidity and mortality amongst the world's poorest populations resulting in severe costs in both health and economic terms and draining resources that could be used to promote development. Unfortunately, treatments for leishmaniasis are inadequate as there are no effective vaccines and existing drugs are old, difficult and often expensive to administer, toxic and ineffective, with drug resistance becoming a growing problem. The development of new safe drugs, or vaccines, for the treatment of these diseases is therefore urgently needed. A better understanding of the biology of the parasite and its interaction with the host will support drug and vaccine discovery.

What outputs do you think you will see at the end of this project?

The main benefit of this project will be the knowledge gained about key biological processes affecting the virulence and pathogenicity of Leishmania which will inform our two main research areas:

1) Identification and validation of new potential drug targets that can be used by us and others to develop anti-parasitic compounds and inhibitors to, for example, protein kinase or peptidase targets.

2) Testing of potential drugs for anti-leishmanial activity and the investigation of pharmacodynamic and pharmacokinetic parameters of drugs, drug combinations and formulations to inform pre-clinical and clinical development such as rate-of-kill, drug exposure at target site (dermal skin layer for CL) and internal organs (liver, spleen and bone marrow) for VL.

Our findings will be published in academic journals and shared with the scientific community through conferences and meetings.

Who or what will benefit from these outputs, and how?

Academic scientist working on drug and vaccine discovery for leishmaniasis.

How will you look to maximise the outputs of this work?

All of these findings will be published in academic journals and further shared with the scientific community through conferences and meetings.

Species and numbers of animals expected to be used

- Mice: 2250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All the research outlined in this project will use mice as an animal model. Mice are a suitable model for these studies because many pathogens that infect humans also infect mice with similar pathogenic outcomes (e.g., Leishmania mexicana, the protozoan parasite that causes cutaneous leishmaniasis in humans). Mice can also respond to drug treatment in a similar way to humans and are thus useful for testing anti-parasite activity of new potential drugs. Research using mice has had a long history of making important contributions to the understanding of human biology and many valuable resources (such as gene-deficient mice) are available. Therefore, they enable us to make scientific advances with an increased confidence of correctly interpreting the outcomes of experiments designed to discover new treatments and therapeutics to improve human health. We will use adult mice because they have a well-developed immune system.

Typically, what will be done to an animal used in your project?

Mice will be infected with Leishmania parasites, some of which may have been genetically manipulated, and the virulence of the parasites assessed by monitoring growth of the parasite and the onset of leishmaniasis disease. The response of the animal to infection may also be evaluated, for example by taking blood samples.

After leishmaniasis has developed, the mice will be treated with potential drugs to assess whether these can cure the disease. To quantify how much pathogen is present, we can use an advanced form of imaging where a chemical is given to the infected animals and reacts with a gene in the pathogen to emit light. The administration of the chemical is done by injection and is repeated several times during the course of the infection.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals used in this project show no outward signs of distress or suffering. Injections produce mild discomfort and some stress associated with handling. Anaesthesia is used for restraint where needed, for example in in vivo imaging, and recovery from anaesthesia occurs within minutes.

Infections are always terminated before any severe symptoms occur and in most cases before any clinical symptoms occur. Weight loss can occur over a period of several weeks, as a result of the infection or during the administration of drugs, but will not exceed 20% body weight and in most cases is negligible. Cutaneous leishmaniasis causes skin lesions

at the site of injection that develop over several weeks, but these do not impede normal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not expect that any procedure will exceed moderate severity and the majority of procedures performed under this licence (>95%) will be of mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our first aim is to understand and reduce the disease caused by Leishmania parasites. To do this we need to understand the mechanisms that parasites use to survive and grow and this includes necessary stages through the mammalian host (eg mouse).

In our second aim on drug discovery we often observe significant anti-leishmanial effects in vitro that don’t necessarily translate to in vivo data. This can be attributed to drug availability in the host. Doing in vivo drug assessment is the only way of evaluating whether a compound would reach and kill Leishmania in the mammalian host. There is currently much interest to better define the pharmacokinetic and pharmacodynamic properties of existing and new drugs so that we may more accurately predict which drugs are likely to be efficient in vivo.

Which non-animal alternatives did you consider for use in this project?

Growth of Leishmania in tissue culture

Why were they not suitable?

In vitro culture techniques for the growth of both Leishmania and mammalian cells have improved over the years and this allows us to do most of our work in vitro. In some cases parasite lines have recently been isolated from humans or animals and require adaptation to in vitro culture. This is often possible but in some cases not and such lines need to be continuously grown in vivo. With the increased use of in vitro culturing it has come to light that there are marked differences between strains grown in vitro and in vivo with effects

seen in, for example, virulence and drug sensitivity. Since a large part of our work relates to drug treatment and virulence we need to assess these in vivo where data may be more relevant for future drug development for treatment of human disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals based on the design of the experiments we wish to carry out and from past experience using the procedures in this application

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental setup proposed in this application is already established and has been used on previous licences. Experience and data from the previous work has allowed the refinement of protocols and the reduction of animals. This has included the use of in vivo imaging to allow longitudinal assessment of parasite burden, the use of pools of bar-coded Leishmania mutants to assess the virulence of multiple parasites in one group of animals and the use of skin microdialysis to replace skin biopsy to investigate pharmacokinetic and pharmacodynamic relationship of new drugs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whole body non-invasive imaging is used to generate longitudinal data from small cohorts of mice

Experiments are often conducted in parallel to allow re-use of tissues/cells between experiments, reducing the number of mice needed only to supply tissues and cells

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models of infection are well established for Leishmania - we are not aware of other mammalian models that can replace rodents.

Why can't you use animals that are less sentient?

Mammals are a natural host for the Leishmania parasite. We require the use of a mammalian species which contains an adaptive immune system that has clear similarities with the human immune system. We must use adult animals that have a fully developed and functioning immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will be refined by continual improvement and discussions with the scientists and animal technicians, NACWO and NVS to create a culture where the welfare of the animals is central to experimental design. Regular training and protocol review will ensure that any refinements will be implemented promptly

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow ARRIVE2 guidelines for reporting of experimental results. The NC3Rs and LASA web sites provide a resource of up-to-date protocols, publications, guidelines, videos and other information that enables the rapid dissemination of the most up-to-date best practices. Discussions with other scientists at conferences and within the establishment will ensure that improvements in local practices are quickly implemented. Examples of where procedures have been recently refined are the single use of needles, providing enrichment in the cages (fun tubes, wood bars), adopting tube handling, and use of animal body cues such as the grimace scale to observe pain.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly discuss refinements for animal experiments with the Named Animal Care and Welfare Officer (NACWO), named veterinary surgeon (NVS), and animal technicians. We will keep abreast of developments discussed and implemented by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) through their monthly newsletters and blogs. The animal facility holds regular forums and updates on the current best practice and latest developments.

38. Pharmacokinetics of Novel Therapeutic Agents and Disease Modification

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, central nervous system, therapy, drug movement through the body, efficacy

Animal types	Life stages
Mice	adult
Rats	embryo, pregnant, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to identify potent compounds that can be developed into novel therapeutic options for patients suffering from cancer or diseases of the central nervous system (CNS). We will assess how the novel compounds move around the body and eliminated and while doing so, how they modulate biological processes that are involved in progression of the target diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer and CNS diseases cause long-term disability or death in humans. There are many types of these diseases and specific and potent therapeutic options are desired. Many of the current therapies have limitations such as incomplete response, relapse or emergence of resistance. Options for CNS diseases, such as Alzheimer's disease, amyotrophic lateral sclerosis (ALS) and Parkinson's disease are even more limited. Discovery of novel drugs will expand the therapeutic options for patients. Work under this programme will lead to identification of novel potent drug pre-candidates that could be developed into such novel therapies.

What outputs do you think you will see at the end of this project?

Benefit from this project would be the identification of novel compounds with good ADME (absorption, distribution, metabolism, and excretion) with low toxicity, as well as the ability to change the behaviours of disease- or symptom-causing molecules within the disease type of interest. In the case of cancer- targeting compounds, we will demonstrate their efficacy in appropriate tumour models. For CNS diseases, we will generate data to support further investigation into safety and efficacy in CNS disease models conducted externally. All results will be used to evaluate, together with our clinical development team, whether the compounds studied are appropriately safe and efficacious to be considered for evaluation in human patients.

Data obtained from our work will be published, thus advancing knowledge of disease processes and drug discovery in the scientific and clinical community. Since 2002, we and our collaborators have published approximately 70 journal articles containing in vivo data in peer-reviewed scientific journals, including 10 articles in the last four years. In addition, we regularly report our findings at national and international cancer and drug-discovery conferences.

Who or what will benefit from these outputs, and how?

Short term, we will have gained knowledge of the biology of the targeted disease processes at the molecular level and how they can be modified by the novel compounds. Selection of models and their validation typically takes 3-6 months. Testing and optimising novel compounds in the chosen screening model will take a further 12-24 months. We will learn how these compounds move around the body and excreted and while doing so, whether they can modify biological processes involved in disease progression. Data generated at each step will help improve compound design. We hope to identify promising compounds to progress into further preclinical investigation. For cancer, we will be able to show efficacy in experimental cancer models.

Data generated on the promising compounds will inform clinical and preclinical investigators as to how the compounds could be used. For oncology drugs, we aim to predict which cancer types are most sensitive to the novel compounds and generate data

using models that resemble such patient populations. Using the various types of data we generate, we will be able to show the dose range and possible schedules to be used in the clinic. In order to maximise the potential benefit, we will also consider developing novel combination therapy options as well as monotherapy use, which could also impact clinical trial design. For CNS diseases, basic compound data, such as how moves around the body, biological effects and possible dose schedules will be used to engage and inform collaborators or further evaluation of the chosen compounds in the most disease-relevant models.

Data on the most promising compounds and their selection processes are also communicated to the wider scientific and clinical community. Typically, we present our findings at conferences first then as peer-reviewed journal articles. As we already have multiple projects in the in vivo testing phase, we will be publishing findings regularly (2-4 journal articles and 5-6 posters at international conferences per year).

How will you look to maximise the outputs of this work?

We collaborate closely with the technical team of the Establishment for scientific procedures. We discuss experimental approaches from both the scientific and technical aspects to maximise output from our work onsite. Their compliance team also provides us with the network to disseminate some of our findings and any refinement of procedures.

We have multiple collaborations with experts, both academic and industrial, in various disease and/or therapeutic areas. We continuously discuss the best approaches to test or use the novel compounds and how to interpret the data. Our discussions include our clinical development team to ensure that we perform the studies most relevant to progression into the clinic.

Our publication strategy includes conference presentations as well as journal manuscript. Conferences are useful means for faster dissemination of new knowledge than via journal manuscript. Unsuccessful approaches will be included in publications where possible and particularly where the drug discovery processes are described. Investigations that led to de-validation of potential drug targets, will be useful for the scientific and clinical community, therefore, considered for publication.

Species and numbers of animals expected to be used

- Mice: 24050
- Rats: 2290

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats will be used because they are the lowest vertebrates that have well-characterised models to study drug exposure patterns and efficacy. They share sufficient anatomy and physiology with humans to be useful for the prediction of how effective the potential therapeutic compounds are in the clinic.

The majority of our studies will use adult mice, as they have been extensively used in initial evaluation of novel therapeutic compounds and detailed standard protocols are available in the literature and in- house. Many strains are also available as hosts for implantation human tumour implantation, allowing investigation of human diseases such as cancer. Very young animals will generally not be suitable for our studies involving compound dosing due to the study duration, compound administration and sample requirements.

This programme also includes the use of animals for providing fresh tissues and organs for testing compounds in the laboratory, where no suitable commercially-available cell lines are available or the use of stem cell-based systems is inadequate. Neuron preparation is more successful from young animals than from adults, therefore, the use of rat embryos and newborns for primary neuron preparation is included.

Typically, what will be done to an animal used in your project?

This programme is designed to assist drug candidate selection and development, through a series of experiments using mice and rats. Regulated procedures include substance administration, blood sampling, minor surgery, subcutaneous tumour cell inoculation and tissue collection under non- recovery anaesthesia. Each study will use one or more of these techniques.

In the initial experiments, we aim to investigate if the novel compound has drug-like properties, in other words, assess how the novel compound moves through the body to predict whether they are likely to cause desired biological effects. Animals will receive one dose of a compound at a low level and blood samples taken at various timepoints. Compound levels are measured in the blood and tissue samples of interest, which are collected after the animals are humanly killed. This will be followed by a confirmatory study using a higher dose levels or after a short period of repeat dosing, and assess whether the compound treatment results in the desired biological effects, such as inhibition of disease-driving proteins.

The subsequent study will test the safety of the predicted therapeutic dose schedule in a small number of animals. Animals will receive repeat compound administration for 1-2 weeks. Bodyweights will be measured and animals monitored regularly for any signs of ill health. The animals may have blood samples collected during the study to confirm the predicted compound exposure.

In studies to assess the efficacy of novel anti-tumour compounds, mice will receive tumour cell implantation under their skin on their flanks. Once the tumour growth is confirmed, a

compound solution or its vehicle will be administered to the animals at a dose schedule that was found to be safe in the previous study. Treatment period is typically 2-4 weeks. Most animals will receive one tumour implantation in their life time. Where we wish to test multiple tumour models, two types of tumour cells with similar growth rates may be implanted on opposite flanks. In all cases, tumour volumes are closely followed and animals humanly killed before the tumours start to impact animal health. Mice that have been cured by the treatment may be challenged by an additional tumour cell injection to test whether any long-term anti-tumour immunity has been induced. We will also assess combination therapies, where more than one treatment are given, which may improve the efficacy. A small number of animals will receive minor surgery to implant tumours or hormone-releasing pellets under their skin.

All animals are intended to be group-housed as isolation is known to cause stress in animals. In some cases, social housing is impossible on the welfare ground (due to aggression, surgical procedures or when we need to collect urine in certain study types). The mice will be housed on their own with increased environmental enrichment where appropriate.

We will investigate compound elimination and excretion of the most promising compounds using bile duct cannulated rats. The cannulation are done externally before arriving at the facility. Animals are given compound solution and bile and urine collected.

What are the expected impacts and/or adverse effects for the animals during your project?

Procedures for substance administration will cause transient pain during and after IV, IP or SC injection and no lasting discomfort.

In-life blood sampling through puncture of the superficial veins can result in transient bruising at the sampling site. Any bruising and swelling from repeat blood sampling may last up to 24 hours.

Administration of novel compounds may cause some bodyweight loss and other ill effects, such as diarrhoea, rashes and general signs of discomfort, similar to the effects experienced by cancer patients undergoing therapy. These typically occur gradually over 4-10 days. These can often be managed by modifying dose levels and frequencies and by providing diet supplements.

Experimental tumour growing under the skin on the flanks of animals cause little adverse effects. We have a set carefully-chosen humane endpoint so the studies are terminated before the tumours can impact the animal health. Tumours growing too close to limbs or on the abdomen could hinder movement or lead to abrasion. A few tumour models cause unintentional bodyweight loss. Tumours from some cell lines are prone to grow into the skin and develop lesions on the skin over the tumour over time. Animals showing these will be excluded from compound treatment studies. There are a few exceptions, such as when

treatments are known to cause inflammation within tumours which can lead to development of dry scabs before tumours shrinkage.

A small number of animals that received minor surgery will be given pain relief therefore no long-term discomfort is expected. Animals that have have received surgery before arriving at the facility are likely to feel some general discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the total mice in this programme, 90% of the total mice used will experience mild severity. They will receive compound injection or blood sampling on one or repeated occasions. Up to 30% of the mice on tolerability studies (2% of total) and 10% of the mice on subsequent tumour studies (6% of total) will experience moderate severity. This is where the first investigation of the effects of repeat-dosing of novel compounds at potentially therapeutic doses are performed. We also test combination therapies, where the toxicity is also likely to be enhanced. Approximately 2% of the mice will experience only procedures under non-recovery anaesthesia.

Of the total rats, we estimate that 85-90% will experience mild severity. They will receive compound injections and needle-stick for blood sampling. 5-10% of the animals will experience only procedures under non-recovery anaesthesia. Up to 5% of rats will have had surgery before arriving at the facility.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For Objective 1, we use animals to provide fresh tissue samples to study neurons and other cell types present in the central nervous system. The number of cell lines that can be used is limited.

For Objectives 2 and 3, we need to use animals to show that the novel compounds are able to move through the body and reach the target diseased tissue to act on, while having minimum toxicity.

Currently, there is no non-animal system that sufficiently mimics the entire body system.

Which non-animal alternatives did you consider for use in this project?

For Objective 1, we are setting up human stem-cell system which can provide neurons and other cell types of human origin for compound testing in the laboratory.

For Objectives 2 and 3, we have considered organs-on-chip and liver organoid assays for pharmacokinetics, tumour organoid assays for drug efficacy and mathematical modeling to predict compound movement through the body and its bioilogical effects.

Why were they not suitable?

For Objective 1, human stem-cell systems are currently being established for future use and not yet ready for regular use in-house.

For Objectives 2 and 3, although useful for testing a few aspects of compound properties, organoid systems cannot sufficiently mimic compound passage through the whole body. We use mathematical modelling to predict relationship between compound exposure and biological effects in animals. This still requires an initial set of data generated in animals to create the model, which can then be applied to later compounds. A confirmatory study in animals is needed to before a compound can be recommended for further investigations including clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the types of studies required for each of our internal projects, and compared against animal use over the past 5 years.

We currently have 8 active cancer and CNS disease projects at different phases. These phases include early exploratory, compound optimisation and clinical translational. The types and the volume of animal work vary depending on the stages. As the projects advance, new projects will be added, therefore, the general volume of the animal work remains constant. We estimate that we will be conducting up to 40 rat ADME studies, 100 mouse ADME studies and 90 biological studies (tolerated dose schedule finding, study of molecular changes, efficacy demonstration) in mice per year. In addition to this, we are including a limited number of mice and rats for organ collection protocol which will be used to provide fresh tissue for assays in the laboratories or as pilot studies for future biology studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have been conducting animals experiments for drug discovery programme since 2002. This includes a range of study designs and output variability for each type of experiment. The study designs have been optimised over the years and routine work standardised in such a way that they allow comparisons to historical data, therefore, most of the studies we conduct under this PPL will be based on these.

Compound exposure studies are designed to allow analysis using specialised ADME software. We will need a minimum of 3 replicates per data point to generate robust results. We will use repeat blood sampling, which reduces the animal requirement by up to 60% in mice and up to 85 % in rats.

Confirmation of tolerability at a predicted therapeutic doses is typically sufficient with 3 mice. The study duration is typically 7-12 days to ensure capturing of both early- and late-onset effects. We predict the the safe therapeutic dose range from tumour- and normal cell potency data together with ADME studies. We typically start by testing the highest predicted therapeutic dose in 3 animals. In majority of the novel compounds we design, generate and test, the originally chosen dose schedule causes no notable ill health. We use a staggered start approach to minimise the number of animals used. If the first animal shows immediate signs of toxicity, the dose can be lowered for the second animal or the study paused for review. In such cases, we may use a total of up to 6 animals.

Most efficacy studies with tumour-bearing animals will need 6-8 mice per treatment to show difference between treated and control-treated. Statistical analysis was performed on several recent data to confirm this. If the treatment is predicted to be highly effective or variability in tumour growth is particularly small, we can reduce the group size.

For protein or gene expression analysis, we have used 3-6 mice per timepoint per treatment. We have reviewed the design and results in recent studies to show that sample size of 3 is generally sufficient to show robust trends in oncology studies. For CNS diseases, where the disease-related signals often are smaller than in cancer, we have found group size of 4-6 is typically necessary.

For investigation of a new potential drug target, we study the literature to understand the possible range and duration of biological effects (differences between the level in diseased and normal tissue) needed to change the course of disease, and use them to modify our study designs. Small-scale pilot studies will be conducted to assess the suitability of the model and further optimise the study design, such as group size, study period and sampling timepoints.

Mathematical modelling is used to predict the relationship between compound exposure and biological effects. An initial set of data generated in animals is used to create the

model, which is then be applied to later compounds. This can remove the need for some studies and ensure only the compounds showing promise are tested further in animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For initial testing of novel compounds, we will use male mice, which are generally larger and able to provide higher volume of blood samples. Compared to using females with reduced blood sampling frequency, this can reduce the animal use by up to 40% in the mouse ADME studies.

For determination of biological effects of compound, pilot studies will be performed to understand the variability of the readout, which will be used to adjust the group size in the subsequent studies.

Experimental data will be used to build a mathematical model to predict the effects using output of low- dose ADME studies, reducing the number of compounds tested in subsequent studies.

In subcutaneous tumour studies, we typically plan multiple studies (efficacy, therapeutic-dose ADME or tolerated dose schedule confirmation) together. From a batch of tumour-bearing mice, those with a certain range of tumours (typically 60 - 250 mm3, 70-80% of the mice) are selected for an efficacy study. Those with tumours above or below this size range or that are awkwardly-shaped and difficult to measure will be used in other types of studies. Compared to preparing tumour-bearing animals for individual study types separately, the usage of tumour-bearing mice is reduced by up to 30%.

We plan to use mice that have failed to develop tumours after subcutaneous cell injection in therapeutic-dose ADME studies or tolerated dose schedule confirmation studies. This reduces the usage of new animals in such studies by up to 20%.

At the end of studies with tumour-bearing animals, tumours and other tissues may be collected from vehicle-treated animals and stored for future use. They are used for the investigation for the same project or future projects.

Treated animals in efficacy studies or tolerability confirmation studies may be blood-sampled to confirm compound exposure and allow correlation to the observed biological effects in the same animals. This removes the need for dedicated repeat-dose ADME studies in non-tumour-bearing animals.

Some cancer models may also be utilised for investigation of CNS diseases if the target protein is the same. CNS disease models are highly variable, requiring a high number of animals, a long study duration and may involve surgery or injecting substances into the brain. We do not propose to conduct such studies under this programme but by external collaborators only with the most promising compounds. We would like to conduct the initial compound selection in a more reproducible and aless stressful cancer model, adapted to

also investigate compound levels in the brain, to reduce the overall usage of animals for the CNS disease project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and rats will be used during this project. They are the lowest vertebrates that share similar physiology with humans and many well-characterised models in these are available for both ADME and efficacy studies.

The majority of our studies will use mice, as they have been extensively used in preclinical evaluation of novel therapeutic compounds and detailed standard protocols are available in the literature and in- house. Many mouse strains are also available as hosts for human cancer implantation, allowing the investigation of human diseases.

Equipment for oral dosing will be chosen according to the species and the size of the animals. In order to administer a specific dose of a compound, we use a syringe attached to a curved blunt needle with a bulb at the end for mice or a flexible tubing for rats. Such needle or a tubing is gently inserted through the mouth into the stomach where the compound in liquid preparation is released. This can be stressful for the animals and without good skills, it can cause damage to oesophagus or trachea. Dipping gavage needles in sugar syrup can mask the taste of some compounds and act as lubricant, generally help reduce animal stress.

Wild-type mice and rats will be used for initial ADME determination. Animals will receive compound administration and serial blood samples will be taken from superficial blood vessels. In mice, we collect blood from a surface vein of the lower hind leg as it is visible and easy to access and requires no anaesthesia or pre-warming which are stressful to the animals. Each mouse is typically sampled 2-3 times but this may be increased if a lower blood volume per sample is required or larger mice are used. For rats, we are able to collect blood samples from more timepoints because of their body size. We use temporary tail vein cannulation which avoids venepuncture and pre-warming each time a blood sample is collected. Temporary tail vein cannulation is quick to prepare and also causes less discomfort than deep-vein cannulation that requires surgery under anaesthesia. These studies typically last no more than 24 hours and animals experience pain once at the time of cannula insertion and only transient discomfort during each blood sampling procedure.

Other studies that require multiple dosing of compounds at higher, potentially therapeutic levels will be monitored closely. Tolerability studies will use mice of the same strain (or the same background strain) as the subsequent disease models in order to reduce variability and for better prediction of safety. In some cases, animals that have undergone tumour cell injection will be used to further improve predictability.

Experimental tumour models induced by injection of cancer cell lines under the skin are extensively used in oncology research. These are quick to prepare, allow the use of cell lines that have been used in laboratories, and cause little discomfort in mice as long as the tumours develop in the flanks.

Tumours are measured externally, and therefore, do not require procedures associated with measuring tumours that develop internally.

Cancer models can be a useful tool for investigating certain types of CNS diseases as they can be caused by deregulation of the same proteins. These proteins may only be detectable in diseased brain or other tissues, making investigation in healthy wild-type animals impossible. CNS disease models generally require a long study period with highly variable results, thus requiring high numbers of animals. Animals are likely to suffer gradual and long-term disease-related symptoms. Instead, a cancer model expressing the target protein offers a less invasive, relatively quick and more predictable method for initial assessment of biological effects of novel compounds in animals. The correlation between compound levels and the biological effects in the tumour can also be applied to brain concentration to estimate the possible level of biological activity in the brain. Promising compounds can then be selected and tested in further disease models.

Why can’t you use animals that are less sentient?

Due to the duration of the compound-dosing studies (typically 24h for ADME, longer for other types of studies), it is not possible to complete all procedures under non-recovery anaesthesia. Use of immature mice or rats will not be be able to meet the requirements for repeat blood sampling or tumour induction.

Demonstrating compound effects on tumours of human origin is necessary for drug discovery. The use of less sentient species for cancer models, such as chick embryo models and the use of zebrafish, have been reported. However, they cannot mimic the compound movement through the mammalian body, therefore, insufficient for drug discovery programmes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We monitor and record animal status in all experiments, including relatively short ADME studies. We have developed study type-specific record sheet in which observations are

recorded at regular intervals so any progressive issues can be found easily and be dealt with quickly.

Tumour-bearing animals will be monitored regularly. For the majority of the models used, tumours double in size every 3-7 days and we have found measuring tumours 2-3 times a week is sufficient. We will increase the measuring frequency when using tumour models that double every 1-2 days.

The surgical procedures included in this project are limited to minor implantation of tumour fragments or slow-drug delivery devices under the skin. Pain relief will be used to alleviate transient pain and discomfort in animals that have undergone surgery. We will purchase all surgically-cannulated animals from reputable commercial sources and we will monitor the surgery wounds and animal health.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Diehl KH, et al., (2001) A good practice guide to the administration of substances and removal of blood, including routes and volumes. J Appl Toxicol, 21:15.

Workman W, et al., (2010) Guidelines for the welfare and use of animals in cancer research. Br J Cancer, 102, 1555.

LASA 2017 Guiding principles for preparing for and undertaking aseptic Surgery. A report by the LASA Education, Training and Ethics section. (E Lilley and M. Berdoy eds.)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We maintain a close working relationship with all facility personnel involved in ensuring our adherence to the principles of 3Rs. This ranges from the facility manager and skilled technical staff, veterinary surgeons and more. We receive regular technical and training review. We will implement improvements according to new guidelines or recommendations as they are published, and undertake 3Rs assessments regularly.

We will also use our network of similar-minded investigators, including academic and industrial collaborators, to obtain further information.

39. Glucocorticoids: Breaking the Link Between Obesity and Insulin Resistance

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Glucocorticoids, Obesity, Insulin resistance, Diabetes

Animal types	Life stages
Pigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand the role of glucocorticoids (stress hormones) in the development of complications associated with obesity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Over 650 million people worldwide are obese and 18 million die annually from its complications including diabetes and cardiovascular disease. In some people with obesity the hormone responsible for controlling blood sugar levels (insulin) stops working as efficiently, the organs in the body become resistant to the effects of insulin, this is known as insulin resistance. In the face of insulin resistance the pancreas produces more and more insulin and this can lead to pancreatic exhaustion (diabetes) and cardiovascular disease. How obesity results in these serious complications in some, but not all people, is unclear. In some diseases, such as Cushing's disease, stress hormones are very elevated and there is a clear link between these hormones and the development of insulin resistance/diabetes. In obesity, however, where there is not an obvious increase in stress hormones in the blood, the situation appears more complicated. Stress hormones are processed by organs in the body such as the liver, fat tissue and muscle. This project aims to understand the role of stress hormones in the development of complications associated with obesity, determine which organ in the body is most important in determining this risk and uncover new genes responsible for complications in people with obesity.

What outputs do you think you will see at the end of this project?

This project will help us understand how stress hormones contribute to obesity complications and therefore help identify people most at risk and develop new targeted treatments. Specifically we hope to determine which organ in the body plays the biggest role in the development of obesity complications like diabetes and identify new genes which are important in determining whether a person is more at risk of obesity complications.

Expected outputs: publications, conference abstracts and seminar presentations, raw data such as sequencing and imaging data sets. Research outputs will be made available through the research outputs portal, PURE. In addition datasets will be deposited in a data share repository.

Who or what will benefit from these outputs, and how?

Over 650 million people in the world are obese and a great proportion of these develop complications such as diabetes and cardiovascular disease. A new understanding of the underlying causes of obesity complications will potentially influence policy or strategic guidelines for healthcare professionals managing people with obesity. It will help them make the most appropriate management decisions and therefore ultimately benefit the patients themselves in terms of improved quality of life and increased life-expectancy. These outcomes are likely to be relatively long-term in their realisation but they will be globally applicable. These outcomes also apply to species such as horses, dogs and cats in whom obesity and its complications are a growing concern. In addition we will increase our knowledge and understanding of glucocorticoids in pigs which could inform work to improve the health and welfare of animals in commercial pork production.

Successful completion of the project will improve our understanding of the interaction between obesity, stress hormones and metabolic risk. This may lead to identification of therapeutic targets that will have an impact on animal and human health. For example, determining the contribution of the liver to diabetes development could lead to liver-specific targets or the re-purposing of drugs already known to act on liver enzymes. Other short-term component benefits include the optimization of experimental methods such as use of habituation and placement of vascular access ports that will offer refinement of existing approaches employed in animal research.

Early capture of intellectual property arising out of hypothesis-led research could assist in securing a competitive advantage for research and commercial activity arising out of the UK, and attract research and development investment from global business.

How will you look to maximise the outputs of this work?

In this project we will be collaborating with other scientists in Spain and Denmark to maximise the value of our research and increase its impact and likelihood of success. We will store all samples collected so that they may be used in future work following appropriate ethical review.

We will publish our findings and our research methods, positive or negative, in peer reviewed journals and present them at international scientific conferences in a timely manner. We will also disseminate information through public engagement events such as public lectures and science festivals.

Species and numbers of animals expected to be used

- Pigs: 60

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we are using an adult pig model of obesity. Pigs have very similar stress hormones to humans and, like humans, when they become obese some, but not all, develop complications such as diabetes. In this study, I will compare the stress hormones and genetics of pigs at high risk of complications and those at low risk to understand how they differ. Using adult pigs we can most closely replicate the development of obesity in adult humans and we can trace the changes through obesity development. The hypothalamic-pituitary-adrenal axis, the main determinant of circulating stress hormones, undergoes minimal changes once an animal reaches adulthood and we can therefore better assess any changes we see as a result of the dietary intervention.

Typically, what will be done to an animal used in your project?

We will use two breeds of pig, one is a fast growing lean breed which is relatively resistant

to the effects of a high-calorie feeding and the other is a slow growing fatty pig which is prone to developing complications when fed a high-calorie diet.

We are studying stress hormones and therefore we will spend a considerable amount of time (2- 3months) before the start of the experiment acclimatising and habituating the animals to handling so that we can examine them, weigh them and take samples without them becoming stressed. We will take samples such as blood and urine at the start of the experiment and while they are being fed a high-calorie diet for 3 months, we will measure stress hormones in these samples to understand what happens in the different breeds of pig. The animals will also be anaesthetised and have abdominal surgery before and during the high-calorie diet. During surgery we will take small samples from the liver, fat tissue and muscle so that we can determine the amount of time of stress hormones in each tissue. We will then give the animal an infusion of stress hormone and we will take samples of blood crossing the liver, fat tissue and muscle over the course of several hours. From these samples we can determine the contribution of each of the organs to stress hormone processing. A group of each breed will also receive a drug which blocks the effects of stress hormones to determine how this affects the risk of developing obesity complications such as insulin resistance.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will undergo procedures that may involve injections and surgery after which they may experience moderate discomfort for a short period of time (1-2 days) but every animal will receive pain relief as specified by a veterinarian. We will be habituating and training the animals for a period of time prior to commencement of the study using positive reinforcement so that any interaction with humans is as positive and stress-free as possible. The animals will be kept together in groups with access to significant enrichment. Based on our experience and the experience of our collaborators we do not anticipate any adverse side affects from feeding a high calorie diet.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The overall severity of this project is moderate because the 90% of the animals will be anaesthetised and have an abdominal incision and tissue samples taken.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In this study we aim to determine the relationships between regulation of stress hormones and the development of insulin resistance and diabetes. This is incredibly challenging to do in humans because studies are often based on single observations or limited in the degree of intervention that is ethically/practically possible. Most studies compare obese and lean states in different individuals at a single timepoint because of the difficulties of studies over time, and there are very few suitable measures which accurately reflect stress hormones for use in genetic studies.

Which non-animal alternatives did you consider for use in this project?

At the moment there is no suitable non-animal alternative for addressing the aims of this project. Cell models have been used to determine the individual effects of stress hormones on certain parameters but they often do not reflect findings in humans or animals because they are too much of an oversimplification of the system. We have done preliminary analysis using human genetic datasets to guide our questions.

Why were they not suitable?

The regulation of stress hormones is incredibly complex and interlinked, with each organ playing a slightly different role. A whole organism approach is therefore essential to unpick the complexities of the system which cannot be replicated in a cell model. There is insufficient data available in humans to rely solely on a genetic studies to answer the questions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animals used in this study will be adult, females of the same age from two breeds. Once a pig reaches adulthood the hypothalamic-pituitary-adrenal axis which controls blood stress hormones levels, does not change significantly and so animals can act as their own

controls when we change the diet. This reduces the number of animals we need to use and improves the data quality. The data from each animal will be compared to the measures at the start of the experiment prior to starting high-calorie feeding. The number of animals is estimated based on pilot data in both breeds and our experience in longitudinal studies of obesity.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs experimental design tool was used to inform our study design as well as consultation with statisticians and collaborators with experience of porcine models of obesity and stress hormone modelling. The experimental approach has been developed to allow acquisition of multiple types of data (blood, tissue, imaging etc) at multiple time points, maximising the amount and quality of data acquired from each animal.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The longitudinal element of this project includes a pilot phase of a small number of pigs (n=4) to ensure the feasibility of each experimental phase and to allow us to refine any techniques. Sample sizes will be reviewed at the end of the pilot phase. Each animal will act as their own control with data collection at baseline and then during the dietary intervention; this reduces the numbers of animals required but maintains the power of the study. The studies are designed to acquire multiple types of data at each time point, maximising the information that can be gained from each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use pigs in this project because of their similarities to humans in genetics, physiology and size particularly with respect to stress hormone biology. My preliminary data show their stress hormone profiles are more similar to humans than rodents or other large animals. We will use blood sampling over time and then intermittent sampling of tissues. These methods are used in humans to accurately study processing of stress hormones. Pigs are suitable for experimental-medicine interventions and longitudinal sampling. Prior to entering the study the animals will be habituated to handling so that they

stand, with minimal restraint, for procedures/sampling so that unstressed samples can be obtained which is essential to achieve the objectives of the project. We will use vascular access ports as much as possible so that blood sampling via a subcutaneous port can be conducted with minimal restraint of the animal . The animals will be anaesthetised for any prolonged procedures so as to minimise handling and stress to the animals. The animals will be given peri-operative analgesia for any invasive procedures and will be monitored closely by technicians experienced in pig handling and assessment. We will use high-calorie feeding to study obesity development in pigs, the diet is designed by experts in pig nutrition to ensure palatability. The study will be conducted in a specialised facility staffed by experts in large animal handling and experimentation, anaesthesia and surgery.

Why can’t you use animals that are less sentient?

Rodent models of glucocorticoid metabolism are fundamentally flawed in the context of translation to humans and other mammals because the primary stress hormone of high mammals, cortisol, is not present in rodents. As such any study of glucocorticoid metabolism relies on conjecture and assumption. The enzyme 11β-hydroxysteroid dehydrogenase type 1, for example, showed promise as a link between glucocorticoids and obesity but its therapeutic potential has not been realised, because of difficulties translating findings from rodents to humans. Its inhibition results in compensation predominantly by the hypothalamic-pituitary-adrenal axis which could not be fully characterised in rodents. In addition the questions that are always left unanswered in rodent models of obesity or genetic manipulation of glucocorticoid regulating pathways are those of causality because it is almost impossible to sample blood or tissue from the same animal at baseline and then longitudinally during an intervention. Other models such as Zebrafish and drosophila are also unsuitable for similar reasons and in fish there is rarely a metabolic phenotype recognised in obesity models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This study is centred on glucocorticoids, stress hormones, as such it is essential that the animals are minimally stressed throughout the experiment. The animals will have access to enrichment (straw, toys etc) throughout the experiment and kept in stable social groups. Before animals enter the experiment for either protocol 1 or 2 they will undergo a period (up to 4 months) of training (using positive reinforcement) to habituate them to human interaction, movement around the facility, standing for sampling and weighing, temporary separation from their group, examination of laparotomy sites and administration of substances via a dosing syringe.

Vascular access ports will be placed early on in the experiment so that blood samples can be obtained via a subcutaneous port rather than repeated venepuncture, this reduces the amount of handling and restraint required and the risk of haemorrhage.

Procedures requiring the animal to be restrained for any length of time will be conducted under general anaesthesia in order to minimise stress. Animals undergoing a laparotomy will receive antibiotics and analgesia routinely.

The study will be conducted in a specialised facility staffed by experts in large animal handling and experimentation with access to state-of-the-art facilities for housing and experimental work.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have designed the experiments following the Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE). We used the 3Rs experimental design tool to inform our experimental design.

The housing of animals will follow the guidelines on enrichment (van de Weerd and Day 2009) and the habituation and enrichment methods used will be reported when we publish our study findings.

For venepuncture we will adhere to the published guidelines from the NC3Rs. https://www.nc3rs.org.uk/3rs-resources/blood-sampling/blood-sampling-pig. We will also followed published best practice for the oral glucose tolerance test (Manell et al 2016, 2021).

We will report our findings in accordance to the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The budget of the project includes ongoing 3Rs training for the animal technicians and researchers involved. We will attend and present our findings at the local 3Rs conference. We subscribe to the NC3Rs newsletter and individuals in the project team are members of the Laboratory Animals Veterinary Association, the Laboratory Animal Science Association and the Large Animal Research Network, attending meetings and staying up to date with developments. We will ensure that in all reporting of the study we include our habituation protocol and details of enrichment for scrutiny by reviewers.

40. Senescence in Early Tumorigenesis & Age Associated Chronic Degenerative Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

senescence, hyperplasia, tumorigenesis, aging, degenerative disorders

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To ascertain the role of cellular senescence and its effector proteins/pathways in early tumorigenesis (the production or formation of a tumour) & age associated chronic degenerative disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a leading cause of death worldwide. Efforts devoted to cancer research over the last decades have been formidable. For instance, a major breakthrough came from the human genome project which has enabled us to know that of the 20,000 or so genes of the human genome, only a handful of usual suspects are most prevalent in tumours. However, it has been extremely challenging, for instance, to move beyond the genetic drivers of cancer to how they lead to the cellular hallmarks of cancer: self-sufficiency in growth signals, insensitivity to anti-growth signals, tissue invasion and metastasis (cancer that spreads from where it started to a distant part of the body), limitless replicative potential, sustained angiogenesis (blood vessel growth), and evasion of apoptosis (cell death).

Harnessing the power of genetic sequencing to study tumorigenesis in humans has revealed sub-types of cancers, again featuring the usual suspects but it also reveals a mess, cancer cell genomes are often fragmented and duplicated. It is very hard to determine, from the kinds of tumours with which human patients present at the clinic, which events have driven tumorigenesis (the production or formation of a tumour) and which have merely come along for the ride. Studying tumorigenesis in animal models allows us to study much earlier stages of the disease, even the first few days of 'cancer'. We believe that by studying these processes in mice we will be better able to understand cancer and also perhaps come up with better tools for early diagnosis, as well as therapeutic interventions.

Our tissues are constantly rejuvenating themselves, the surface of our skin is effectively replaced every three weeks and the surface of our intestines even faster still. This is thought to be to combat the harshness of our environment. At a more fundamental level our cells turn over their protein complement rapidly too, through processes such as autophagy (self eating, akin to cellular recycling). However, if cells do accumulate damage e.g. through exposure of deeper layers of the skin to ultraviolet (UV) radiation from the sun or even through mistakes made during the natural cell division that takes place to replace all these cells we shed, they may undergo a defence mechanism that results in a permanent stop of the division cycle: senescence. Studies in mice have relatively recently shown that if these senescent cells are removed then symptoms of aging can be reversed and the mice rejuvenate. The lifespan of these mice was overall unaffected but they lived a much healthier life, free from age associated diseases such as e.g. osteoarthritis. Removal of these senescent cells also reduced the numbers of mice which died of cancer.

In some tissues, senescent cells can be eliminated naturally by the immune system. However, if senescent cells persist they can accumulate forming premalignant lesions or tumours that the immune system is not able to eliminate. Senescent cells secrete a complex cocktail of inflammatory and tumour-producing factors in the surrounding tissue, which may also interfere with the immune system’s clearance and allow damage cells to

persist. We now have strong evidence, including from mouse studies, of a causal role between senescent cells and the origins of cancer.

What outputs do you think you will see at the end of this project?

Knowledge and collaboration

The primary output of this programme of work will be to increase knowledge of:

1. The different sub-types of senescence that exist within the body, rather than the senescence that occurs in cells in a petri dish. We aim to make a gene expression 'atlas' of the different types of senescence that occur in the different organs and tissues of the body across an animal's lifespan.

2. The genetic and epigenetic (additions to DNA, e.g. methylation) alterations that occur during ageing and age-reversal and whether that senescence response changes with age.

3. The interactions of senescent cells with the immune system and how that affects the clearance of senescent cells, potentially avoiding tumorigenesis.

Newly developed knowledge will be disseminated through:

1. Publication of results in Open Access, peer-reviewed, high impact scientific journals and regular presentation of data at national and international meetings.

2. Dissemination of study data through open access repositories such as GEO datasets for the genomic data.

3. Fostering collaboration and sharing knowledge between the collaborating centres.

Who or what will benefit from these outputs, and how?

This project will be of direct benefit to researchers working in the fields of senescence, aging and age- related disorders as well as epigenetics. Since our mouse model of premature aging uses autophagy perturbation, this will also be of benefit to researchers in the field of autophagy.

Developing methodologies, and mouse models

1. Publication of methods and technologies in Open Access, peer-reviewed scientific journals or online. Where methods are considered to be particularly innovative or novel publication in a methods-focused peer-reviewed scientific journal will be considered (e.g. Nature Protocols / Methods).

2. Any new mouse models will be shared with research communities upon publication or under a collaborative basis prior to publication.

How will you look to maximise the outputs of this work?

We aim to publish our new results (i.e. scientific findings, as well as the methodologies mentioned above) in Open Access, peer-reviewed, high impact scientific journals and will regularly present our data at high-profile meetings. Genomic data will be disseminated through open access repositories such as GEO datasets. Any new mouse models will be available to the research community.

Communication of significant findings will be enhanced with support from dedicated PR teams, in addition to social media platforms, such as Twitter.

Our location benefits from a thriving biotech environment from small-medium enterprise (SME) to large pharmaceutical companies. We will look to leverage the results of this study and foster academic- industrial links with segments of this community to accelerate translation into the clinic and society.

Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the predominant animal used in cancer research and are also one of the most prevalent organisms used in genetic research. Laboratory strains of mice have been highly inbred over the last century, to the point where the mice within a strain are nearly genetically identical allowing for experiments to be standardised and thus highly reproducible. Crucially, there are large repositories of genetically modified mice available. Key genes involved in the development of cancer have been genetically engineered so that their cancer associated forms can be expressed, at will, by the researcher, even simply by changing the mouse's diet. Together these innovations make mice the ideal animal model for research into the development of cancer.

In terms of our choice of life stage. Although there are juvenile forms of cancer, and our colleagues study these, cancer is predominantly a disease which affects adults, and indeed the likelihood of getting cancer increases with age, and we will nearly always be using adult mice in our research.

Typically, what will be done to an animal used in your project?

We will use a number of ways of causing senescence and/or tumorigenesis in our mice for our studies. For instance inhalation of genetically modified viruses by the mice will lead to

the development of tumours within the lungs. Also we inject plasmid DNA into the tail veins of our mice which leads to the development of liver tumours. We are however interested in the very early stages of tumour development, the first few days to weeks, and as such the majority of the mice we study will not go on to develop tumours, but rather at most hyperplasia (an increase in the number of cells in an organ or tissue).

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of our mice will be culled days to weeks after e.g. virus administration to the lung or plasmid DNA injection to target the liver. This will allow us to study the appearance, and immune- system mediated removal, of senescent cells in the first few days after the delivery of an oncogenic (cancer causing) mutant gene. Thus the adverse affects will originate solely from the those associated with the techniques of viral or plasmid delivery themselves.

Occasionally longer-term experiments will be necessary, where the rate of tumour development is an important end-point. We require the mice to develop measurable tumours to, for instance, allow sufficient biological material to be obtained for analysis. Where possible tumour growth will be tracked using imaging, which will allow us to identify and follow the tumour, without the need for emergent clinical signs in most cases.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice which undergo, for instance, hydrodynamic tail vein injection and/or develop tumours are deemed to have undergone a moderate severity of suffering. Based on previous usage we expect around a third (33%) of animals will fall within the moderate category. As stated above, we are interested in studying the very early stages in cancer development, the first few days to weeks. Hence, we will only need to leave mice for longer, to develop tumours, in a small proportion of our experiments.

The breeding of genetically altered (GA) animals will produce surplus mice not bearing the required alleles, as determined by Mendelian genetic ratios, and as such we expect around 59% of our mice to undergo no discernible suffering at all (techniques we use herein, such as viral delivery to the lungs and hydrodynamic tail vein injection, help to combat the wastage resulting from the breeding of GA mice). We expect the remaining mice will fall either into the mild severity category (7.6%) or the severe severity category (0.4%).

What will happen to animals at the end of this project?

- Killed

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The interactions of cells with other cells within a tissue are too complex to recapitulate in a culture dish; for this reason it is essential to carry out some experiments on animals.

Which non-animal alternatives did you consider for use in this project?

Alternatives to animals in cancer research chiefly come down to

(a) cells grown in petri dishes, alone or in co-culture

(b) cells cultured in organoids

(c) cells cultured in tissue slices

Why were they not suitable?

With regards to (a) not all the cells of the body can be grown successfully in petri dishes. Cells of the liver for instance will either die or de-differentiate (cease to function like liver cells) for unknown reasons (presumably a lack of growth factors) once taken out of the environment of the body. Those cells that most readily grow on plastic are cancer cells, however by the time they have become a fully blown cancer cell it is almost too late to study them, as their genomes (DNA) for instance are often fragmented, duplicated, and are frankly messed up. Of the cells that can be taken directly from the body for study, fibroblasts grow most readily and have relatively normal genomes. We do use these in our studies and have based much of our work to date on them. However, due to this we now have a skewed picture of what defines a senescent cell. The senescence described in vitro (on glass or plastic dishes), mostly in fibroblasts, with a particular stimulus will, most likely, not represent senescence in different cell types / lineages, with different stimuli, across different tissues and at different ages. We therefore want to characterise senescence in different cells of the body in the context of their microenvironment in this application. Cells can be co-cultured, i.e. two cells types grown together, however this can often only be performed with two cells types, e.g. cancer cells and a single immune cell type (which is often itself a cancer cell). Increasingly it is becoming evident that cells of the immune system 'talk' to each other through release of messaging factors (chemokines and cytokines) and so in order to get an accurate picture of what is happening with regards to the clearance of senescent cells by the immune system we ideally need to study living organisms where these processes are fully competent. Cells grown in organoids (b) or

tissue slices (c) are one step closer to modelling living organisms but cannot currently fully recapitulate living organisms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This will be the third project licence that has been held be the lab. The estimated number of animals we will use is based on our usage for the previous 5 years. We consult with a professional statistician where possible and the numbers of mice entered into experimental cohorts are carefully considered together with them. However, the majority of our estimated usage (~60%) arises from the breeding of genetically altered mice, despite our breeding strategies being optimal (and under constant review). Note that innovations such as the administration of virus to the lungs or hydrodynamic delivery of plasmid DNA to the liver enhances the numbers of mice we can use in experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A professional statistician is employed by our establishment for the purpose of helping to design our experiments so that we use the optimum number of mice (or indeed plates of cultured cells). As well as consulting with them we also use online tools such as the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The majority of our mouse usage comes from the breeding of genetically modified lines where unfortunately a large number of surplus animals are generated due to the nature of Mendelian genetic inheritance. We have optimised our breeding strategy to minimise the generation of surplus animals.

We have also adopted techniques which reduce or remove the need to breed mice altogether. Our intravenous injection of plasmid DNA technique for introducing that DNA into the liver (which we refer to as 'hydrodynamic transfection') or our viral administration of DNA into the lungs can produce genetically altered mice without the need for breeding genetically altered animals and thus reduces mouse usage.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This programme of work is exclusively concerned with the use of mice as a model system. Mice have been used in the study of cancer for much of the last century and indeed mouse models of cancer are now really quite refined. Mouse genetics has developed to the point where a researcher can induce cancer simply by adding a completely innocuous substance to their diet or drinking water, thereby inducing the genetic alterations within the genome of those mice.

Our work is concerned with studying the development of cancer within the first few days to weeks after its initiation. As such the majority of our mice will not develop tumours nor the pain and suffering associated with that.

Why can’t you use animals that are less sentient?

Although there are childhood forms of cancer, which our colleagues work on, cancer is primarily a disease of adult animals, and indeed its incidence increases with age, so to use animals at an immature life stage is not appropriate to our studies.

Whereas, arguably less sentient animals can develop cancer, there is always the question as to how well this recapitulates human cancer. Mice offer the possibility to study cancer in a mammalian organism that recapitulates human cancer very well, whereas at the same time they are quick to breed and relatively easy to house.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Using as an example one of the main techniques that we use, hydrodynamic tail vein injection (HDTV). We have extensive experience with using this technique over the last 8 years. We have refined the technique in order to maximise success and minimise adverse effects for the mice. For instance, we have determined an optimum age range for the mice to be injected mice to be between 6 and 9 weeks of age, before they have put on excess weight necessitating increased injected volume. We will attempt continued refinement of the technique going forward during this proposal. There is interest in the potential use of this technique under general anaesthesia however, there is no data demonstrating non-inferiority of successful delivery of the injection to the animal, or the plasmid DNA to the liver, when using this approach. Therefore, during this project we will trial the HDTVi

delivery of our plasmid DNA in awake and anaesthetised animals to analyse the scientific validity of HDTVi under anaesthesia in these key metrics.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The scientific literature includes journals dedicated to the publication of protocols, which often represent best practice and include tips for refinements to techniques. We also are in close communication with other labs that perform the same techniques as us, including discussing any refinements they have made and/or are currently making.

Unless otherwise specified, the work in this project will be undertaken in accordance with the principles set out in the Guidelines for the Welfare and Use of Animals in Cancer Research: British Journal of Cancer (2010) 102:1555-1577 (referred to subsequently as the ‘NCRI Guidelines’) and in the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery (2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The 3Rs of scientific animal work are replacement, reduction and refinement. Refinement is concerned with methods that alleviate or minimize potential pain and distress, thus emphasizing animal well- being. In the UK a national centre for the 3Rs (NC3Rs) was setup in 2004 and it produces a monthly news letter to which we subscribe.

We are also in contact with other groups which are involved in similar research to ours and use similar techniques. This kind of 'word of mouth' is often the best way or staying up-to-date with the latest up- and-coming techniques and advances. There is also a monthly meeting of people using our animal facility, attended by representatives from each lab, where our facility's NACWOs and the NVS provide us with suggestions on the latest refinements and 3Rs advancements.

41. Mitochondrial Regulation of Neuronal Presynaptic Function in Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neurodegeneration, Synapses, Mitochondria

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to further our understanding of how mitochondria regulate neurons in three areas:

1) Studying the precise location of mitochondria at neuronal synapses, to establish how this regulates synaptic transmission and how this changes in Parkinson's disease,

2) Studying how mitochondria interact with other components of neurons at synapses, such as the endoplasmic reticulum (which also regulates signals that can alter neurotransmission), and how this is altered in Parkinson's disease,

3) Studying whether mitochondria located at synapses are different to mitochondria located elsewhere in neurons.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A pivotal contribution to the success of complex life has been the evolution of the nervous system, since it enables organisms to respond in a rapid and coordinated manner to their environment.

However, it comes at a high price: the human brain is just 2% of the body's mass, yet demands 20% of the body's energy. Much of this energy is used to power synapses, where neurons connect and communicate with each other. An individual neuron contains many hundreds of synapses, which vary in their activity over time. So neurons need a way to meet changing energy demands from one part of the cell to another, and also from one point in time to another. Mitochondria are perfectly suited to help with these changing demands. Mitochondria are key components of cells that can generate useable cellular energy from fuel sources. Furthermore they are mobile, so they can move around within cells to provide energy to where it is most needed. It follows that mitochondria are frequently located at synapses.

As well as providing energy to support activity at synapses, our recent work has shown that mitochondria can also reduce activity at individual synapses by mopping up a signal that triggers neurotransmitter release at synapses. Furthermore, the ability of mitochondria to move to and from synapses, and to alter the levels of this signal, is impaired in mouse models of Parkinson's disease, suggesting that the balance of energy provision and signal regulation provided by mitochondria is important in maintaining normal synaptic function. Therefore we need a more complete understanding of why mitochondria have this dual role in regulating neuronal synapses, and the molecular mechanisms by which this regulation occurs, and also how this regulation changes in neurological and psychiatric disease. Understanding this form of synaptic regulation could provide new approaches to treating conditions such as Parkinson's disease.

What outputs do you think you will see at the end of this project?

Anticipated outputs include the generation of new scientific knowledge, specifically furthering our understanding of synaptic regulation by mitochondria. The primary output would be peer-reviewed scientific papers, and presentations at scientific conferences.

Who or what will benefit from these outputs, and how?

Impairment of synapses contributes to many diseases, including autism spectrum disorder, schizophrenia, epilepsy and stroke, as well as neurodegenerative disorders (which arise due to the premature death of certain types of neurons, seen in Parkinson's disease, Alzheimer's disease and motor neuron disease amongst others).

In the short term, this program of work will provide insight into synaptic regulation which will benefit research groups working on related areas. In the longer term, given that we know relatively little about how mitochondria support and regulate synapses, this program of work has the potential to be relevant to a wide range of diseases that currently have few if any treatments available. The ultimate goal of this research is to provide additional mechanistic insight into how mitochondria contribute to synaptic dysfunction in neurological and psychiatric disease, and therefore provide novel therapeutic opportunities to treat these diseases.

How will you look to maximise the outputs of this work?

The results from this project will be initially communicated at scientific conferences and via publicly available pre-prints, and then in peer reviewed journals. The nature of the work is highly collaborative and will allow the building of new research teams to continue active investigation.

Species and numbers of animals expected to be used

- Mice: 15000
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are used as the lowest vertebrates with a nervous system that closely resembles that of humans. The majority of experiments will be performed on nervous tissue obtained from embryos (wildtype or transgenic mice and wildtype rats) or neonatal mice, with some experiments performed on adult mice. Although some mice with gene mutations that cause Parkinson's disease can develop motor symptoms akin to

Parkinson's, the number of mice so affected will be kept to the absolute minimum, and mice will be sacrificed at the end of the experiments.

Typically, what will be done to an animal used in your project?

We estimate that for the majority of experiments (approximately 75%), mice or rats will be mated, and the pregnant dams sacrificed. Nervous tissue will be obtained from embryos, and grown in culture, then used in subsequent experiments. Neuronal cultures may also be generated from early postnatal mice that have been humanely killed.

In a further 15% of experiments, brain tissue (slice cultures) will be obtained from early postnatal mice that have been humanely killed. Some brain tissue (slices) may be obtained from adult mice that have been humanely killed.

In approximately 5% of experiments, mice will be aged beyond 12 months. These animals may undergo non-invasive behavioural testing that would cause no harm or distress. Brain tissue (slices) may be obtained from these aged animals that have been humanely killed.

In approximately 5% of experiments, mice will undergo surgical procedures under deep anaesthesia to provide access to the brain, during which devices for recording activity of nerve cells or delivery of substances into the brain. Some of these mice will be fitted with cranial windows and head fixation devices to enable microscopy. For all of these experiments, all animals will receive pain relief and will be closely monitored during recovery. In most cases, mice will undergo one or two surgical procedures, with sufficient time between surgeries to allow for complete recovery. In some experiments the mice may have head movements restricted (via head fixation) to allow recording of neural activity and/or reliable presentation of sensory stimuli. In these cases, mice will be habituated to head fixation and the experimental setup to minimise stress and discomfort.

What are the expected impacts and/or adverse effects for the animals during your project?

All rats and the majority of mice will undergo either subthreshold or mild experiences, typically associated with breeding or earclipping for genotyping or identification, and are brief. The vast majority of adult mice carrying mutations that cause Parkinson's disease will be sacrificed before they develop symptoms. Adult Parkinson's mice that are not sacrificed at this early time point will be carefully monitored for development of signs of distress, and sacrificed if this occurs.

For mice undergoing surgeries required for access to the brain, pain resulting from surgical procedures may reach moderate severity for short periods of time immediately following surgery. Animals will be closely monitored for signs of pain after surgery and appropriate analgesia will be provided. Head fixation is expected to result in only mild stress during initial habituation to the experimental apparatus.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All rats and the vast majority of mice (95%) will experience subthreshold severity. Otherwise severities are mild or moderate (5%).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed work aims to advance our understanding of how mitochondria behave in neurons in a system resembling the intact brain as closely as possible. For this reason, experiments are carried out on neurons grown in culture from mice or rats (75% of experiments), or on brain slices obtained from mice (20%), where normal connections between neurons are reasonably well preserved, or in vivo (5%). Mice and rats have been chosen since these are the lowest vertebrates with a nervous system sufficiently similar to humans to enable conclusions to be drawn that are relevant to the advancement of clinical care.

Which non-animal alternatives did you consider for use in this project?

Wherever possible, alternatives to animals will be used, for example induced pluripotent stem cell- derived neurons from Parkinson's patients, which enables us to examine the effects of Parkinson's- causing mutations in the specific human cells that are affected by disease. We have also searched existing databases of results which we can apply to our research questions, without needing to repeat the experiments in animals ourselves.

Why were they not suitable?

Stem cell-derived neurons do not fully recapitulate synaptic connections in vitro, and so whilst they are a valuable additional model, they are not sufficient to fully replace rodent studies for the planned work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate of mouse and rat numbers is based on experimental experience, aiming to balance reduction in use with producing robust, reproducible, and meaningful results. Statistical techniques have been used to estimate the number of mice or rats included in each experimental group, to reduce the risk of false positive or negative results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3R's Experimental Design Assistant, and employed statistical calculations using analysis software.

Additionally, we use rats as an alternative to mice where non genetically altered neurons in culture or slices are to be studied. Rat neuronal cultures are more robust and easier to maintain than mice cultures, and more neuronal cultures can be generated per animal. Therefore this reduces the overall number of animals that are needed for experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A key element of the usage of mice is the breeding of genetically-altered animals, therefore we will optimise breeding strategies to reduce surplus animals which would otherwise need to be culled.

The experimental utility of each mouse or rat will be optimised by maximising the number of measurements taken from each animal, and tissue will be shared when possible to reduce the need for mouse or rat use by other groups. The project will use the least number of mice or rats necessary for appropriate statistical power and reproducibility. In all cases, steps will be taken to reduce systematic bias, including blinding of genotype, using both genders where applicable, and appropriately replicating results in independent experiments. For large datasets, expert statistical advice will be sought where required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experimental methods and models we will employ are all well established as techniques which provide robust and reproducible results carefully balanced against causing unnecessary harm. We use rats to generate neuronal cultures which can then be labelled for proteins of interest and used in experiments. We use mice which carry genetic instructions to tag mitochondria with a fluorescent protein that enables us to visualise mitochondria under the microscope. We also use mice that have genetic instructions that direct this tag to be expressed only in midbrain dopaminergic neurons, which are the neurons most susceptible in Parkinson's, so that mitochondrial function can be studied specifically in these cells. These genetic instructions are harmless to the mice.

We also use mice that carry mutations that cause Parkinson's disease, or that affect mitochondrial function or mobility, which can lead to neurodegeneration, however symptoms only develop after a period of time. This enables us to closely monitor the mice, and humanely sacrifice any that develop distressing symptoms, to minimise harm.

For limited experiments, surgical procedures will be conducted under deep anaesthesia following aseptic technique and mice will be carefully monitored following surgery to ensure complete and uneventful recovery.

Why can’t you use animals that are less sentient?

Rodents are the least sentient animals that have a nervous system similar enough to humans to be able to begin to generalise results, and in which human neurological disease can be modelled. The availability of disease models allows us to test whether new treatments might be effective in humans, and whether side effects are likely.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement relevant to this project would be ensuring that harm to animals carrying mutations that cause neurodegeneration are not kept alive longer than is absolutely necessary for the proposed experiments.

Appropriate analgesia will be used during surgical procedures and mice will be closely monitored during recovery. In experiments involving head-fixation, mice will be gradually habituated to the experimental setup to minimise stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE, PREPARE, and FELASA guidelines, and we will follow the guidelines set out in LASA Guiding Principles on Preparing for and Undertaking Aseptic Surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We closely follow the neuroscience literature relevant to the project, continuously looking for techniques which will allow us to refine the animal work which we conduct. We are also following NC3Rs initiatives closely, both on their website and as disseminated through the institute and university.

42. Investigating Mechanisms of Biomechanical Stress and Inherited Heart Disease (Cardiomyopathy)

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Inherited heart disease, Modelling diseases, Therapeutic approaches to disease, Biomechanical stress

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to better understand a group of human inherited heart diseases called cardiomyopathies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inherited heart diseases called cardiomyopathies contribute substantially to the burden of heart disease in the UK (Overall cost of heart diseases to the UK economy is estimated to be £19 billion each year, with over 7.6 million people estimated to be living with heart diseases in the UK).

The majority of cardiomyopathies are caused by genetic 'spelling mistakes' in proteins important for cardiac contraction and there is a reasonably good understanding of how they cause disease. This project will focus on less investigated novel group of proteins associated with the hearts ability to sense stress, or other proteins found to be associated with the disease. Alterations in these proteins can lead to detrimental alterations in the hearts structure i.e the heart becomes bigger and stiffer, it may also be unable to work efficiently to sustain a healthy delivery of blood to the rest of the body's organs.

Our work will provide novel understanding of "what goes wrong" at molecular level in the presence of the "spelling mistakes" and we will focus these investigations on signalling networks, e.g. on how the heart senses and responds to mechanical demand (a process called bio-mechanical stress signalling). This will advance our knowledge of which signalling pathways are crucial for maintaining normal cardiac function and how they are affected in the presence of disease-causing "spelling mistakes", both in "traditional" disease genes affecting cardiac contractile units (responsible for generating force) and in newly identified "unconventional" disease genes, e.g. coding for proteins sensing and responding to mechanical demand. The work will help to uncover novel key players in these signalling networks and thereby identify potential therapeutic targets for specific treatments of cardiomyopathies.

What outputs do you think you will see at the end of this project?

This research will help to gain insights into how variations in key proteins responsible for sensing and responding to mechanical demand can cause heart diseases, such as cardiomyopathy. The project will generate mouse models of human disease, by taking "spelling mistakes" identified in patients and introducing them in mice. Our experiments will tell us which cellular pathways 'go wrong' resulting in disease presentation.

Based on the findings and better understanding of the disease-mechanisms, potential therapies can then be developed to treat or prevent these diseases.

Our research will be disseminated to other researchers (e.g. through conferences, peer-reviewed journal articles).

Who or what will benefit from these outputs, and how?

Short term- A deeper understanding about specific gene alterations and bio-mechanical stress signalling pathways linked to cardiomyopathy. Our research and knowledge gained

from this project will be disseminated to other researchers/clinicians e.g. through conferences and peer-reviewed journal articles.

Medium term- The mechanisms and pathways identified will enable the development of therapeutic targets to potentially treat/prevent disease.

Long term- Help to inform Geneticists in the NHS how to interpret certain findings of genetic testing in human patients and how to advise patients and clinical practitioners on the findings. We will also explore how the disease can be ameliorated or treated.

How will you look to maximise the outputs of this work?

To maximise the outputs from this work, our findings will be presented at conferences and published in peer-reviewed original research articles.

Species and numbers of animals expected to be used

- Mice: 7650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cardiomyopathy and other heart diseases are complex and involve a wide range of interactions and pathways across tissues and cells that cannot effectively be studied exclusively in vitro. Whole animal models provide a greater insight into the mechanisms of a disease at organ level, over that of cell models and human studies. Mice are sufficiently similar genetically and in terms of heart structure and function to that of humans, despite differences in size and physiology. Introduction of genetic variants identified in human cardiomyopathy can also be achieved efficiently in mouse models. As the diseases we are studying usually occur later in life, adult mice are the most appropriate life stage for most of our work.

Typically, what will be done to an animal used in your project?

Typically, animals possessing genetic alterations relevant to the human condition of cardiomyopathy will be produced and maintained in order to characterise mechanisms of the disease. Non-invasive assessment of structural and functional changes to the heart will be undertaken by echocardiography (an ultrasound investigation of the heart). In mice this is carried out under general anaesthesia to minimise stress to the animal. We will perform this investigation at multiple time points to determine disease progression in adult mice. Some animals will have non-invasive electrocardiographic (ECG) assessment to identify those at risk of arrhythmias in conscious animals.

Some animals that do not show signs of cardiac disease will be challenged by the administration of drugs to induce bio-mechanical stress. These will be delivered over longer periods of time by an osmotic mini-pump implanted under general anaesthesia. Mice will be monitored daily for their general well-being and weighed on a weekly basis. If animals show signs of distress, they will be humanely killed. The drugs given will mimic the effects of high-impact endurance training on the heart and will help to reveal defects in signalling pathways, which may not be visible otherwise in the mouse model.

In other sets of experiments, we will use our insights into “what goes wrong” in cardiomyopathies to test how treatments, which are predicted to reverse these pathways, may ameliorate disease by injection.

At the end of the studies the animals will be killed and their organs will be used for molecular studies or the heart will be excised under terminal anaesthesia for further Langendorff perfusion or cell isolation for assessment of cardiac and cellular function to maximize the data obtained from each animal.

What are the expected impacts and/or adverse effects for the animals during your project?

From previous experience we assume that the introduction of the genetic variants (“spelling mistakes”) will have little effect on the majority of mice, despite being present for the whole duration of the mouse's life. Mice may not show any signs of cardiac disease or signs are subtle and can only be picked up by specialist tests (such as echocardiography, see above). In some cases, mice may develop symptomatic heart failure similar to humans, identified by deep abdominal breathing and lethargy. In this case animals will be humanely killed.

Some animals will undergo mini-pump implantation under general anaesthesia. This will allow the delivery of mechanical stress inducing drugs over the course of 2-6 weeks in order to exacerbate the impact of a genetic variation on heart structure and function.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity- approximately 25%
Moderate severity- approximately 75%
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use bioinformatics predictions, biochemical experiments and cellular models to understand the impacts of the genetic “spelling mistakes” on heart cells. While these experiments are informative for certain aspects of disease (e.g. they can show binding to other proteins is affected), mouse models are needed to understand the effects of the genetic “spelling mistakes” on the whole organ level, e.g. how these genetic “spelling mistakes” can cause changes to cardiac size and function as well as electric conduction.

In our in vitro experiments, we use human cardiomyocytes derived from blood or skin biopsies via an exciting novel technology called "induced pluripotent stem cells". These cells are human to reflect best real human heart cells and future work will show which aspects of animal work can be replaced by these cells. Over the course of the project we will review and potentially incorporate alternatives as they become available.

We also pursue approaches to use computational modelling (in silico predictions) to reduce the number of animals used in research. This is particularly useful to predict changes in electrophysiology, which can predispose to arrhythmic events.

Which non-animal alternatives did you consider for use in this project?

We have explored the use of stem cell-derived cardiomyocytes. Work on stem cell-derived cardiomyocytes is a parallel core activity in my lab and we are currently replacing animal work where possible.

Why were they not suitable?

Stem cell-derived cardiomyocytes are immature and do not fully recapitulate the complexity of the heart, including many cell types and physical and neurohormonal local controls. Heart diseases such as cardiomyopathies are complex, involving changes in blood flow, oxygen supply to other tissues and changes in heart structure over time, therefore exploration of this disease requires a multi-factorial approach.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Expected effect size and number of animals have been determined through consultation of the literature, previous experience of techniques proposed or through small pilot experiments when possible. we will seek advice from a statistician where applicable.

Furthermore, breeding strategies are designed to produce the required numbers without having excess of unwanted genotypes (e.g. avoiding crossing heterozygous animals with each other, and using only wildtype pairs and homozygous pairs to generate the required genotype.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing the experiments, we performed statistical analysis to ensure we use the minimum number of mice per group that will be informative. Importantly, we also employ a variety of approaches to reduce animal usage, including:

1. Using littermate pairs where possible, to reduce variability of genetic and behavioural background

2. Performing and analysing experiments in a blind fashion where possible to reduce investigator- induced bias

3. Using standardised experimental methods to reduce variability 4.The NC3Rs EDA tool will be used to design experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To maximise the information gained from a single animal, we aim to perform multiple in vivo and in vitro analyses. Cell line work (especially using stem cell derived cardiomyocytes) and in vitro manipulations will be employed where possible to reduce animal usage.

Better reporting of research should result in better science and more effective use of animals in experiments. Therefore, our findings will be reported (using the ARRIVE guidelines) in the scientific literature and at conferences, thereby minimising risk for future unnecessary animal experiments conducted by others.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used for all experiments, as methods are available to introduce genetic “spelling mistakes” easily and mice are similar enough to humans in terms of cardiac physiology, e.g. their hearts have four chambers like the human heart.

The team has long-standing expertise and experience in all experimental procedures; we will constantly refine techniques and apply best practice to all animal work.

Cardiac phenotyping

We make extensive use of non-invasive imaging technologies (especially echocardiography). The use of serial non-invasive measurements e.g. echocardiography examinations, reduces numbers since it is not necessary to kill animals at all time points. The majority of animals will undergo at least one echocardiography examination under general anaesthesia with recovery in their lifetime. We will be careful to balance the refinement of imaging at multiple time points with the impact of multiple anaesthesia events. Animals may also undergo electrocardiogram without anaesthesia (tunnel used for restraint due to the short nature of the protocol (<5 minutes)) if arrhythmic event is suspected in line with the genetic alteration they possess.

The aim is to find the earliest time point where impairment of cardiac function can be measured reliably; this is often long before the onset of external clinical signs. We will then use these early "sub- clinical" time points in subsequent experiments e.g. to investigate the hierarchy of specific signalling pathways involved in cardiomyopathy and to study potential interventions.

Drug induced bio-mechanical stress and cardiomyopathy

Drug-induced models of cardiomyopathy will be used as a refinement to induce cardiomyopathy phenotypes in genetically altered mice (and wild-type control mice of the same genetic background for comparison) where scientifically valid instead of applying the more invasive aortic banding procedure, used elsewhere. While aortic banding is a commonly used approach to induce pressure overload cardiomyopathy, it is invasive and requires thoracotomy (“open heart surgery”). Drug-induced models of cardiomyopathy are relatively less invasive, and have intrinsically lower inter-animal variation and require less time than aortic banding to produce a phenotype. We will aim to deliver drugs via implanted osmotic mini-pumps wherever possible, especially for prolonged treatment times to minimise the need for frequent injections. We will adhere to the maximum volumes and frequencies given below (applies to all protocols and is based on LASA guidelines).

Investigation of therapeutic approaches to cardiomyopathy

For one of our models of cardiomyopathy, we have shown that a variation in the DNA causes the lack of a specific protein, important for heart structure. Based on this, we are now investigating whether expressing more of the protein in the heart can ameliorate disease. For this we introduce the missing protein into the heart with the help of an adeno-associated virus (AAV). Pilot experiments carried out in wild-type animals (C57bl6) will be used to establish optimal dosing for therapeutic treatments through injection of these novel reagents. This will be given via intravenous injection adhering to the maximum volumes and frequencies outlined in the LASA guidelines We aim to establish the lowest dose to give a robust read-out, but with minimal adverse effects. Treatment will then be given to a genetically altered mouse model for cardiomyopathy to observe the efficiency of the treatment to alleviate disease.

Why can’t you use animals that are less sentient?

Zebrafish hearts only have two chambers and therefore cannot recapitulate function and physiology of the human heart. The mouse is the least sentient mammal that is most similar to humans in terms the way their heart works (e.g. four chambered morphology) and specific disease pathways (e.g. how it senses and responds mechanical demand). Therefore, we can avoid working with larger mammals such as dogs or pigs.

As the disease we investigate are adult onset in humans, it requires us to work with adult mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Substances that require multiple dosing regimens will be delivered via osmotic mini-pumps which require only minimal surgery to be implanted. This slow release device means we can avoid twice-daily injections of the animals, hence reducing stress and discomfort in the mice.

Subcuticular sutures rather than wound clips will be used where possible, for wound closure following mini-pump implant. Sutures are flexible and therefore, are more comfortable for the animal.

Analgesic will also be given before animal undergoes surgery for implant and after when needed.

We will utilise refined handling techniques to reduce the distress that animals experience during handling.

For non-invasive electrocardiogram measurements, animals will be placed into a secured tunnel to remove the need for anaesthesia and to minimise stress to the animal. While for non-invasive echocardiography, light anaesthesia will be used for restraint to reduce stress of the animal during the procedure.

For all procedures, the mice will be carefully monitored and if adverse events are observed, monitoring will increase in frequency and steps will be taken to alleviate them or the affected mice will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the PREPARE guidelines to ensure our experiments are planned and conducted in the most refined way. LASA guidelines will be consulted to ensure correct dose volumes are selected for

the specific route of injection/blood sampling. We will also stay up to date with the NC3R website resources and guidance on the best and most refined practices. All the data will be published according to the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly monitor the guidance given by the NC3R's website as well as emails circulated by the establishments 3R’s committee, making use of the online resources to ensure the project is carried out efficiently and using the best methods for animal welfare.

43. Pathophysiology of Vascular and Renal Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

kidney, vessels, diabetes, hypertension

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our research programme aims at understanding the mechanisms of vessel and kidney disease in animal models with the goal of finding new treatments that could subsequently be applied to humans.

Specifically, our work will focus on novel mechanisms involved in organ repair in diseases. We plan to alter the levels of genes, proteins (factors), in animals and subsequently study their role in normal and disease (diabetes, hypertension) conditions. If these factors demonstrate a protective role in treating a disease of the vasculature or kidney, future

work will aim at developing new medicines that could be utilised to treat/cure diseases in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vascular and renal diseases are serious illnesses and, at times, life threatening. A suboptimal vascular/renal function (closely linked together) leads to illness, and ultimately death. Although people can be treated with drugs that help vessels/renal function, the prevention of these devastating diseases is crucial for the well-being of patients. Diabetes and hypertension are the major causes of vascular/renal disease. Diabetes and hypertension affect approximately 600 million people worldwide. High blood glucose and hypertension drive diseases that lead to vessels/renal damage. The understanding of vessels/renal diseases and their causes (e.g.: diabetes, hypertension), will help health care professionals in finding new therapeutic approaches for the prevention of vascular and kidney disease.

Our studies aim at understanding the mechanisms of vessels/renal disease, which will help the assessment of new therapies, which hopefully will be of benefit to patients.

What outputs do you think you will see at the end of this project?

This work will provide novel information on the molecular processes underlying the regulation of vessel and renal function, and on the specific role of the kidney in the regulation of water, small solutes/molecules, in physiology and in disease conditions.

Specifically, this work will contribute towards the identification and understanding of novel pathways believed to contribute to vessels, kidney glomerular capillaries and renal tubular cells dysfunction in diseases. The understanding of these pathways will have a significant impact on the identification of potential novel targets for treatment in the field of vascular medicine and nephrology. The growing epidemic of diabetes and hypertension and its associated vessels and kidney disease call for new treatments to be able to maximize end-organ protection thereby preventing or delaying progression of vessels and/or renal injury.

Who or what will benefit from these outputs, and how?

This work will help identifying novel pathophysiological mechanisms of vessels/renal disease (short term benefits - publications and dissemination to international scientific society) and potential novel target for treatment in animals and humans (long term benefits - translation).

How will you look to maximise the outputs of this work?

This works has been planned with the collaboration of different institutions in the UK and abroad.

Results will be presented at scientific meeting and to the lay community and published in scientific Journals.

Dissemination of information will include positive and negative findings as well as methodological approaches and refinements which may be useful to other researchers.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our experimental plan uses the least sentient species (e.g.: mice) which we can use to model diseases and test our proposed treatment strategies.

We will study genetically modified (and wild-type) adult mice to define the effect of diabetes, administration of specific diets (e.g.: high salt, high fat) and infusion of angiotensin-2 on vascular and renal function/blood pressure.

Further we will modify specific cellular pathways to generate a proof of principle for potential new treatments that could, in the future, be translated to humans.

Typically, what will be done to an animal used in your project?

In this project mice may:

1) become diabetic and/or develop high blood pressure (hypertension). Diabetes will be induced by either the injection of a substance that inactivates the insulin production in the pancreas, or by diets rich in fat (or combination of the two), or by using mice that have a genetic alteration or which makes them susceptible to developing diabetes naturally. Both are well defined and characterised animal models of diabetes. The housing and care of animals will be adjusted when animals become diabetic, for example by providing extra water and bedding to keep them comfortable.

2) become hypertensive by administration of agents or diets (with different salt content) that cause a raise in blood pressure. Animals will be monitored for progression of disease. This will involve taking small blood and urine samples. Some animals might undergo surgery to implant devices for the delivery of molecules and/or measurement of

blood pressure. After surgery animals will receive analgesia and will be monitored closely during their recovery.

In our experiments, we will study specifically the vessels and the kidney using non-invasive techniques which will allow us to study their function in health and disease. The presence of diabetes should only cause minimal impairment of vessels/ renal function. Animals may be kept in metabolic cages, and we do not expect any significant impediment from repeated experimental procedures.

3) At the end of the study animals will be humanely killed and tissues collected for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

For most animals used, no adverse effects are expected either in wild-type or genetically altered animals.

Although not anticipated, animals will be monitored regularly for signs of distress or suffering such as weight loss, abnormal behaviors such as lack of grooming, hunching or reduced mobility.

Diabetes may induce a degree of weight loss that is minimised by the specific model utilised to induce diabetes and/or by administration of insulin. The length of diabetes will be for 20 weeks maximum (usually diabetes occurs after 10-14 days from the first administration of streptozotocin).

Mice may be implanted with telemetry devices for blood pressure determination and mini-pump for angiotensin infusion. Mice will be closely monitored after surgery.

Individually caged animals will be adapted in metabolic cages by using home cage bedding for few days. Urine collection will be performed during the last 24 hours, home cage bedding will be removed during this time. Maximum continuous time in metabolic cages will be up to 5 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This project is expected to use 3500 animals.

~60% animals will experience a mild severity banding (P1)

~40% animals will experience a moderate severity banding (P2, P3 and P4)

In case of sudden health deterioration, animal will be treated or humanely killed.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The physiology and pathophysiology of the vessels/kidney system is regulated by a myriad of factors that function as links between different cells, tissues, and organs. To study organ physiology, we need to conduct experiments in mammals, such as mice. This approach maximises the potential to translate our discoveries to humans.

In our clinical practice, we study human patients with vessels and renal disease, and we are limited to the nature of studies we can perform; patients will often have been receiving treatments for some years and it is rarely possible to study patients before they develop disease or in the early phase of the disease itself. As a result, we need to use animal models of disease that allow us to study the mechanisms of diseases from the earliest stage and during disease progression; this will allow us to monitor the effect of specific molecules, in a controlled and standardised setting.

Further, the study of different organs and their interaction is only possible in animals. By using animals, we can investigate the contribution of specific pathways in a specific tissue in different experimental conditions.

Our plan of work clearly reflects the need to study the whole animal. Where possible we will utilise non- animal laboratory-based approaches to complement the in vivo work.

Which non-animal alternatives did you consider for use in this project?

Where possible, the use of cells grown in the laboratory (e.g.: human glomerular endothelial cells, human mesangial cells, mouse tubular cells) or organoids (to replace animal work) will be utilised to answer our questions.

We will continue to use in vitro methods/techniques to validate the efficacy of novel potential intervention compounds or strategies before considering animal studies.

The in vitro cell/organoid work will also complement the in vivo work by answering questions that cannot be answered in the whole organisms such as changes in the activation of specific molecules and cellular signaling pathways.

Why were they not suitable?

Use of cells or organoids is a close approximation of animal (whole organism) physiology and pathology, but it cannot adequately answer some of the questions we want to ask in vivo.

The complex interplay between different organs, tissues and cell types seen in vascular and kidney physiology/diseases cannot be modeled sufficiently using cells/organoids or other non-animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is based on breeding strategies and experimental plan programmed in the next 5 years of research.

We have been generating preliminary data. Animal estimates are based on our vast experience in breeding and using animals in the experiments proposed. Our previous experiments have been peer and statistician reviewed during the publication process.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We established methods to reduce the number of animals studied and enhanced animal well-being. As an example, after terminal anaesthesia we can isolate one of the two kidneys after clamping the renal artery/vein before the animal is perfused with fixative. This allows us to obtain tissue (kidney) from the same animal that is suitable for different experimental procedures/analysis allowing a reduction in animals to be studied.

Good planning of experiments and regular interaction with colleagues and statisticians significantly helps towards a reduction in the number of animals utilised in our research.

We have setup and will utilise experimental techniques that maximise the acquisition of experimental information (e.g.: physiological parameters analysis such as blood pressure measurements, paralleled by blood, urine, tissue collection for different determinations) from the same animal without significant increase in harm, thereby reducing the animals required.

Breeding strategies have been planned to maximise the number of genetically altered animals and controls, whilst minimising the numbers of animals used.

Our previous experience, preliminary data, interaction with other laboratories, and previous literature will help us with the design and statistical power of our experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Genotyping will be planned pre-weaning. By avoiding inefficient or delayed genotyping we can avoid producing a surplus of animals.

We have previous experience in breeding genetically modified animals, and we have established efficient breeding strategies to reduce the number of animals bred throughout this license.

Some preliminary and pilot work has been carried out and this would therefore help in reducing the animal numbers further. Pilot studies allow accurate power calculations and help plan the adequate number of animals required in the experiments.

We will be using similar mice strains utilised in the past; our knowledge and experience will allow more efficient experiments.

For blood pressure determination, the use of telemetry will provide a more detailed information on the blood pressure day profile and better-quality measurements that could help reduce the number of animals needed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Experimental models of diabetes include genetic models, diet induced models, and models which use drug-mediated damage of the insulin producing cells.

We opted for the induction of diabetes by injection of a substance called streptozotocin. Streptozotocin will be administered at a low-dose for five consecutive days. Reports suggest that multiple low-dose injections of streptozotocin induces a delayed but progressively increasing state of hyperglycaemia in mice. This method does not

completely damage the insulin producing cells of the pancreas and usually does not warrant insulin administration (injections), nor lead to dramatic weight loss. The slow progression of diabetes in this model (which allows the maintenance of a "diabetes status" for 26-30 weeks) allows investigators to investigate the long-term effects of diabetes on tissues and organs (e.g.: time course for blood pressure, albuminuria) which will allow better and solid information to aid answering the scientific questions posed.

We may administer streptozotocin alone or in conjunction with high fat diet. Streptozotocin administration alone (causing reduced insulin secretion) and streptozotocin administration + high fat diet (causing reduced insulin secretion and insulin resistance) are two well-established models of diabetes validated for the study of diabetic kidney disease.

The choice of model between streptozotocin administration alone or streptozotocin administration + high fat diet will depend on the pathways that we will study as per reports in the literature.

For blood pressure measurements, we will use telemetry (involving surgery) and tail cuff methodology. As model of hypertension, we may utilise angiotensin-2 administration (subcutaneously with mini- pump), or high salt diet up to 4% sodium. These interventions are established models that result in a consistent increase in BP around 10-30 mmHg.

Blood pressure telemetry methodology offers state-of-the-art blood pressure determination with decreased need for multiple repeated measures, despite the need of a surgical procedure.

To ensure that animals do not suffer unnecessarily because of repeated testing (e.g.: assessment of blood pressure, glucose control, metabolic cages for water/salt balance), we will only conduct the minimum number of procedures needed to answer our scientific research questions and will ensure that animals have a suitable recovery period in-between procedure.

Why can’t you use animals that are less sentient?

We will study mice as these are least sentient animal that can be used to mimic human disease conditions and can be used to investigate specific genetic manipulations of relevance to vessel and renal physiology and pathophysiology of diseases.

Mice are mammals and will help the translatability of our observations to humans. We therefore need complex organisms where we can study different tissues/organs and their role in physiology and disease settings.

We will implement terminal anaesthesia for tissues and blood collection at the end of the study so the animal is unaware of the procedure as is under anaesthesia throughout and is not recovered.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In diabetic mice, where necessary, we might administer insulin to prevent excessive weight loss.

Use of low doses of streptozotocin with dietary changes (high fat diet) to produce insulin deficiency in conjunction with insulin resistance may be utilised to monitor specific pathways/endpoint that are more pronounced with this experimental approach.

In post-surgery (telemetry), we will utilise analgesia for pain relief, and we will continue to improve and refine the post operative care.

Refinement of our techniques with animal work is always ongoing. We always try to improve our animal research techniques (e.g.: such as bedding in metabolic cages for adaptation to long periods) by

animal monitoring especially as disease progresses (e.g.: long diabetes duration), by improvements of our surgical skills and reassessment of post-operative care routines and adjustments where necessary to optimise management of pain.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All animal work will be conducted with the aim of being compliant with the ARRIVE guidelines for publication of animal research. This ensures minimum standards are met with regards to experimental design, powering, randomisation, inclusion/ exclusion criteria, blinding, outcome measure reporting, and statistical methods.

These guidelines also set out the minimum standards for reporting experimental animal use and experimental procedures, including the rational for proposed procedures to ensure experiments are performed with sufficient scientific rigor without compromised animal welfare.

Further we will regularly consult the NC3Rs website.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will be having continuous discussion with colleagues and staff (e.g.: veterinary, the Named Animal Care and Welfare officer and colleagues) within our animal facility.

We are subscribed to the NC3Rs newsletter.

44. Understanding the Role of the Non-Coding Genome in Brain Development, Function and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Gene Therapy, Cell Therapy, Advanced therapeutics, ATMPs, Lung gene transfer

Animal types	Life stages
Mice	neonate, juvenile, pregnant, adult, embryo, aged
Rats	juvenile, neonate, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to develop advanced therapeutics, namely gene and cell therapy-based treatments for pulmonary and non-pulmonary diseases by using topical delivery of gene and cell therapy products to the lungs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many diseases such as cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura have significant unmet clinical needs (see details below). Gene and cell therapies have been successfully developed for several diseases indications and offer promise for others.

Cystic fibrosis (CF)

CF is a genetic disease (most prominent in Caucasians) with an incidence of approximately 1:2000 live births and approximately 100,000 people affected in Europe and North America alone. Although life expectancy has significantly increased from 0.5 yrs in the 1940s to approximately 35 years to date, treatment options are expensive, time-consuming and not sufficient to prevent pre-mature mortality in a large number of patients.

Pulmonary alveolar proteinosis (PAP)

PAP is a rare genetic lung disease (0.1 to 1 cases per million) characterised by the presence of lipids in the lungs, leading to decreased gas exchange and defective host defence. A molecule called GM- CSF is critical for the reduction of lipid deposition in the lungs. In some forms of the disease, patients develop antibodies to GM-CSF which reduce its effectiveness and cause lipid deposition.

Alpha 1 antitrypsin deficiency (AATD)

A1AD is one of the most common genetic diseases. Worldwide, an estimated 1.1 million people have A1AT deficiency Individuals with A1AD may develop chronic obstructive pulmonary disease (emphysema) during their thirties or forties even without a history of smoking, though smoking greatly increases the risk. Symptoms may include shortness of breath (on exertion and later at rest), wheezing, and sputum production. Symptoms may resemble recurrent respiratory infections or asthma. Conditions associated with alpha-1 antitrypsin deficiency, occurring due to paucity of AAT in circulation allowing uninhibited inflammation in lungs

Thrombotic thrombocytopenic purpura (TTP)

TTP is a rare (~1 case per 200,000) but life-threatening disease which is characterised by the presence of blood clots (thrombi) within the vasculature, commonly within the brain, heart and kidney. In the majority of cases TTP is caused by the production of antibodies against a protein called ADAMTS13. ADAMTS13 is protein which is involved in reducing inappropriate formation of blood clots (thrombi) in small blood vessels. If left untreated, these thrombi can cause organ failure and death in the majority of cases.

Interstitial pulmonary fibrosis (IPF)

In 2012, about 32,500 people had IPF in the UK and around 50 people in every 100,000 had been diagnosed at some time in their life with IPF. The cause of IPF is unknown but certain environmental factors and exposures have been shown to increase the risk of getting IPF. Cigarette smoking is the best recognized and most accepted risk factor for IPF, and increases the risk of IPF by about twofold. Other environmental and occupation exposures such as exposure to metal dust, wood dust, coal dust, silica, stone dust, biologic dusts coming from hay dust or mold spores or other agricultural products, and occupations related to farming/livestock have also been shown to increase the risk for IPF.

Current treatments include daily physiotherapy, pancreatic enzyme supplementation, intravenous or inhaled antibiotics, administration of anti-inflammatory drugs and bronchodilators in many cases, but are not sufficient to increase life-expectancy. A number of drugs that potentiate or correct the defect protein have recently been licensed, but their long-term efficacy and safety is not yet proven. In addition, these drugs are ineffective in patients with mutations that completely prevent expression of the mutated protein (~15% of patients).

What are the problems with current treatments which mean that further work is necessary?

PAP

The standard of care for PAP is mechanical removal of the accumulated lipids by "washing out" the lungs with many litres of liquid. In aPAP, daily sub cutaneous as well as twice daily inhaled GM-CSF protein administration has been shown to be well tolerated and effective. GM-CSF is not licenced for PAP and has to be imported on a named-patient basis and used off-licence. Costs vary but are around

£30,000 for 6 months treatment. Gene therapy offers an alternative approach and may overcome some of the problems and limitations encountered by protein replacement therapy.

AATD

Treatment of lung disease may include bronchodilators, inhaled steroids, and, when infections occur, antibiotics. People with lung disease due to A1AD may receive intravenous infusions of alpha-1 antitrypsin, derived from donated human plasma. This augmentation therapy is thought to arrest the course of the disease and halt any further damage to the lungs. Long-term studies of the effectiveness of A1AT replacement therapy are not available.

TTP

Most current treatments involve regular blood transfusions and in some cases removal of antibodies to ADAM13 from blood of patients. Individuals usually develop acquired TTP from 20-60 years of age, with one third of cases becoming chronic. Individuals suffering an

acute TTP attack undergo plasma exchange, which has reduced mortality rates from 90% to 20%. Due to the high treatment burden and reliance on donor plasma, a novel therapy for TTP is required.

IPF

There is currently no cure for IPF. The clinical course can be unpredictable. IPF progression is associated with an estimated median survival time of 2 to 5 years following diagnosis.

What outputs do you think you will see at the end of this project?

We have a strong track record for translational bench-to-bedside research and have carried our several gene therapy trials. At the end of this project, we anticipate to conduct further gene or cell therapy trials for diseases such as cystic fibrosis, alpha 1 antitrypsin deficiency, pulmonary fibrosis and thrombotic thrombocytopenic purpura. Our research will certainly lead to conference presentations and peer reviewed publications. In addition, we anticipate that our research will identify new treatment options for the named diseases which currently have an unmet clinical need.

Who or what will benefit from these outputs, and how?

Our disease targets include cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura. We anticipate, that these patient cohorts will benefit, if our translational research programme is successful. More specifically:

Short-term: Proof-of-concept that gene and cell therapy can improve or stabilise disease in our pre- clinical disease models.

Medium term: Translation of gene and cell therapies into clinical trials.

Long-term: Licensing and adopting of gene and cell therapy-based treatments for disease with unmet clinical needs.

How will you look to maximise the outputs of this work?

Collaboration: Approximately 20 years ago we founded a consortium consisting of scientists and clinicians across several UK Universities. We form the largest group worldwide involved in developing advanced therapeutics for pulmonary diseases.

We disseminate new knowledge through interaction with academics at conferences and publications. Importantly, we publish all results regardless if they are proving or disproving our hypothesis.

In addition we are actively involved in patient and public education around advanced therapeutics.

Species and numbers of animals expected to be used

- Mice: Over 5 years we anticipate to use approximately 5000 mice
- Rats: Over 5 years we anticipate to use approximately 100 rats

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Over 95% of animals used in our studies are normal healthy mice or mice in which disease is induced. The vast majority of mice used will be treated when more than 6 weeks old. We anticipate that advanced therapeutics for the disease indications that we are describing in this license will be administered to adult populations rather than children. Mice > 6 weeks old therefore mimic the intended age of the proposed patient cohorts.

Mice are used because relevant disease models have been generated through our ability modify and shut-down genes.

Occasionally, but very infrequently, we confirm data generated in rats. This is particularly relevant for research related to cystic fibrosis. CF knockout mice do not develop CF lung disease, whereas CF rats develop characteristic pulmonary features of CF.

Typically, what will be done to an animal used in your project?

A typical experiment (see more details below) includes administration of a gene transfer agent or of gene modified cells to the lungs of mice using non-invasive delivery methods via nose or mouth. At specific time-points we may collect small volumes of blood via the tail vein or will collect urine. In some animals we may collect breath under anaesthesia by putting mice into a breath collection chamber or we may image gene expression in anaesthetised mice. Most animals (~90%) are humanely killed within a few months post gene/cell transfer. A small number of animals is followed up for longer periods (max 24 months) to assess duration and impact of the treatments on the disease . In addition to wildtype mice, disease-specific genetically modified mice may be used. In a typical experiment animals will be treated with an advanced therapeutic once and culled at a specific time-point post treatment.

Please see below specific details describing the typical protocol for mice and rats on this license.

Life-history: typical scenario protocol for mice

1. Determination of destruction of specific genes (used to generate a model with lung disease). This will for example include taking an ear punch from the animal.

2. Anaesthesia (not more than 12 times over at least 6 months)

3. Administration of the novel drug to the nose, which is then "inhaled" into the lung (animals may receive 1 to 12 doses over 6 months)

4. Blood and urine sampling (typically 6-10 collections over 6-12 months)

5. Collection of breath under recover anaesthesia and/or lung function measurement under terminal anaesthesia (typically 1 measurement)

6. Humane killing

Proportion of mice/rats treated using the typical protocol: >90% Severity limit of the typical protocol: mild

Some animals (<5%) may be housed and observed for up to 24 months

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority (>95%) of our procedures are classified as sub-threshold or mild and do not induce pain or discomfort. Occasionally animals show signs of being unwell for a few hours after treatment (most often this will be visible by looking at the fur, with raised hair (piloerection) being a common sign. The need for human killing of animals post-treatment due to side-effects is extremely rare.

The impact of a typical experiments described above may include a slight and transient discomfort while collecting an ear punch. Gene transfer to the lung may induce transient local inflammation, which generally resolves within 24 hours after treatment and may result in raised hair. Blood sampling via a tail vein may cause transient discomfort due to needle prick. Collection of breath and imaging protocols will be performed under anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

95% mild, 5% moderate

Rats:

100% mild

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We aim to develop advanced therapeutics, namely gene and cell therapy-based treatments for pulmonary and non-pulmonary diseases by using topical delivery of gene and cell therapy products to the lungs. Many diseases such as cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura have significant unmet clinical needs. Gene and cell therapies have been successfully developed for several diseases indications and offer promise for others.

As part of our translational research programme we have to assess efficacy and duration of gene expression, as well as toxicity in relevant rodent disease models. Assessment of transduction efficiency and duration of expression requires all cell types that our vector transduces (eg ciliated airway epithelial cells, goblet cells, Club cells, basal cells and pneumocytes) as well beating cilia to be present. Assessment of toxicity and inflammatory responses requires a model in which inflammatory cells such as neutrophils, lymphocytes and macrophages can migrate from the bloodstream into the lungs in response to a challenge such as vector administration. These conditions are only provided in living animals.

Which non-animal alternatives did you consider for use in this project?

In parallel to work in mice we conduct studies in human air liquid interface cultures, human precision cut lung slices and in ex vivo lung perfusion models.

Why were they not suitable?

However these human ex vivo models do not have an intact immune system which impacts on toxicity and efficacy and also don't allow us to assess changes in relevant disease biomarkers.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The projected number of animals in the license reflects the number necessary to achieve the scientific objectives outlined in the programme of work and covers development of new therapies for a number of diseases with unmet clinical needs. The numbers are also based on our previous experience generated over the last 10 years as part of 2 previous project licenses and estimates of the requirements of translational research studies by us and scientists. Projected n numbers also reflect requirements of the regulators (eg bodies such as the Medicines and Healthcare products Regulatory Agency (MHRA)).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have over 25 years experience designing mouse experiments and always aim to minimise n numbers as much as possible through:

- randomisation

- validation of endpoints and biomarkers in pilot experiments to generate baseline data for subsequent power calculations.

- careful selection of endpoints and biomarkers to reduce variability and hence n numbers

- use of the NC3R EDA tool

- ensure that operators are trained to high standards

- careful planning and discussion of experiments to ensure all appropriate control groups are included in the design

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We routinely assess and adapt the size and output of our breeding colonies.

As mentioned above we conduct pilot studies to generate data for subsequent power calculations.

We carefully archive materials from control animals (eg blood, DNA, other body fluids) and reuse this material during analysis of experiments where appropriate.

We use tissues as efficiently as possible (for example by tying of the bronchus to the left lung for RNA extraction before fixing the right lung for histology)

We frequently use a histology core facility to ensure optimal processing, cutting and staining of tissue sections.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will mainly use wildtype mice and genetically modified murine disease models. AATD, TTP and PAP mouse models are mild, breed normally and do not show outward signs of disease. CF knockout mice frequently suffer from intestinal disease leading to high post-weaning mortality. However, we have in the past and will continue to use refined CF models in which the intestinal disease has been corrected through more sophisticated molecular biology strategies.

Gene transfer is performed through topical non-invasive administration to the mouse lung and sometimes through intravenous injections or nebulisation. These methods are minimally invasive.

In some experiment wildtype rats may be used to confirm studies in a larger rodent model.

Why can’t you use animals that are less sentient?

Mouse models are the most commonly used model for gene transfer studies. Although the lung structure and cell composition is not identical to human lung, mice present the best low ranking species for these studies.

We can't terminally anaesthetise mice because for assessment of efficacy and toxicity after gene and cell therapy, the animal has to be alive for indicated times post-dosing.

Some of our gene transfer agents achieve gene expression for prolonged periods of time (sometimes for the life-time of the animal after a single dose). Long-term follow up of efficacy and toxicity is therefore necessary in some experiments.

On rare occasions we may conduct gene transfer in neonates to mimic treatments of babies/children in which the organs are still growing.

In contrast to CF knockout mice, CF knockout rats develop certain features of CF lung disease. We will use wildtpye rats in some experiments to characterise the expression profiles of our advanced therapeutics in rats to allow future studies in CF knockout rats.

Non-protected animals (e.g. invertebrates such as insects, decapods, nematodes) or less sentient animals (eg zebrafish) cannot be used to meet some or all of your objectives of our studies largely. We require a model with lung structure and cell composition as well as the immune system that closely mimic human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

If required for some experiments we may increase post-treatment monitoring and post-treatment care.

Our experiments are generally mild and do not require any post-operative pain management. However we will seek advice from experts if pain management is required.

In our experience provision of wet food in the cages enhances post-treatment care following general anaesthesia and we provide wet food.

In regular meetings, we also share experiences in animal handling amongst the team to ensure everybody uses the most advanced methods

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are several best practise guidelines that are published and that we are fully aware off and will adhere to. Some examples are listed here: www.aaalac.org/resources;www.reference- resourcesarchanimaltraining.com; (https://norecopa.no/PREPARE).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will carefully review all information communicated by the home office and establishment staff/relevant named persons as well as our establishments 3Rs group. In addition we will keep updated with the NC3Rs website and relevant other activities.

45. Development of Advanced Therapeutics for Pulmonary and Non-Pulmonary Diseases through Topical Delivery to the Lung

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Gene Therapy, Cell Therapy, Advanced therapeutics, ATMPs, Lung gene transfer

Animal types	Life stages
Mice	neonate, juvenile, pregnant, adult, embryo, aged
Rats	juvenile, neonate, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to develop advanced therapeutics, namely gene and cell therapy-based treatments for pulmonary and non-pulmonary diseases by using topical delivery of gene and cell therapy products to the lungs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many diseases such as cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura have significant unmet clinical needs (see details below). Gene and cell therapies have been successfully developed for several diseases indications and offer promise for others.

Cystic fibrosis (CF)

CF is a genetic disease (most prominent in Caucasians) with an incidence of approximately 1:2000 live births and approximately 100,000 people affected in Europe and North America alone. Although life expectancy has significantly increased from 0.5 yrs in the 1940s to approximately 35 years to date, treatment options are expensive, time-consuming and not sufficient to prevent pre-mature mortality in a large number of patients.

Pulmonary alveolar proteinosis (PAP)

PAP is a rare genetic lung disease (0.1 to 1 cases per million) characterised by the presence of lipids in the lungs, leading to decreased gas exchange and defective host defence. A molecule called GM- CSF is critical for the reduction of lipid deposition in the lungs. In some forms of the disease, patients develop antibodies to GM-CSF which reduce its effectiveness and cause lipid deposition.

Alpha 1 antitrypsin deficiency (AATD)

A1AD is one of the most common genetic diseases. Worldwide, an estimated 1.1 million people have A1AT deficiency Individuals with A1AD may develop chronic obstructive pulmonary disease (emphysema) during their thirties or forties even without a history of smoking, though smoking greatly increases the risk. Symptoms may include shortness of breath (on exertion and later at rest), wheezing, and sputum production. Symptoms may resemble recurrent respiratory infections or asthma. Conditions associated with alpha-1 antitrypsin deficiency, occurring due to paucity of AAT in circulation allowing uninhibited inflammation in lungs

Thrombotic thrombocytopenic purpura (TTP)

TTP is a rare (~1 case per 200,000) but life-threatening disease which is characterised by the presence of blood clots (thrombi) within the vasculature, commonly within the brain, heart and kidney. In the majority of cases TTP is caused by the production of antibodies against a protein called ADAMTS13. ADAMTS13 is protein which is involved in reducing inappropriate formation of blood clots (thrombi) in small blood vessels. If left untreated, these thrombi can cause organ failure and death in the majority of cases.

Interstitial pulmonary fibrosis (IPF)

In 2012, about 32,500 people had IPF in the UK and around 50 people in every 100,000 had been diagnosed at some time in their life with IPF. The cause of IPF is unknown but certain environmental factors and exposures have been shown to increase the risk of getting IPF. Cigarette smoking is the best recognized and most accepted risk factor for IPF, and increases the risk of IPF by about twofold. Other environmental and occupation exposures such as exposure to metal dust, wood dust, coal dust, silica, stone dust, biologic dusts coming from hay dust or mold spores or other agricultural products, and occupations related to farming/livestock have also been shown to increase the risk for IPF.

Current treatments include daily physiotherapy, pancreatic enzyme supplementation, intravenous or inhaled antibiotics, administration of anti-inflammatory drugs and bronchodilators in many cases, but are not sufficient to increase life-expectancy. A number of drugs that potentiate or correct the defect protein have recently been licensed, but their long-term efficacy and safety is not yet proven. In addition, these drugs are ineffective in patients with mutations that completely prevent expression of the mutated protein (~15% of patients).

What are the problems with current treatments which mean that further work is necessary?

PAP

The standard of care for PAP is mechanical removal of the accumulated lipids by "washing out" the lungs with many litres of liquid. In aPAP, daily sub cutaneous as well as twice daily inhaled GM-CSF protein administration has been shown to be well tolerated and effective. GM-CSF is not licenced for PAP and has to be imported on a named-patient basis and used off-licence. Costs vary but are around

£30,000 for 6 months treatment. Gene therapy offers an alternative approach and may overcome some of the problems and limitations encountered by protein replacement therapy.

AATD

Treatment of lung disease may include bronchodilators, inhaled steroids, and, when infections occur, antibiotics. People with lung disease due to A1AD may receive intravenous infusions of alpha-1 antitrypsin, derived from donated human plasma. This augmentation therapy is thought to arrest the course of the disease and halt any further damage to the lungs. Long-term studies of the effectiveness of A1AT replacement therapy are not available.

TTP

Most current treatments involve regular blood transfusions and in some cases removal of antibodies to ADAM13 from blood of patients. Individuals usually develop acquired TTP from 20-60 years of age, with one third of cases becoming chronic. Individuals suffering an acute TTP attack undergo plasma exchange, which has reduced mortality rates from 90% to 20%. Due to the high treatment burden and reliance on donor plasma, a novel therapy for TTP is required.

IPF

There is currently no cure for IPF. The clinical course can be unpredictable. IPF progression is associated with an estimated median survival time of 2 to 5 years following diagnosis.

What outputs do you think you will see at the end of this project?

We have a strong track record for translational bench-to-bedside research and have carried our several gene therapy trials. At the end of this project, we anticipate to conduct further gene or cell therapy trials for diseases such as cystic fibrosis, alpha 1 antitrypsin deficiency, pulmonary fibrosis and thrombotic thrombocytopenic purpura. Our research will certainly lead to conference presentations and peer reviewed publications. In addition, we anticipate that our research will identify new treatment options for the named diseases which currently have an unmet clinical need.

Who or what will benefit from these outputs, and how?

Our disease targets include cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura. We anticipate, that these patient cohorts will benefit, if our translational research programme is successful. More specifically:

Short-term: Proof-of-concept that gene and cell therapy can improve or stabilise disease in our pre- clinical disease models.

Medium term: Translation of gene and cell therapies into clinical trials.

Long-term: Licensing and adopting of gene and cell therapy-based treatments for disease with unmet clinical needs.

How will you look to maximise the outputs of this work?

Collaboration: Approximately 20 years ago we founded a consortium consisting of scientists and clinicians across several UK Universities. We form the largest group worldwide involved in developing advanced therapeutics for pulmonary diseases.

We disseminate new knowledge through interaction with academics at conferences and publications. Importantly, we publish all results regardless if they are proving or disproving our hypothesis.

In addition we are actively involved in patient and public education around advanced therapeutics.

Species and numbers of animals expected to be used

- Mice: Over 5 years we anticipate to use approximately 5000 mice
- Rats: Over 5 years we anticipate to use approximately 100 rats

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Over 95% of animals used in our studies are normal healthy mice or mice in which disease is induced. The vast majority of mice used will be treated when more than 6 weeks old. We anticipate that advanced therapeutics for the disease indications that we are describing in this license will be administered to adult populations rather than children. Mice > 6 weeks old therefore mimic the intended age of the proposed patient cohorts.

Mice are used because relevant disease models have been generated through our ability modify and shut-down genes.

Occasionally, but very infrequently, we confirm data generated in rats. This is particularly relevant for research related to cystic fibrosis. CF knockout mice do not develop CF lung disease, whereas CF rats develop characteristic pulmonary features of CF.

Typically, what will be done to an animal used in your project?

A typical experiment (see more details below) includes administration of a gene transfer agent or of gene modified cells to the lungs of mice using non-invasive delivery methods via nose or mouth. At specific time-points we may collect small volumes of blood via the tail vein or will collect urine. In some animals we may collect breath under anaesthesia by putting mice into a breath collection chamber or we may image gene expression in anaesthetised mice. Most animals (~90%) are humanely killed within a few months post gene/cell transfer. A small number of animals is followed up for longer periods (max 24 months) to assess duration and impact of the treatments on the disease . In addition to wildtype mice, disease-specific genetically modified mice may be used. In a typical experiment animals will be treated with an advanced therapeutic once and culled at a specific time-point post treatment.

Please see below specific details describing the typical protocol for mice and rats on this license.

Life-history: typical scenario protocol for mice

1. Determination of destruction of specific genes (used to generate a model with lung disease). This will for example include taking an ear punch from the animal.

2. Anaesthesia (not more than 12 times over at least 6 months)

3. Administration of the novel drug to the nose, which is then "inhaled" into the lung (animals may receive 1 to 12 doses over 6 months)

4. Blood and urine sampling (typically 6-10 collections over 6-12 months)

5. Collection of breath under recover anaesthesia and/or lung function measurement under terminal anaesthesia (typically 1 measurement)

6. Humane killing

Proportion of mice/rats treated using the typical protocol: >90%

Severity limit of the typical protocol: mild

Some animals (<5%) may be housed and observed for up to 24 months

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority (>95%) of our procedures are classified as sub-threshold or mild and do not induce pain or discomfort. Occasionally animals show signs of being unwell for a few hours after treatment (most often this will be visible by looking at the fur, with raised hair (piloerection) being a common sign. The need for human killing of animals post-treatment due to side-effects is extremely rare.

The impact of a typical experiments described above may include a slight and transient discomfort while collecting an ear punch. Gene transfer to the lung may induce transient local inflammation, which generally resolves within 24 hours after treatment and may result in raised hair. Blood sampling via a tail vein may cause transient discomfort due to needle prick. Collection of breath and imaging protocols will be performed under anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

95% mild, 5% moderate

Rats:

100% mild

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We aim to develop advanced therapeutics, namely gene and cell therapy-based treatments for pulmonary and non-pulmonary diseases by using topical delivery of gene and cell therapy products to the lungs. Many diseases such as cystic fibrosis, pulmonary alveolar proteinosis, alpha-1 antitrypsin deficiency, interstitial pulmonary fibrosis and thrombotic thrombocytopenic purpura have significant unmet clinical needs. Gene and cell therapies have been successfully developed for several diseases indications and offer promise for others.

As part of our translational research programme we have to assess efficacy and duration of gene expression, as well as toxicity in relevant rodent disease models. Assessment of transduction efficiency and duration of expression requires all cell types that our vector transduces (eg ciliated airway epithelial cells, goblet cells, Club cells, basal cells and pneumocytes) as well beating cilia to be present. Assessment of toxicity and inflammatory responses requires a model in which inflammatory cells such as neutrophils, lymphocytes and macrophages can migrate from the bloodstream into the lungs in response to a challenge such as vector administration. These conditions are only provided in living animals.

Which non-animal alternatives did you consider for use in this project?

In parallel to work in mice we conduct studies in human air liquid interface cultures, human precision cut lung slices and in ex vivo lung perfusion models.

Why were they not suitable?

However these human ex vivo models do not have an intact immune system which impacts on toxicity and efficacy and also don't allow us to assess changes in relevant disease biomarkers.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The projected number of animals in the license reflects the number necessary to achieve the scientific objectives outlined in the programme of work and covers development of new therapies for a number of diseases with unmet clinical needs. The numbers are also based on our previous experience generated over the last 10 years as part of 2 previous project licenses and estimates of the requirements of translational research studies by us and scientists. Projected n numbers also reflect requirements of the regulators (eg bodies such as the Medicines and Healthcare products Regulatory Agency (MHRA)).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have over 25 years experience designing mouse experiments and always aim to minimise n numbers as much as possible through:

- randomisation

- validation of endpoints and biomarkers in pilot experiments to generate baseline data for subsequent power calculations.

- careful selection of endpoints and biomarkers to reduce variability and hence n numbers

- use of the NC3R EDA tool

- ensure that operators are trained to high standards

- careful planning and discussion of experiments to ensure all appropriate control groups are included in the design

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We routinely assess and adapt the size and output of our breeding colonies.

As mentioned above we conduct pilot studies to generate data for subsequent power calculations.

We carefully archive materials from control animals (eg blood, DNA, other body fluids) and reuse this material during analysis of experiments where appropriate.

We use tissues as efficiently as possible (for example by tying of the bronchus to the left lung for RNA extraction before fixing the right lung for histology)

We frequently use a histology core facility to ensure optimal processing, cutting and staining of tissue sections.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will mainly use wildtype mice and genetically modified murine disease models. AATD, TTP and PAP mouse models are mild, breed normally and do not show outward signs of disease. CF knockout mice frequently suffer from intestinal disease leading to high post-weaning mortality. However, we have in the past and will continue to use refined CF models in which the intestinal disease has been corrected through more sophisticated molecular biology strategies.

Gene transfer is performed through topical non-invasive administration to the mouse lung and sometimes through intravenous injections or nebulisation. These methods are minimally invasive.

In some experiment wildtype rats may be used to confirm studies in a larger rodent model.

Why can’t you use animals that are less sentient?

Mouse models are the most commonly used model for gene transfer studies. Although the lung structure and cell composition is not identical to human lung, mice present the best low ranking species for these studies.

We can't terminally anaesthetise mice because for assessment of efficacy and toxicity after gene and cell therapy, the animal has to be alive for indicated times post-dosing.

Some of our gene transfer agents achieve gene expression for prolonged periods of time (sometimes for the life-time of the animal after a single dose). Long-term follow up of efficacy and toxicity is therefore necessary in some experiments.

On rare occasions we may conduct gene transfer in neonates to mimic treatments of babies/children in which the organs are still growing.

In contrast to CF knockout mice, CF knockout rats develop certain features of CF lung disease. We will use wildtpye rats in some experiments to characterise the expression profiles of our advanced therapeutics in rats to allow future studies in CF knockout rats.

Non-protected animals (e.g. invertebrates such as insects, decapods, nematodes) or less sentient animals (eg zebrafish) cannot be used to meet some or all of your objectives of our studies largely. We require a model with lung structure and cell composition as well as the immune system that closely mimic human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

If required for some experiments we may increase post-treatment monitoring and post-treatment care.

Our experiments are generally mild and do not require any post-operative pain management. However we will seek advice from experts if pain management is required.

In our experience provision of wet food in the cages enhances post-treatment care following general anaesthesia and we provide wet food.

In regular meetings, we also share experiences in animal handling amongst the team to ensure everybody uses the most advanced methods

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are several best practise guidelines that are published and that we are fully aware off and will adhere to. Some examples are listed here: www.aaalac.org/resources;www.reference- resourcesarchanimaltraining.com; (https://norecopa.no/PREPARE).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will carefully review all information communicated by the home office and establishment staff/relevant named persons as well as our establishments 3Rs group. In addition we will keep updated with the NC3Rs website and relevant other activities.

46. Development of Humanised Mouse Models for Study of Cancer Immunotherapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Transplantation, Cancer, Treatment, Immunotherapy, Safety

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to study how the immune system recognises cancer cells, and test the safety and effectiveness of drugs that can kill tumour cells by interacting with the immune system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is one of the leading causes of death in the world. It is now recognised that the immune system has a critical role in how cancers develop, and that drugs that manipulate the immune system have great potential as better therapies. The proposed project will allow a better understanding of how the immune system recognises tumours, and to test the safety and effectiveness of drugs that can kill tumour cells by acting on the immune system. This could lead to development of new therapies that are more effective and cause fewer side effects to patients.

What outputs do you think you will see at the end of this project?

It is expected that the proposed project will ultimately enable novel models of human tumours to be used not only to study cancer biology in vitro, but also to enable drug development and screening. Moreover, it is anticipated that advanced immunotherapies can be developed and optimised that will enable highly effective tumour eradication without the devastating side-effect profile associated with classical chemotherapy agents. The insights generated by this project will be shared through publications to enable other researchers to incorporate the findings into their research programs.

More specifically, we expect to generate at least one new therapy and advance it to a stage that it can be investigated further in large animal models. In the long-term (5-7 years), we expect that the findings of this study will result in the design of at least 1 human clinical trial to test the safety and efficacy of a novel therapy developed in this project.

Who or what will benefit from these outputs, and how?

In the short-term (1-3 years), the primary beneficiaries of the proposed project will be other researchers who are also developing immune-related therapies for treatment of cancers. We anticipate that the findings of this study will be of broad relevance to the research community in this field. In the medium term (3-5 years), we anticipate that industrial companies involved in the manufacture of immunotherapies, who are essential for the ultimate production of these therapies, will also benefit from the findings of this study. In the long-term (5-7 years), this project will benefit patients with cancer. The benefit will initially be limited to those patients enrolled in clinical trials investigating the safety and efficacy of immunotherapies developed in this project. We hope that ultimately (7-10 years) large numbers of patients will benefit from the findings of this study, once the immunotherapies have been shown to be safe and effective in clinical trials and can be manufactured at large scale.

How will you look to maximise the outputs of this work?

We will disseminate all findings of our studies, including unsuccessful approaches, through publication in peer-reviewed journals, presentation at scientific conferences, and through meetings with other researchers. All publications will be open access, including through platforms such as F1000Research. This project includes collaborations with a large

number of researchers with expertise in complementary areas, and this network will be utilised to maximise the dissemination of the new knowledge gained through this project.

Species and numbers of animals expected to be used

- Mice: 3475

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use adult mice. Mice are the lowest species with a comparable physiology that enables useful information to be gained relating to the safety and effectiveness of human immunotherapies.

Importantly, genetic strains of mice are available that allow studies to be designed that can generate valuable information about specific cellular therapies. Moreover, mice can be used effectively to model the human immune system by injecting them with human immune cells, followed by transplantation with human cancer cells, thus allowing the study of the human immune response to cancer.

Typically, what will be done to an animal used in your project?

In the typical experiment, an adult mouse will receive sublethal irradiation, followed by adoptive transfer of human immune cells through injection into the abdominal cavity. After several (typically 4-

12) weeks later, the animal will be surgically transplanted, on one occasion, with tumour (or control) cells or tissue into the abdomen under general anaesthesia. After 2-4 weeks, the animal will be given an immunotherapy agent by intraperitoneal injection on a number (typically 3-5) occasions over 1-2 weeks. The animal will then be killed by Schedule 1 methods (humane killing of protected animals under the Animal (Scientific Procedures) Act 1986), several (typically 4-6) weeks later. Some animals may undergo non-invasive imaging on a number (typically 3-5) of occasions. The typical animal will undergo one or two surgical procedures and be kept for approximately 16 weeks, when it will be killed electively while still well and without clinical signs. In some cases, the animals will be killed by removal of organs while under deep general anaesthetic.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that most (more than 90%) of animals will recover rapidly and well from tumour cell transplantation.

Injections with immune cells (such as white blood cells) is also generally well tolerated and most (more than 90%) animals will not experience adverse effects from this procedure.

In some cases, the animals may experience weight loss, reduced food intake, reduce movement or an abnormal coat. In such cases, the animals will be culled if these clinical signs do not respond to treatment (such as high energy and easily digestible diet) and persist for up to 24 hours.

When rapid adverse effects may be expected, animals will be monitored very frequently (up to one hourly) during the initial period (~6 hours) when adverse effects are most likely to occur (based on data from previous animal experiments and clinical studies).

Animals will also be culled if they experience clinical signs that approach the limits described in the project according to the Home Office guidelines.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 65% of animals will undergo a surgical procedure and will therefore experience moderate severity, or experience moderate severity as consequence of administration of immunotherapies. Approximately 25% of animals will only receive cells by intraperitoneal or intravenous injection and will experience mild severity. The remainder (10%) may be culled for tissue and will experience subthreshold severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The definitive examination of the efficacy and safety of anti-cancer drugs requires examination in intact animals, including those with a competent immune system. This is a necessary and pre-requisite ‘final’ step for the clinical translation of these cancer therapies and cannot be completed without animal experiments. Much of the proposed work is carried in the laboratory and using human tissue only, thus minimising the need for animal experimentation. Importantly, it is anticipated that this work will lead to the refinement and

optimisation of laboratory models of cancer which can be ultimately used to replace experimental use of animals.

Which non-animal alternatives did you consider for use in this project?

We have 3 key strategies for the development and use of non-animal alternatives.

1. We intend to use humans cancer cells and tissue in the vast majority (>95%) of our studies. Animal cells will only be used if they are necessary control for the use of human cells, or where equivalent human cell alternatives is not available. We therefore anticipate using very few animals for the generation of tumour cells.

2. We will continue to make extensive use of sophisticated human cell culture systems, such as organoids and tumoroids technology, to study the safety, functions and immune response to cancer in vitro.

3. We have developed mechanism for perfusing human organs ex vivo, on a specialised machine, for prolonged periods in order to test the functions of transplanted human cells and tissue.

Why were they not suitable?

We are using all of these three alternative approaches to reduce the number of animals used in the proposed experiment. However, the definitive investigation of the immune response to tumours, and the safety and efficacy of immunotherapies requires an intact and functional immune system in an animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals have been estimated based on the range of studies that are planned, as well as based on the previous similar studies we performed during the last five years. Based on our previous experience, we are able to predict, for each study, the number of animals that are required to generate reliable and reproducible data. Using our previous experience, we are also able to predict how many studies we can perform in a given time period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have generated a wealth of data from previous experiments that enable us to estimate the anticipated effect size and variation in the experimental data. This data will be used to ensure appropriate experimental group sizes. We routinely randomise animals to experimental and treatment groups and all experiments are conducted and/or data analysed in a blinded manner to reduce bias. When a new tumour cell or immunotherapy is under investigation, we will first perform pilot experiments with small animal groups (typically 2-3 animal per group) to confirm the appropriateness of the experimental design and to generate pilot data to enable group sizes to be formally calculated. We will also use tools such as the NC3Rs Experimental Design Assistant to ensure experiments are appropriately planned to generate reliable and reproducible data. We will also take into consideration any regulatory requirements relating to the reproducibility of the data, in order to ensure data generated from this study is suitable for informing design of future clinical trials.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to reduce the number of animals we use through a number of simultaneous strategies:

1) We will share excess breeding animals with other researchers and use any animals culled as tissue donors for use by our group or by other researchers.

2) Where possible, we will use each animal as its own control, for example by transplanting control and tumour cells in two separate sites (for example, into each kidney) in the same animal. This will reduce inter-animal variation and reduce the number of animals used.

3) By generating large quantities of human cells, where appropriate, we can continue to perform new studies using the same human tumour, which reduces the variation associated with different human donors and reduce the number of animals used.

4) By monitoring animals for prolonged durations, and through the use of non-invasive monitoring techniques (such as imaging), we can generate longitudinal data about tumours and immunotherapies without the need to cull animals at numerous timepoints.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experimental models and techniques used in this project can be broadly divided into three groups:

1) Transplantation of tumour or control cells or tissue into animals to assess the tumour biology

2) Reconstitution of the animals with a human immune system to assess immune response to the tumours

3) Administration of immunotherapies to assess their safety and efficacy in reducing tumour growth

All experimental models have been refined to ensure they cause the least pain and suffering. Importantly, none of the procedures are expected to result in severe clinical signs (such as persistent abnormal behaviour or persistent weight loss). Animals will be culled if they display clinical signs that do not respond to treatment (such as easily digestible food or pain relief medication). Animals therefore will not be permitted to experience lasting harm.

Why can’t you use animals that are less sentient?

Mice are the least sentient animals that can be used to generate valuable data to investigate the therapeutic potential of human immunotherapies. As the immune response to tumours, and the action of immunotherapies takes days to weeks to manifest, experiments cannot be performed exclusively under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In close collaboration with the staff at our animal facility, we have a robust mechanism for the post- operative monitoring of our experimental animals. Animals are also given routine post-operative pain relief medication, which has been proven to be effective in previous similar studies. When adverse effects may be expected, we readily increase the frequency of monitoring to identify animals that may be experiencing adverse effects. We also have our own dedicated animal technician who ensures that our animals receive close attention if there are any concerns. We have achieved a number of significant refinements during the previous series of studies. These include enhanced environmental enrichment (such as extra card-board housing) and use of high-energy or tasty diets to prevent weight loss, improved techniques for transplantation of cells in the kidney or abdomen (such as using special needles to shorten the duration of the procedure). Where adverse effects may be expected, we will perform particularly close and frequent monitoring of animals, including

through the use of observation sheets and body weight records. particularly where. We will continue to strive to develop new refinements.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will be conducted and reported in adherence to best practice guidelines including those published by the Laboratory Animal Science Association (LASA), such as guidelines for record keeping, performing surgery, education and training, and reporting of experimental results. We will also follow the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines on experimental conduct including study design, randomisation, avoiding bias and statistical analysis of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a current project license holder, I am closely involved with the activities of the 3Rs committee at my institution, including the development of recommendations and dissemination of information relating to advances in 3Rs. I intend to continue with my activities, including through review of relevant publications, guidelines and best-practice information.

47. Modulation of Synaptic Transmission in Mammalian Central Nervous System

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

synapses, interneurones, hippocampus, cerebral cortex, mental health

Animal types	Life stages
Rats	adult, pregnant
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this continuing project is to study the properties of neuronal synaptic connections in the brain, understand their roles in the circuitry and characterise modulators of these connections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cortical regions contain millions of neurones that are connected to each other through millions of synapses. These connections involve different types of cells that have distinct properties and roles in the circuitry. Understanding how neurones are connected to each other in healthy animals and how specific drugs modulate these connections are ultimately key elements to building information towards understanding pathological behaviours and their treatments.

What outputs do you think you will see at the end of this project?

This project will further our understanding on how the brain processes information and produce data that is of importance to a large number of basic and clinical scientific questions. The work described here identifies the basic building blocks of this circuitry, how its dynamic properties shape information as it is processed, how the exquisite precision observed in adult brain develops and how drugs can induce minor changes to this connectivity and result in a change in the brain response after a prolonged treatment. The in-depth studies of brain regions outlined here will provide many other scientists with the circuit components needed for an understanding of how the brain acquires, processes and stores information and what may go wrong in disease, while the recording of brain connectivity and morphological data will be widely used by computational neuroscientists in the construction of models that explore information processing without further use of animals. Information on the effect of modulators of brain connections will also allow us to understand changes that occur in the brain and are responsible for the reduced reaction to certain drugs after repeated use. All data will be presented at national and international conferences and published in scientific journals.

Who or what will benefit from these outputs, and how?

These outputs will benefit to:

- Scientists/doctors studying brain connectivity and its implications in disease states.

- Computational scientists who will use the outputs from this project to build realistic models based on experimental data.

- Information from this project will also be useful for patients who suffer from mental health disorders and scientists who are studying the causes and treatments of these conditions. This project will give invaluable information on the appearance of tolerance following treatment and potential new therapeutic avenues to prevent it.

How will you look to maximise the outputs of this work?

All data will be presented in national and international conferences, discussed with experts in the field and published in scientific peer-reviewed journals. Follow-up funding based on the data collected will be sought.

Species and numbers of animals expected to be used

- Mice: 280
- Rats: 260

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All experiments outlined in this licence will be performed on either adult rats or mice. The basic brain circuits of rodents appear to be sufficiently similar in all mammalian species to allow fundamental scientific questions relating to the human brain to be addressed. A large part of the data that has been obtained in our laboratory and other across the world for most of the past century comes from small rodents. The work that is presented here will allow comparisons and further advance our understanding of brain connectivity. The use of adult rodents will allow the study of a fully developed brain and the potential change in connectivity using drugs that are used in patients.

Typically, what will be done to an animal used in your project?

Some animals will be terminally anaesthetised, perfused with artificial cerebro-spinal fluid to remove the blood and allow better analysis of the data and brains will be removed. Brain slices will then be obtained for recording of neuronal activity and further analysis.

In some experiments, mice will be injected twice a day with modulators of neuronal connectivity for up to one month. They will then be terminally anaesthetised and perfused prior to the removal of their brains. Behaviour experiments will be performed before injection, then once weekly to monitor tolerance and before the culling of the animals.

What are the expected impacts and/or adverse effects for the animals during your project?

The side effects expected in the animals will be mild. We will be looking to use minimally-effective doses of drugs that will lead to tolerance in the animals with minimal side effects. Due to the drugs used, animals will be mildly sedated. However, abnormal behaviour is not expected with the drugs and doses that will used in this project.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The protocol described in this license is of mild severity overall with a large number of the animals following a non-recovery protocol. The injections may lead to mild side effects, however, these will be of short duration and will not affect the behaviour of the animals. Rodents will be culled either by a schedule I method or under terminal anaesthesia. Each licensee will be expected to obtain the Home Office PIL A/B and be trained appropriately. Supervision will be in place until the licensee is deemed competent in practicing the procedures described in the protocol minimising animal suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals is essential for obtaining data that will increase our understanding of information processing, memory and behaviour in absence of disease. The relationship between role and functions of cells in the brain, their response to drugs and brain anatomy can only be explored in living tissue.

This will allow existing and new data to be linked, compared directly and the more complete picture that emerges to contribute to models of brain cells and circuits. These models/circuits can provide invaluable insight when the questions addressed become too complex. The varied nature of our data will allow some parameters to be used to build the models (e.g. highly detailed anatomy of brain cells) and others (such as the properties of the connections between these cells) to be used to ensure that these models behave appropriately. The preservation of these valuable data will prevent repetition of experiments that are costly in time and expertise as well, importantly, as in animal use.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives considered included the use of immortal cells and computational modelling.

Why were they not suitable?

Cultures of immortal cell lines will be used to answer some of the questions set in this license on how the connections between brain cells are formed. Most of our knowledge of how these connections are altered in many neurological disorders has been extrapolated from the research done using animal models that have different brain anatomy and display different behaviours. However, a number of mutations discovered in humans do not in fact cause disease states when introduced into rodents. The potential impact, both in basic

research and medicine development, of model systems based on human-derived neuronal tissue that is able to transform into a cell type of interest is therefore substantial. In parallel to the cultures of immortal cell lines, a new co-culture model system which will allow us to 'build' the human inhibitory synapses 'in a dish', and study how individual mutations discovered in patients affect this process. This is an important step towards understanding how the connections are formed and test new therapeutic targets. However, cell cultures do not replicate the entire biological system and will only give limited information. The characterisation of neuronal connectivity and modulation of the transmission of information following therapeutic treatment associated with some change in animal behaviour will ultimately require the use of animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

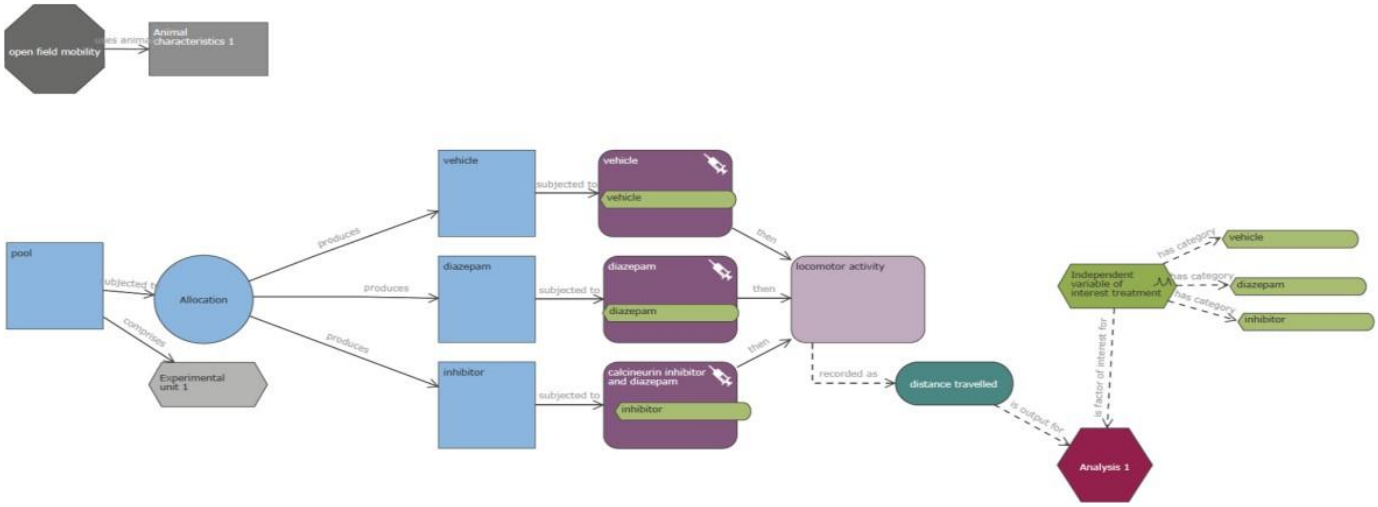
The number of animals needed for this project was estimated using previous knowledge and experience in neuroscience research. Previous experiments allowed us to predict the amount of variability between experiments and to estimate the minimal number of animals that will be required to obtain a clear answer to the research question/objective using power calculations. Typically, each animal used will provide a large amount of data towards more than one objective.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power calculations were used to predict the number of animals needed to achieve all the objectives on this licence. Advice taken from local statisticians and the use of the results from preliminary experiments obtained on another licence helped in the design of future experiments. The amount of data/information gathered per animal in one single experiment will be maximised in order to reduce the number of animals to be used in this project and answer all the questions set in each objective.

Negative results will also be reported to prevent unnecessary studies to be conducted by other laboratories. Allocation to treatment groups will be randomised and all experiments and analyses will be blinded to maximise the statistical power of each mice used in the study.

Example of experimental design



What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Training of all research staff will be compulsory for all the techniques used in this project to ensure good practice and reproducibility of the results. The use of brain tissues (from each experimental group) will be maximised to increase the amount of data collected from each experiment. Pilot studies with few animals will be carried out for each new drug to be tested to ensure that the best dose regimen is used and animal welfare is appropriately addressed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Although primates are closer to humans in behaviour and brain formation, the basic brain circuits of rodents appear to be sufficiently similar in all mammalian species to allow fundamental scientific questions relating to the human brain to be addressed. A large part of the data in our archive, like much of what has been obtained in other laboratories across the world for most of the past century, comes from rats or mice. The data obtained in this licence will use the same species and similar protocols to allow existing and new data to be compared directly and the more complete picture that emerges to contribute to models

of neuronal circuits. We will use healthy adult rodents to provide a detailed study of brain circuits in the absence of disease and the methods used will be of mild severity.

Why can’t you use animals that are less sentient?

All animals used in this licence will be adults to allow the neuronal circuitry to fully develop and drugs to be tested on an 'adult' model. Animals that have been terminally anaesthetised will be used to obtain data towards some of the objectives of this licence.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We consider the welfare of the animals of paramount importance and the procedures will be regularly reviewed for potential refinement. Single housing will not be considered in this project and rodents will be provided with high quality bedding material. We do not expect any complications following treatment of the animals. However, pilot studies will dictate appropriate doses and animals will be closely monitored. Animals will be handled with tunnels or cupping, acclimated to their environment before the behavioural testing and trained appropriately according to the test used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will ensure that experiments are conducted in the most refined way by following standard operating procedures from the Home Office and institution and the guidelines for the use of animals [Animal Behaviour (2018)].

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My link to the NC3Rs through the newsletter and social media allows me to keep up-to-date with any advances in this domain. Updates from the NC3R regional manager during the AWERB meetings will also inform me of new information on experimental design, good practice and replacement methods. Any new development of new 3Rs technologies related to this project will be scrutinised, implemented if possible and shared with NC3RS regional manager and community.

48. The Testing of Bone Scaffolds in Sheep

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

bone repair, scaffold, sheep

Animal types	Life stages
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

In this study we will test the ability of a biodegradable polymer based scaffold to encourage bone growth. This will be tested in a bony defect in the knee of sheep. The material to be tested is a 3- dimensional (3D) scaffold with a high number of linked pores, which should allow cells to migrate through the defect whilst providing support for the bone to grow. In addition, the scaffold will be coated in substances which encourage bone to grow which should increase the rate of bone growth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Worldwide there are a large number of surgeries carried out that require bone grafting, even though there are significant risks associated with it, for example rejection and infection, multiple surgeries, increased hospital stays and greater demand and costs put on the NHS. There is also usually a lack of sufficient bone graft, therefore donor bone may be needed. The materials we are working with will hopefully be able to support bone growth, cell migration and the formation of blood vessels within a defect site, and could benefit humans. This in turn should reduce the number of surgeries and infections associated with bone grafting and provide a material which encourages better bone fill to a defect site.

What outputs do you think you will see at the end of this project?

Data will be used to create publications which will be submitted to high impact factor peer-reviewed journals. In addition the data will be presented at international conferences.

The aim of this period of funding will be to develop a biodegradable biomaterial implant which is capable of promoting and inducing bone regeneration and vascularisation in bone defects. Hopefully removing the need for several surgeries, an increased recovery time and the risk of donor-site morbidity.

Who or what will benefit from these outputs, and how?

The data derived from this project will be used by scientific researchers, industrial partners, clinicians and veterinarians.

Short term benefits (1 - 3 years) - information shared through peer-reviewed journals and international conferences

Medium term benefits (3 - 5 years) - successful regulatory approval of the material; GMP manufacturing, packaging and storage

Long term benefits (5 - 10 years) - phase 1 clinical trials; reduction in the use of autograft and therefore the associated complications and the replacement of products on the market which have proved imperfect or require several surgeries

How will you look to maximise the outputs of this work?

We will be collaborating with different research groups and any industrial partners to develop our technology further. In addition, we will be publishing the results of this study as well as presenting our findings in symposiums and conferences

Species and numbers of animals expected to be used

- Sheep: 24

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Cell based studies are useful to look at how cells will behave in contact with the scaffold, however cell assays alone cannot adequately model the complete array of effects important in bone modelling or repair. Using stem cells we have shown that cells were viable, proliferated, and were evenly distributed throughout the scaffold, suggesting that the material would not be toxic and encourage bone growth.

Predictions of degradation rates and pore numbers have been obtained from these studies for varying formulations; however none of these assays can adequately model the in vivo environment of a whole animal. Therefore we need to test the material in an animal model before it can be translated into use in a human.

The animal to be used is a skeletally mature female sheep as they have a similar body size and rate of bone remodelling as humans.

Typically, what will be done to an animal used in your project?

The model is a bone defect with a maximum width of 11 mm x 15 mm height that is drilled into the medial femoral condyle of both hind legs as this reduces the number of animals used in the study as each leg acts as a separate sample. We have previously shown that the sheep tolerate bilateral surgery very well. We do not see animals remaining recumbent and unable to stand post-operatively after creating defects in both hind legs (therefore 2 defects per sheep). The sheep are slightly lame for up to three days when compared to un-operated sheep, but are then typically 100% sound with no effect on gait with a return to pre-operative normality. This is evident by the fact that sheep have previously been able to stand on their hind legs shortly after surgery in an attempt to reach food, showing that the analgesia is highly effective. The gold standard for bone grafting is the use of autograft, which is the positive control in this study. Bone trephines have been designed to allow sufficient bone cores to be collected from two femoral condyles in a single sheep to fill one defect with bone graft, therefore removing the need for bone harvesting from the iliac crest. An empty defect is used as the negative control.

The animals will be housed indoors in small pens for a week post-surgery and monitored clinically for any signs of pain following injection and then allowed to roam free in a field/barn for the remainder of the study during which further activity (e.g. Fitbark) and clinical monitoring will be undertaken.

At the end of the study, animals will be euthanised and when dead the femoral condyles will be removed and fixed for a period of at least one week. Defects will then be scanned using micro- computed tomography (micro-CT) before carrying out histology and immunohistochemistry to assess bone quality and cell types.

What are the expected impacts and/or adverse effects for the animals during your project?

The overall severity of this procedure is moderate. We expect that the animals will be slightly lame for a couple of days and then will have no adverse effects of the surgery. The animal may show mild signs associated with recovery from general anaesthetic, such as appearing slightly ataxic and sedated, but this is transitory and our experience is that sheep are usually standing within 15 minutes of the end of the general anaesthetic. Analgesia will be given for 72 hours post-operatively, unless an animal is assessed by the NVS to require additional pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

During this protocol 100% of the animals will suffer moderate levels of severity as a result of the surgical procedures conducted under general anaesthesia.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vitro studies are helpful as a first stage test to look at cell proliferation, cell differentiation, toxicity and cytocompatibility. However, in vitro assays alone cannot adequately model the complete array of effects important in bone and cartilage modelling or repair. Previous work has been carried out looking at the growth of mesenchymal stem cells on the product. This study showed that the cells were viable, proliferated, and were evenly distributed throughout the scaffold. Degradation and porosity studies were investigated by submerging samples in saline solution. Predictions of degradation rates and porosities have been obtained from these studies for varying formulations; however none of these assays can adequately model the in vivo environment of a whole animal.

All products will have been thoroughly tested in vitro for biocompatibility and cytotoxicity before delivery into the sheep. The next stage of the study is to demonstrate the bone tissue’s response to the scaffold material. Therefore, we plan to use a bone defect sheep model to look at ingrowth into the product.

Which non-animal alternatives did you consider for use in this project?

In vitro testing was carried out to assess the biocompatibility and cytotoxicity of the material, but it is not possible to recreate the in vivo bone environment.

Why were they not suitable?

It is not possible to achieve the aim of this project without implanting the material directly into a bony defect within a living animal, as in vitro approaches cannot, to date, mimic the complex physiological in vivo microenvironment involved in tissue repair.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will always seek to use the minimum number of animals necessary to achieve the objectives of the project whilst maintaining statistical validity of results. We have based the numbers of sheep required on previous studies we have carried out and that we have published in the literature. In this project we will be creating two defects per sheep, one in each hind leg, which allows us to reduce the animal numbers used per study. We will be using a minimum of 7 defects per experimental and control group.

In our research we will randomise our experiments to avoid bias, for example we randomise which animals get which treatment i.e. biomaterial or control and in what order they undergo procedures. We will analyse our data in a blinded fashion and use coding systems to anonymise data, thereby reducing unconscious bias. In some instances we may ask our collaborators to randomly allocate animals to experimental groups and to retain the information as to which group and animal belongs until the final results are collected. We believe that these methods contribute to the robustness of our data interpretation. We are committed to working to the PREPARE guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3R Experimental Design Assistant was used to create a study plan. This allowed us to critique the plan and run a power calculation. Values from our previous studies (amount of bone formation) were used in the EDA and also PS Power and Sample Size (version 3). Setting the power of the experiment at 80%, $p<0.05$ and a standard deviation of 8 we require a minimum of 7 defects per group. At a power of 90% the number of defects required is 8.

We will also maximise the data obtained from each sheep e.g. activity data, micro-CT data, histological and immunohistochemistry data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At the end of the study any unwanted tissue may be harvested by other groups for further research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The drawback of utilising small animal orthopaedic models, for example mice, lies in the inherent differences in terms of bone composition, bone density, and quality when compared to humans. These models are therefore not suitable for evaluating products close to the human market as results cannot be directly extrapolated to human conditions. For this reason we have chosen a larger species, sheep, which is more analogous to humans with a similar pattern of bone ingrowth into porous implants over time. Sheep are placid and easily handled with a similar body weight to humans. They have been used in the study of numerous musculoskeletal conditions and diseases including biomaterial evaluation. Sheep have cancellous and cortical bone, undergo bone remodelling and have a similar healing rate as humans, but they also have plexiform bone (akin to woven bone) and fewer Haversian canals, with differences in bone composition and fracture stress levels. Even though the rabbit is the most commonly used species (approximately 35% of all musculoskeletal research) it shows the least similarities to human bone, with gross differences in bone anatomy in comparison to humans and have a faster skeletal change and bone turnover.

Why can’t you use animals that are less sentient?

Cell based studies are useful to look at how cells will behave in contact with the scaffold, however cell assays alone cannot adequately model the complete array of effects important in bone modelling or repair. Predictions of degradation rates and pore numbers have been obtained from these studies for varying formulations; however none of these assays can adequately model the in vivo environment of a whole animal. Therefore is not possible to achieve the aim of this project without using animals as the only authentic test

of a product designed to encourage bone formation is to place it into challenging bone defects and quantify its effectiveness at encouraging bone formation, and we need to test the material in an animal model before it can be translated into use in a human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Sheep will undergo only 1 surgical event to create bone defects in each hind leg within the femoral condyle. This allows us to use fewer animals in a study, and we have also previously shown that the sheep tolerate the double defects very well. The region is low weight bearing, not within the joint and previously we have had no issues with significant lameness in any sheep. All surgery will be carried out aseptically in dedicated facilities, according to the LASA guiding principles for preparing for and undertaking aseptic surgery.

The sheep will receive analgesia (e.g. fentanyl patches), as advised by the NVS, pre-operatively and post-operatively to allow for a continuous supply of analgesia for an appropriate period. If for unforeseen circumstances the surgery must be cancelled the patches will be removed and the sheep returned to the flock. Sheep will not then be re-patched and starved for a minimum of 72 hours. In addition, the sheep will receive local anaesthetic in the injection/incision site. To reduce the risk of infection the sheep will receive antibiotics pre-surgery and post-surgery. Non-steroidal anti- inflammatories will be used for up to 72 hours after injection, with the initial dose given before first incision. Animals will be housed in dedicated recovery accommodation post-surgery for 24 hours (or until recovered from the immediate effects of the anaesthesia) and then returned to either the barn or the field for group housing. The decision to transfer the animal from one housing regime to another is dependent upon recovery from the surgery and is therefore made on an individual basis for a particular animal.

There are three clinical score sheets to guide us when monitoring the animals. One covers the mobility, food intake and water consumption, fever, demeanour and respiratory rate and is routinely used for all animals for a minimum of 3 days post-operatively. There is a posture and locomotion scale that is used to assess the levels of lameness and we use the grimace scale to assess levels of pain in the sheep. If any sheep is not recovering as expected, enhanced monitoring will be carried out and the NVS contacted for advice.

After the injectable anaesthetic agents are given all sheep must be intubated for bone defect creation. Sheep are at a high risk of aspiration pneumonia due to a large volume of rumen contents and saliva, but this risk is reduced after the cuff is inflated in the endotracheal tube in addition to tilting the surgical table. Generally the larynx is sprayed with a local anaesthetic agent, for example lidocaine, before the lubricated endotracheal tube is placed using a laryngoscope. This is a challenging procedure in a sheep as visualisation of the airway is difficult due to the narrow opening of the mouth. If intubation is not possible the sheep may be recovered, but strict criteria must be followed to ensure the animal is a viable candidate for recovery and re-use after NVS assessment. No

obvious damage must be seen at the back of the throat and minimal rumen contents should be present in the mouth. A maximum of 6 intubation attempts, over a 30 minute duration, will be made to place the tube. The sheep must

recover properly and be well immediately afterwards. Antibiotics may be given as a prophylactic for aspiration pneumonia. The NVS will be contacted for advice at the time and will then assess the sheep before another anaesthetic event. The animal will be allowed to recover for a minimum of 7 days after a failed intubation procedure. Only one failed anaesthetic attempt and recovery allowed per animal, therefore if the second anaesthetic event (6 intubations) is unsuccessful, the sheep with be humanely killed.

Delivery of any material to a defect site will be closely monitored to ensure that there is not significant inflammation. If inflammation occurs the sheep will be carefully monitored and graded using a locomotion scoring system after consultation with the NVS. Any severe soft tissue inflammation will be treated with antibiotics and local pain relief provided to the animal. If this has not improved the animal's condition over 24 hours then the NVS will be consulted regarding the short term use of an NSAID. If the sheep is significantly lame on both hind legs and is not responding to additional analgesia it will be killed.

During a study animals may be injected with fluorochromes, at 2 known time points for example 19 and 24 weeks post-operatively, to allow assessment of the rate of bone growth within the defect. The stain binds to calcium ions on the mineralisation front and stabilises after 24 – 36 hours after injection. This was used in previous studies under PPL 40/3599 and no adverse effects were seen.

An activity monitor (e.g. Fitbarks) may be worn by animals for either part or all of the duration of a study. The monitors allow us to continuously record the ‘play’, ‘rest’ and ‘activity’ of the sheep before and during the experiment. This allows us to identify early indicators of reduced welfare in the animals and to intervene accordingly. If reduced activity or play and increased rest is noted, the NVS will be asked to examine the animals to identify the cause of the reduced mobility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgery will be carried out aseptically in dedicated facilities, according to the LASA guiding principles for preparing for and undertaking aseptic surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

During the study we will be in contact with the NACWO and the NVS in addition to monitoring any updates from the NC3Rs website.

49. Central Nervous System Repair by Cell Transplants

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

(i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

CNS injuries, cell therapy, repair, transplantation, regeneration

Animal types	Life stages
Rats	adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Repair of CNS injuries by transplantation of olfactory ensheathing cells

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Injuries to the brain and spinal cord can lead to devastating and lifelong disability in patients, which also creates an enormous financial burden for families and society. Despite

some advances, there is still no effective treatment. Cell therapy is one of the most promising strategies to restore neurological functions after injury.

The olfactory system is a unique area where the nerve cells in the nose are continually formed through adult life. Their newly formed axons are supported by the special type of glial cells – olfactory ensheathing cells (OECs) and grow from the nose into the brain. Our previous studies have shown that transplantation of OECs into the injured regions of the spinal cord could repair damaged nerve fibres and restore loss of functions. We plan to translate our findings into clinical applications. We will collaborate with clinicians to work on human OECs and test the cell functions in our established experimental models. The outcome of the study will provide important and valuable information for future clinical applications.

What outputs do you think you will see at the end of this project?

The objective is to establish a standardised protocol of the therapeutic cell production and surgical procedure that will be quintessential requirements for OEC transplantation to be applied as a treatment of human brain and spinal cord injuries.

Who or what will benefit from these outputs, and how?

Short term benefits will be to understand and compare the composition of olfactory cultures from the rat and humans and help to develop standardised cell preparation protocols and transplantation procedures which would be applied as a clinical guideline.

Medium-term, our published studies have shown transplantation of rat OECs into our experimental models can repair damaged nerve fibres and restore loss of functions. We now need to compare whether the transplantation of human OECs will have the same reparative ability.

The ultimate benefit of these studies will be the ability to repair central nervous system injuries in man.

Improving nerve regeneration in injured patients may improve their limb power, sensation, bladder, and bowel control. Results will be published in peer-reviewed journals to inform other scientists, clinicians, and patients.

Future applications in patients may extend beyond spinal cord and root injuries to include stroke, head injury, and patients with visual impairment. These treatments will allow the patients to resume a degree of normal life functions and reduce the burden of care on the community.

How will you look to maximise the outputs of this work?

We have been collaborating with researchers and clinicians in the UK and internationally. We frequently communicate with all our collaborators to discuss the research progress and

regularly attend scientific conferences to report our results. Our results are also published in peer-reviewed scientific journals.

Species and numbers of animals expected to be used

- Rats: Total adult: 980; Day 1-8 pups: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats have been selected for this work, as they are the lowest vertebrate group with a well characterised central nervous system that we can model the human system. Adult rats from three months old are used in this study since the damaged CNS nerves are not able to regenerate spontaneously. We use early postnatal rats (postnatal day 1-8) for the pilot in vitro study since the neural tissues retain viability in culture conditions at this life stage.

Typically, what will be done to an animal used in your project?

All animals will undergo non-invasive behavioural tests pre- and post-surgery; the duration of one session per rat is around 5 minutes, one or two sessions per week for up to six weeks.

Under general anaesthesia, animals receive laminectomy at the cervical or thoracic level and lesion of the spinal dorsal column or the dorsal roots. About 60% of animals will receive the implantation of therapeutic cells. The exposure will be closed by muscle and skin sutures. The duration is up to one hour.

All animals will receive the administration of analgesic agents after surgery. Some will receive immunosuppressive drugs or control substances by intraperitoneal, subcutaneous injection or drinking water under Laboratory Animal Science Association (LASA) guidelines.

At the end of experiments, the animals will be terminally anaesthetised by exposure to carbon dioxide gas in a rising concentration followed by perfusions.

What are the expected impacts and/or adverse effects for the animals during your project?

All the rats will undergo surgery. Post-surgery pain will be mitigated by the administration of analgesic drugs during the first week.

The animals may show reduced activity and about 5% weight loss during the first week post-surgery. Some locomotor changes will be present when animals are undergoing

specific tests. Neurological signs may include inflammation of paws and self-mutilation in a small number of cases during the six- weeks experimental period. This happened through past experiences in our studies. We used a mildly aversive tasting substance such as picric acid or paw gloves to ameliorate or prevent this from happening.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate. In all rats with surgical procedures.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In the past decade, alongside the in vivo work, we explored a few in vitro models e.g. culturing neonatal spinal cord slices. However, (1) Failure of CNS axon regeneration occurs in mature age. However, adult neural tissue does not survive robustly in culture; (2) Failure of axon regeneration is not only the intrinsic properties of the neurons but also due to the complex CNS tissue environment; (3) The in vitro models cannot replace the in vivo models for assessing neurological function outcomes;

(4) Surgical procedures for transplantation cannot be simulated on the cultured tissue.

For translating our work to future clinical applications it is essential to investigate the methodology of introducing and incorporating transplanted cells into adult animals so that we can model the human system. Since the criterion of success is the outcome of motor and sensation functions it is not possible to dispense with the animal models.

We will use early postnatal brain slice and spinal culture models alongside the in vivo work as an initial screen to test the therapeutic effects of cell types and numbers on neurite outgrowth before undertaking in vivo experiments to minimise the number of animals used, to reduce and avoid the animal welfare issues associated with surgery and caring for rats with spinal cord injury.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We plan to have 5 batches of in vitro brain slice assay to screen the efficacy of the cells produced. Eight pups will be used for each batch. Two hundred pups in total will be needed for 5 years.

We plan to use 2 experimental models to test the reparative olfactory cells from rats and humans. Each model needs about 14 rats per batch, 2 batches (n=28) for testing rat cells and 2 batches (n=28) for human cells each year. Around 560 rats would be needed for 5 years. Around 70 rats would be needed for tissue culture work each year, around 350 rats for 5 years. The total number of rats for 5 years would be around 980.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All candidate cells are first tested in vitro for their ability to fasciculate, elongate, and induce axon growth. These in vitro assays are being constantly improved and extended so that they enable a more complete profile of the reparative abilities of the candidate cells to be assembled.

This avoids the use of living animals to establish these cellular properties. The findings of the investigations are subjected to parametric and non-parametric statistical analysis to ensure the use of only the minimal amount of material needed to establish the reparative properties of the cells. It is only once these properties have been established in vitro that in vivo experiments are required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In the dorsal roots lesion model, we will only make lesions on one side. The behavioural test deficits will be only on the ipsilateral side of the lesion, the normal (contralateral) side will be used as a control to reduce the use of animal numbers. Without stressing the animals and with rationally allocated resting periods multiple behavioural tests will be carried out using the same animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The dorsal spinal roots and dorsal column lesions will be used during this project. We have been using these models to test transplanted cells to repair damaged CNS axons for more than 20 years. The surgical procedures are less invasive and take a shorter duration compared to others. Animals recover quickly after the surgeries with little effect on their normal cage activities. The functional defects are only shown in the specially designed behavioural tests. The functional tests in this application are based on normal animal behaviours, which are not induced nor forced. The models provide reliable and consistent results and cause the least pain, suffering, and distress to the animals.

Why can’t you use animals that are less sentient?

These investigations constitute an animal model of repair of the human spinal cord and other nerve injuries by transplantation. It is only by studying the method of introducing and incorporating transplanted cells into animals that we can model the human system. Since the criterion of success is the outcome in terms of motor performance and behavioural functions it is not possible to dispense with the animal model.

Rat models are most widely used to study CNS injuries including spinal cord injuries. They have well- understood anatomy and few surgical infections. There are also well-established functional analysis techniques in rats. Although animals such as Zebrafish are less sentient but regenerate their spinal cord after injury, both at larval and adult stages, studies using animals with such spontaneous regenerating ability provide useful information on comparative biology, but they are not suitable for modelling the human condition.

Adult rats around three months are used in this study since the damaged CNS nerves are not able to regenerate spontaneously, which models the human condition.

The therapeutic cells – olfactory ensheathing cells used in this study were originally discovered and obtained in rodents, and the large quantity of research data on their application in neural repair has been from rodent models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have used these established models with over 20 years of experience. Although we consider there is not a more refined way to conduct these in vivo studies we will, however, regularly review and discuss with the NVS and the UCL representative NC3R's regional manager all the advances in instrumentation and procedures and will integrate them into our procedure if they are applicable. We will continue endeavouring to minimise the invasiveness of the surgical procedures by avoiding any tissue damage, bleeding or infection.

- During the surgical procedure, the level of anaesthesia will be constantly monitored.
- An infection will be prevented by strictly following aseptic procedures and using disposable sterile gloves, dressing packs and sterile instruments.
- Perioperative and postoperative analgesia will be given to reduce pain.
- 5 ml of sterile isotonic saline is injected subcutaneously using a sterile 23G needle at the scruff of the neck region to hydrate the animals.
- After the operation, the animal will be kept warm using a thermostatically controlled heat mat s in a recovery box and supervised until they are fully recovered and moving freely around the cage.
- Cages for post-operative animals have been adapted to have more easily accessible water and areas of increased heating, providing the animal with normal and elevated cage temperature areas. The Diet of post-operative animals is supplemented with wet food e.g. DietGel® 76A (ClearH2O).
- The functional behavioural tests will not start until the animals are fully recovered, at least 1 week after surgery. The tests in this application are based on normal animal behaviours, which are not induced nor forced, to avoid stress on the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ASPA; PREPARE: guidelines for planning animal research and testing. Laboratory Animals 2018, Vol. 52(2)135–14; LASA Current Publications; ASPA; NC3Rs advice. ARRIVE guidelines 2.0.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow closely the advance in research using animals to adopt new animal models with less adverse harm to animals. We will also follow advances in research using tissue

culture, especially with mature tissue to replace animals in the in vivo work and to reduce animal numbers. We will communicate with the Home Office Inspector, NVS, NACWO, NTCO, and NIO to discuss the implementation of potential advanced technology and to periodically view the NC3R's website.

50. Models of Neurological Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

neurodegeneration, neurons, glia, motor system

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate the processes and mechanisms of disease in human neurological disease using genetically modified mouse models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work is important because there are currently very few effective treatments for neurological disease. This is due in part to an incomplete understanding of disease mechanisms.

What outputs do you think you will see at the end of this project?

At the end of this project we expect to have advanced understanding of neurological disease. Outputs from the project are expected to be scientific publications, but may also include intellectual property relevant to the development of novel therapeutics.

Who or what will benefit from these outputs, and how?

In the short term this research will benefit other scientists and clinicians. In the longer term we hope our research will benefit patients with neurological disease.

How will you look to maximise the outputs of this work?

To maximise outputs we collaborate with other scientists (locally within our institution and overseas) and pharmaceutical companies. We will also disseminate our findings at research conferences and through the media.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use genetically modified mice as these allow us to work with the most accurate and genetically tractable models that are currently available. The majority of our research currently utilises cultured neurons and glia obtained from embryonic stages, as this allows us to investigate the underlying biology of disease using live fluorescence microscopy. We also use adult mice to characterise disease progression and pathology. For example we are able to investigate specific hallmarks (e.g. pathological, phenotypic) of disease and whether these manifest in genetic mouse models in the same way as they do in human patients.

Typically, what will be done to an animal used in your project?

Typically mice will be born, genotyped, and then used for breeding to generate embryos for experimental studies in vitro. Other mice will be bred and then allowed to reach adult stages to allow us to follow disease progression. Typically these mice will be euthanised in order to obtain tissues for lab-based studies.

What are the expected impacts and/or adverse effects for the animals during your project?

Some mouse models of disease develop moderate phenotypes associated with neurological disease, such as motor symptoms that manifest as reduction in the ability to walk. Typically the models we use also develop pathology in their nervous system associated with phenotypic changes in behaviour.

Genetic models of amyotrophic lateral sclerosis do not gain weight as quickly as their control siblings, but we do not see any signs of adverse effects associated with this.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We anticipate that the majority of mice will show mild severity, with approximately 20% showing moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ideally we would replace animals with human cell models of disease. However these are not currently available for some of the diseases we work on, e.g. hereditary spastic paraplegia. In addition we sometimes need to study effects that are happening in situ in the nervous system of animals at an advanced age, when clinical symptoms are present. These are extremely hard to replicate in laboratory cell culture systems.

Which non-animal alternatives did you consider for use in this project?

We considered human patient derived cell models.

Why were they not suitable?

In some cases human cell models do not currently exist for the diseases we are investigating. Even if they did, they would not be useful for studying age-related processes involving multiple cell types in an intact nervous system. For example in disorders of the

motor system we need to investigate upper motor neurons, lower motor neurons and muscle. In an animal these are connected by synapses, and this is extremely difficult to reproduce faithfully in cell culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on the number of mice we need to maintain in order to preserve breeding colonies of genetically modified animals (100/year) and the number of animals likely to be required for experimental studies (400/year).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For this project we need a regular supply of time mated female mice carrying embryos that will be an appropriate mix of genotypes. Based on experience with these models we require 15 females to be bred using timed-mating each week, in order to ensure that we obtain a minimum of 2 pregnancies. With an average litter size of 7 this give us high confidence that we will obtain at least 2 embryos that are wild type and 2 that are homozygous mutants. These are the minimum required for the live microscopic imaging techniques that we utilise. Fr studies with adult mice we need at least 5 per group in order to obtain reliable results (for example for pathology, protein biochemistry, quantitative PCR).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Over the past 20 years we have reduced the number of animals used for individual experiments considerably. For example we have determined the minimum number of G93A mutant SOD1 mice required for in vivo studies, and optimised breeding strategies to obtain the required numbers of animals for our experiments (e.g. time matings, see above).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using genetically modified mouse models of neurological disease. The majority of our methods use cells and tissues collected from embryonic mice, thus minimising suffering. In a few situations it is necessary to collect tissues/samples from older mice that manifest disease symptoms. In these cases we have optimised husbandry so that the mice experience minimal distress.

Why can’t you use animals that are less sentient?

We are already using embryos for the majority of our work. In some cases we have replaced mice with zebrafish animal models, which are considered to be less sentient. However this is not always possible, in which case we use genetically modified mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Principally we will use animals as early as possible in their disease course, before they develop symptoms classified as severe. In most cases we use embryos, which are essentially asymptomatic.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow NC3Rs best practice guidance, and where relevant we follow specific guidelines for the use of animal models of amyotrophic lateral sclerosis (Ludolph, et al (2010). Guidelines for preclinical animal research in ALS/MND: A consensus meeting. Amyotrophic Lateral Sclerosis: Official Publication of the World Federation of Neurology Research Group on Motor Neuron Diseases, 11(1-2), 38–45.)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To stay informed, we follow NC3Rs on social media to stay up to date with the latest advances in the 3Rs. We also regularly review new publications relevant to our in vivo work. If these advances are applicable to our research we will implement them in a controlled way, to determine whether the measures impact on the number of animals or phenotypes under investigation.

51. Research on Products Used in Prevention and Therapy of Tuberculosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

BCG, TB, vaccine, safety, potency

Animal types	Life stages
Guinea pigs	adult
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to provide quality assurance that vaccine and therapeutic products used in medicine for tuberculosis (TB) are safe and likely to be effective, including situation of co- infection (TB and malaria). This also includes studies of how these medicines work in a living body.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

As current knowledge advances, new medicines like vaccines and therapeutics products are continuously developed. It is important that we have an improved understanding of whether a new vaccine or therapeutic product is likely to be safe, how it works and how its quality will be regulated. This is to provide assurance that vaccine and therapeutic products used in medicine for TB are safe and likely to be effective. This PPL includes protocols for investigating how these medicines protect in a living body with TB infection or TB-malaria co-infection. A high level of assurance is particularly important for vaccines given to healthy people. If public confidence in vaccine safety and effectiveness falls, vaccine uptake and coverage may be reduced and diseases that were previously well controlled by vaccine can re-emerge. The knowledge gained will be used to inform regulatory process in the UK and worldwide.

What outputs do you think you will see at the end of this project?

The scientific data and new information to be generated from this project will be published in peer reviewed scientific journals and used by both local and collaborative scientists to further our understanding of TB infection and disease (including situation of co-infection of TB and malaria), in terms of pathology, prevention and treatment. These data may also be utilised by regulatory authorities if appropriate.

Who or what will benefit from these outputs, and how?

The potential benefits will include:

1. Evaluation in the quality of product candidates and provision of assurances on the safety and potency of existing and novel therapeutic and vaccine products used in medicine.

2. Provision of information if new generation therapies or new formulations/delivery systems for vaccines antigens are likely to be effective.

3. Research and development studies on correlates of protection that will provide effective methods for potency and efficacy assessment of new vaccines, immunotherapy including cell-based therapies, chemotherapies and related complex therapeutic interventions, including Investigational Medicinal Products destined for clinical trials and will benefit the scientific community.

The knowledge gained will be used to inform regulatory process in the UK, in Europe and worldwide. The data from this research project will also be used by both internal and

external collaborative scientists to further our understanding of TB infection and disease. Specific benefits will depend on the vaccine formulation and the scientific questions addressed but examples include: information of humoral and cell mediated immune responses and whether the response is likely to be protective; the effect of adjuvant; the ability of antigens to stimulate cross protective response to antigen variants; or whether a strain used in live vaccine is sufficiently attenuated and so on.

This project will provide relevant and sensitive assays for biological activity/ quantitation that are developed and applied in clinically relevant settings; these benefit patients and enable the regulatory authorities to make informed decisions on public health issues as well as ensuring prudent and effective use of these powerful biological modifiers. The programme of work has provided, and will continue to provide, a theoretical and experience-based framework for determining the safety and efficacy of existing and potential therapeutic agents for the treatment of human disease using biological mediators.

How will you look to maximise the outputs of this work?

Some of our planned studies in this project are part of the collaborative research projects with external collaborators. Scientific data and new information generated will be disseminated by presentations (oral or poster) in scientific meetings or conferences, and subsequently will be published in peer reviewed scientific journals. This in turns will foster more collaborations with scientists in the UK and worldwide from academic bodies and research organisations working in the same scientific field.

Species and numbers of animals expected to be used

- Mice: 1900
- Guinea pigs: 160

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Small laboratory animals including adult mice and guinea pigs will be used in this project. The use of adult guinea pigs for safety and potency evaluation of mycobacterial products is stated in the standardised protocols used by regulatory authorities, such as in European Pharmacopoeia. Adult (at least 6 – 8 weeks of age) mice with a mature immune system are commonly used small laboratory animals. Their use has been the gold standard for the evaluation of vaccine and therapies for TB because of their small size, low husbandry costs, well-defined health and genetic backgrounds. A large array of tools to investigate immune responses are also available.

Typically, what will be done to an animal used in your project?

Typically, injections or other routes of administration of vaccine or therapeutics will be given to small laboratory animals. Protocol 1 - 4 using guinea pigs have 2 - 3 steps without any repeat. Protocols 5 - 8 using mice receiving immunisation can be repeated up to 4 times. For monitoring of immune responses, mice may undergo multiple whole body imaging step and/or blood sampling step throughout the experiment. Typically, the number of repeats of these steps are 4 - 10 times. Protocol 6

- 8 using mice challenged with TB and/or malaria infection will also be used and TB infection can be repeated one more time. The duration of experiments is usually ranged 2 - 5 months depending on the experimental design. It should be noted that studies involving induction of protection against infection by slow growing organisms (such as Mycobacteria) may need to be continued for many months (rarely beyond 6 months) after challenge for the data to be meaningful. For some routes of administration, anaesthesia may be used and the maximum number of anaesthesia in the lifetime of the animals is rarely beyond 20 times. At the end of an experiment, all animals will be killed by a schedule 1 method or mice may undergo terminal anaesthesia with exsanguination.

What are the expected impacts and/or adverse effects for the animals during your project?

The project including 8 protocols consist of procedures of mild up to moderate severity level. The animals may receive substances such as vaccines by standard routes (for example subcutaneous and oral). Following vaccination, the majority of animals are not expected to experience more than mild to moderate adverse effects (for example skin irritation, local swelling as inflammatory reaction at injection sites).

Blood samples may be taken and this does not expect to have adverse effects for the animals that are more than mild and transient. Non-invasive imaging may be carried out under short duration of anaesthesia and no adverse effects are expected.

Mice may be challenged with TB and/or malaria. TB infection (rare in non-high dose groups and more frequently in high dose groups) may result in moderate adverse effects with gradual loss of body weight (>10%) and reduced physical activities. Malaria infection via mosquito bites may result in swelling, redness or itchiness at the site of mosquito bite. Malaria infection with lethal species may lead to symptoms or adverse events such as gradual body weight loss (>10%), paleness and reduced physical activity if untreated. Combination of TB and malaria infection may lead to symptoms or adverse effects as mentioned above, such as gradual body weight loss (>10%), change of food and water consumption, paleness or changes in observed behaviour or activity level, e.g. pronounced inactivity (‘lethargy’) which deviates from the expected norm during the infection period.

Frequent monitoring and supportive husbandry measures are used to reduce the impact of these adverse effects. At the end of all tests, animals are humanely terminated. The impact of these adverse effects is reduced as far as possible by frequent observations of

the animals by experienced staff and the application of recognised humane end points where necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on our experience using the same protocols, under this licence approximately 65% of mice and approximately 10% of guinea pigs are expected to experience mild severity due to the timepoints at which the experiments will be concluded (humane endpoints). Approximately 35% of mice are expected to experience moderate severity and approximately 90% of guinea pigs are expected to experience low moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Some protocols used in this project are performed according to methods described in regulatory guidance. Protection and safety of a biological medicine cannot be fully examined without the use of animal procedures, as multiple factors contribute to protective response and the immune system itself is too complex to be modelled in cell culture. Efforts are continuing to develop suitable alternatives to some of the methods that are retained in this project licence.

The detection of biomarkers of protection could in the long-term result in progression towards suitable

in vitro detection systems to replace some of the in vivo work.

Which non-animal alternatives did you consider for use in this project?

In vitro assays based on viability for live vaccine, such as BCG as surrogates for potency. Molecular biology tests to detect residue virulence gene of BCG or other live attenuated mycobacterial products are in development. In some cases, sufficient information on the immune responses together with results from non-invasive whole body imaging to monitor the biodistribution and persistence of live mycobacterial vaccines in Protocol 5 can be obtained without resorting to the use of infection models (Protocol 6 - 8). For example, antibody titres can be measured using in vitro serological assays or in vitro surrogates of

protection (such as bactericidal or opsonophagocytic assays), cell-mediated immunological responses.

Why were they not suitable?

Many of the tests used to evaluate the quality of new vaccines or vaccine formulations do not involve the use of animals. However, these tests are limited to the assessment of the physico-chemical properties of the vaccine products for production consistency monitoring only. The same for in vitro assays based on viability (for live vaccine, such as BCG) as a surrogate for potency may only indicate production consistency. Thus they can be applied for routine batch release purpose to monitor product quality, but of less value for research purposes where the immunological responses will also be investigated.

There are currently no validated alternatives that can provide reliable and sensitive results for detecting the excessive dermal reactivity and/or absence of virulence of BCG vaccine and other live attenuated mycobacterial products.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates of the number of animals that will be used in the course of this project are based on experience over the course of the current project licence over the last 4 - 5 years and the predicted maximum usage in the coming 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Research to evaluate the potency and safety of new vaccines is generally hypothesis-driven and the interpretation of data therefore depends on the statistical comparison of an experimental group with controls. Controls would include a group of unimmunised animals and may also include other similar vaccines or components for comparison depending on the hypothesis being addressed. Experiments will be powered to use the minimal number of animals required to produce significant data by a biostatistician. The minimal number will depend on the variability of a particular method. The variability of results can be determined either from pilot studies or from systemic review of literature reporting on a similar model. In general, challenge-based potency tests tend to be more variable and therefore require more animals than their serological counterparts. Experiments may be based on existing pharmacopoeial procedures that have been refined involving

considerable statistical input over the years. These procedures may be used for guidance on the number of animals required per dose

(group) and number of groups. Experimental design and the suitability of particular statistical tests for hypothesis-led research will be planned in consultation with expert biostatisticians. The experimental design will take into account previous experience of similar research whenever this is available, and the use of online tool such as NC3R's Experimental Design Assistant. As a result, this process is considered the minimum required to give reliable results of satisfactory precision.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For some protocols used in this project, the number of animal groups and size of each group are based on optimised and validated methods that are described in regulatory guidance. The number of groups and/ or group size of the other protocols are based on previous experience on small pilot studies, or on information from published literature or collaborators gained with the similar procedure and the advice of experienced biostatisticians. Many tests require the use of one or more control groups and where possible, many test samples will be included together in a single experiment to maximise the use of these control groups and therefore minimise the total number of animals used during the project. New whole body imaging method is also introduced for monitoring distribution of biological medicine within a sedated live animal in order to reduce number of animals sacrificed at various time points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All procedures used to assess the safety of vaccines are documented in specific pharmacopoeial monographs. The protocols involving infection with TB and malaria are designed to reduce signs of disease and severity, such as frequent monitoring and daily body weight check after high dose TB infection. Although lethal species of murine malaria will be used, it is not intended for the infected mice to develop the disease and show persistent clinical symptoms apart from parasitaemia in the blood.

Once parasitaemia (> 3%) is established, infected mice will be treated with oral chemotherapy (voluntary dosing if appropriate) to clear the infection. For immunisation, no Freund adjuvant will be used, and no adjuvant will be used if intravenous route is required to avoid any adverse reactions. Humane end points are determined such that animals can be killed at the earliest stage of suffering from adverse events which are deviated from normal to minimize the impact of infection on animals. Following experimental procedures (such as vaccination and infection as mentioned above) that adverse effects are expected, frequent monitoring by experienced staff, including out-of-hours checks for some procedures ensure that animal welfare is maintained. Standard husbandry practices include animals being housed in caging suitable for the species used, with a range of varied and appropriate environmental enrichment to allow natural behaviours.

Why can’t you use animals that are less sentient?

All procedures used to assess the safety and potency of vaccines are documented in specific pharmacopoeial monographs that stated the use of guinea pigs. This work will also employ mice from information published in literature or as required from other regulatory guidance or documents on the basis of generating relevant biological effect and suitable dose responses. Because rodents are mammals whose genetic make-up closely resembles that of humans and are commonly used for investigation of human diseases. Many of the TB research questions can be replicated in mice and hence, provide scientists with reliable answers. Previous studies have contributed a significant amount of information on the use particular species or end point.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Efforts continue to refine procedures with moderate severity limits. For immunisation, no Freund adjuvant will be used, and no adjuvant will be used if intravenous route is required to avoid any adverse reactions. Any animals with progressing body weight loss exceeding 10% is a good indicator of mice experiencing progressive TB infection even if there is no sign of physical change or impact on the well-being of the animals. Efforts continue to explore ways to refine end point by introducing frequent monitoring by experienced staff, including out-of-hours checks and daily body weight checks after high dose TB challenge to ensure that animal welfare is maintained. Mice with body weight loss

>10% may be given supplementary diet with easy access to aid improvement. Increase body weighing and monitoring at peak of TB infection have also been introduced.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are different practical guidance available from the NC3Rs website – 3Rs resource library, such as blood sampling, mouse handling and evaluating environmental enrichment.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information on advances in the 3Rs can be obtained from NC3Rs website – 3Rs resource library. Relevant information will also be disseminated by Named Persons e.g. Named Animal Care and Welfare Officer (NACWO) and Named Veterinary Surgeon (NVS), and by proactively keeping up to date via conference attendance, collaborations, own research etc.

52. Novel Vaccine Development for Porcine Reproductive and Respiratory Syndrome Virus

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Porcine reproductive and respiratory syndrome virus, Pig, Immunology, Virulence factors, Vaccines

Animal types	Life stages
Pigs	juvenile
Mice	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop safer and more efficacious vaccines to aid control of porcine reproductive and respiratory syndrome viruses

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Porcine reproductive and respiratory syndrome (PRRS) remains one of the most economically important infectious diseases affecting the global pig industry, with an estimated cost of over €4 billion each year. Vaccination is a key component of PRRS control. However, current vaccines have safety concerns and provide limited protection, which drives the evolution of an ever-expanding diversity of PRRS virus (PRRSV) variants. More effective vaccines are required to better control PRRSV and alleviate the significant animal welfare and economic burden they cause.

What outputs do you think you will see at the end of this project?

New information on the viral components that determine the severity of disease caused by PRRSV will enable the design of new vaccines that can be safely used to protect pigs.

New information on how arteriviruses dysregulate the immune system by studying lactate dehydrogenase elevating virus (LDV) infection in mice, which could inform the development of improved PRRS vaccines.

Proof-of-concept that engineering live attenuated PRRSV to express immunomodulators can improve their potency.

Proof-of-concept that RNA vectors expressing PRRSV glycoproteins can induce virus neutralising antibodies.

Providing vaccine candidates for further development as products.

All results from the project will be published in Open Access scientific journals once intellectual property has been protected.

Who or what will benefit from these outputs, and how?

The scientific community will benefit from the improved knowledge of PRRSV virulence factors, immune evasion by arteriviruses, and the performance of new vaccine approaches. This could lead to the development of safer and more efficacious vaccines that result in enhanced PRRSV control and consequently improved animal welfare and productivity in the pig industry. This would bring benefits to policy makers involved in livestock disease control, the pharmaceutical and veterinary sector, and the general public through improved food security.

How will you look to maximise the outputs of this work?

All outputs from this project will be published in Open Access scientific journals; this will include unsuccessful PRRS vaccine approaches. Outputs of this work will also be disseminated to other stakeholders and the general public through press releases, presentations at meetings/congresses and social media channels.

Species and numbers of animals expected to be used

- Pigs: 93
- Mice: 114

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The only species known to be susceptible to infection with PRRS virus are pigs and wild boar. The pig is therefore the most suitable animal to study PRRSV infection and to evaluate the effectiveness of vaccine approaches. Weaned piglets will be used as they are most reproducibly infected with PRRSV.

LDV, which naturally infects mice, is closely related to PRRSV. We hypothesise that the principal mechanisms that underlie impaired antibody responses are shared between PRRSV and LDV. We can exploit the wealth of tools available in the mouse, including transgenic models, to better dissect and understand these mechanisms. Findings from the LDV-mouse system, will direct studies with PRRSV in pigs.

Typically, what will be done to an animal used in your project?

Typically, pigs used in this project will be immunised by injection of PRRSV vaccine candidate into the muscle. This will typically be conducted once or twice. Blood and nasal swab samples will be taken at intervals to characterise the immune response and to assess shedding of the vaccine. Vaccinated and unvaccinated animals will typically be challenged once by administration of PRRSV into the nose.

Blood samples and nasal swabs will again be taken at intervals to quantify levels of challenge virus and immune responses. This will typically be done twice weekly. Animals will then be culled humanely to assess lung pathology and tissues will be collected to assess PRRSV loads and for further analysis of immune responses. The typical duration of an experiment is 21-56 days.

Typically, mice used in this project will be infected with LDV by injection once into the peritoneal cavity. The typical duration of an experiment is 14 days. At the end of a study, animals will then be culled humanely to assess virus loads and immune responses.

What are the expected impacts and/or adverse effects for the animals during your project?

Mild to moderate clinical signs for a few days' duration may be observed following inoculation with PRRSV. This will most commonly present as an elevated temperature and lethargy. Sneezing, nasal discharge, coughing and lack of appetite may be observed. No

adverse effects are expected following immunisation with live attenuated PRRSV expressing immunomodulators. However, all animals will be clinically monitored both post-vaccination and -challenge. Assessments and interventions as appropriate will be performed at predefined frequencies in the experimental protocol, including euthanasia on welfare grounds if required. The impact of blood sampling, swabbing and inoculation of vaccine or virus will be both mild and transient.

No clinical signs of disease are expected for mice inoculated with LDV and any adverse effects due to procedures are mild and transient

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maimum expected severity for pigs that are vaccinated and challenged is mild. Unvaccinated control pigs that are also expected to experience a mild severity due to the selection of a low virulence PRRSV as the challenge strain.

To map virulence factors, pigs are expected to experience mild-moderate clinical signs of disease depending on the PRRSV strain used.

It is estimated that 74% of pigs will be in the mild severity category and 26% of pigs in the moderate severity category.

The maximum expected severity for mice that are infected with LDV is mild.

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due to the complex nature of the immune system, it is not currently possible to study immune responses to vaccination/infection and to determine whether they are protective without the use of animals.

It is necessary to use animals to assess the effects of identified virulence factors on PRRSV pathogenicity and immunogenicity.

Which non-animal alternatives did you consider for use in this project?

Cell culture-based systems will be used to generate and characterise vaccine strains, cultivate vaccine and challenge virus strains and to evaluate virus-neutralising antibody characteristics. In vitro cell- based assay systems will first be used to map and study PRRSV virulence factors before confirmatory studies are conducted in pigs. Expression of immunomodulators by recombinant PRRSV, and their properties, will be analysed in vitro prior to evaluating these as vaccines in pigs.

We will explore murine macrophage cell lines and primary macrophages as an in vitro system for propagating and titrating LDV.

Why were they not suitable?

No replacement options are available to replace the whole animal at this time as an entire organism, including the immune system, need to be present.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers to be used have been estimated using data previously collected from similar studies in consultation with a statistician.

Pilot studies using small numbers of animals will be performed for new investigations. Small animal numbers may be used to propagate and titrate LDV.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical analysis of data collected from previous related studies. Samples will be stored in a biobank, and we will maximise collection of samples post-mortem to facilitate further investigations without the requirement for additional animal experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of in vitro models to map and study PRRSV virulence factors and to characterise novel PRRSV vaccine strains. Basing study design on recently conducted relevant studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The only species known to be susceptible to infection with PRRS virus are pigs and wild boar. The pig is therefore the most suitable animal to study PRRSV infection and to evaluate the effectiveness of PRRSV vaccine candidates. .

A well characterised live attenuated PRRSV strain will be selected to be engineered to express immunomodulators. These peptides have previously been evaluated as vaccine adjuvants by our collaborators in mouse models with no adverse effects. Vaccinated and unvaccinated control pigs will be challenged with a previously characterised low virulence PRRSV strain. This enables us to assess protection, by reduction in virus infection, without the animals having to suffer clinical disease.

Previously characterised PRRSV strains of known low and moderate virulence will be used to map virulence factors. In vitro cell based assays have been established that have shown to correlate with PRRSV virulence in vivo. The exchange of virulence factors between these strains is not expected to increase the virulence beyond that of either parental strain.

Mice are natural hosts of LDV, a close relative of PRRSV. LDV infection in mice provides a natural virus-host system to provide insights into how arteriviruses modulate the immune system. This could then be explored in the context of PRRSV in pigs and inform PRRS vaccine development.

Characterised strains of LDV will be used that are not expected to cause clinical disease.

Animals will be inoculated with vaccine or challenge virus in the smallest volume commensurate with the aims of the procedure.

Why can’t you use animals that are less sentient?

The only species known to be susceptible to infection with PRRSV are pigs and wild boar.

The only species known to be susceptible to infection with LDV are mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be housed together with bedding and other items of enrichment. Highly trained animal technicians will monitor these animals throughout the day, ensuring they are comfortable and to maximise their welfare status. We have 24/7 CCTV surveillance which can be used to monitor the animals' behaviour over time.

Pre-study meetings involving the NVS, NACWO and animal services staff will be held to discuss any advances in animal care. Meticulous records will be kept of behavioural, physiological, immunological, and virological measures in order to identify predictive markers and refine humane endpoints. All experiments will be followed by a wash-up meeting to discuss all aspects of the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Adherence to the ARRIVE guidelines for reporting these studies, as well as reference to the FELASA guidelines for pig health monitoring to help ensure the most robust health assurance for animals used in this study. FELASA guidelines for administration of substances has been used to limit the maximum volumes for each of the routes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through continued CPD and frequent review of the CAAT (Center for Alternatives to Animal Testing) and NC3Rs websites, I will keep informed about advances in the 3Rs. Included in CPD will be annual attendance at relevant science conferences.

53. Gene Regulation During the Development of Xenopus

Project duration

3 years 6 months

Project purpose

- Basic research

Key words

development, FGF, myogenesis, transcription, capicua

Animal types	Life stages
Xenopus laevis	adult
Xenopus tropicalis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand how cell signalling regulates gene expression in the context of a developing vertebrate embryo.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are two main reasons to undertake this work: First, how a single cell (the fertilised egg) gives rise to a complex multicellular organism with hundreds of different types of cells all working together is a fascinating biological problem that underpins life itself and is worthy of investigation for the sake of enhancing knowledge. Second, over the past

decades we have learned that the genes that regulate development are often the same genes that go wrong during human disease, therefore a better understanding of these genes will contribute to more applied studies and lead to better therapeutics.

What outputs do you think you will see at the end of this project?

This project will lead to publications in peer-reviewed journals and dissemination of new information at international conferences including the International Xenopus Conference, the spring meeting of the British Society for Developmental Biology, and the Gordon Conference on Myogenesis. Researchers involved in this project also contribute to outreach and public communication of science in formats such as Pint of Science, an annual international science festival that aims to communicate science to the public by bringing scientists to pubs and cafés to share their research and findings.

Who or what will benefit from these outputs, and how?

The main beneficiaries of this project are:

1. Other scientists: In the short term, dissemination of our findings in research talks and papers will inform scientists in the same or related fields to contribute to their ideas and shape their hypotheses for further research into how cell signalling and transcriptional regulation of gene expression results in cell and tissue differentiation.

2. UK and international society: In the longer term, the researchers trained as part of this project will go on to careers in science and train other scientists. These researchers will contribute to the enrichment of knowledge and enhance the highly skilled workforce in the UK and abroad.

3. Human health: In the long term, a better understanding of the genes that regulate vertebrate development will contribute to the understanding of the molecular basis of diseases, including cancer, and underpin clinical advances in human healthcare.

How will you look to maximise the outputs of this work?

Collaboration is an important part of this project and will help maximise its outputs. We are working with a researcher at another establishment who uses human stem cells to test if our findings in Xenopus can be extended to what happens in human cells. We are also working with another Xenopus researcher at another establishment to investigate how our findings on FGF signalling relate to his findings on Wnt signalling; this will allow us to have a more detailed map of the genetic hierarchies and the cross-talk of cell signalling pathways that regulate development.

Species and numbers of animals expected to be used

- Xenopus laevis: 30
- Xenopus tropicalis: 40

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project seeks to understand gene regulation during vertebrate development and the frog species Xenopus laevis and Xenopus tropicalis are excellent models for this purpose. Both species provide hundreds of embryos on demand, and these embryos develop outside the mother with no need for any complex culture media. The embryos are accessible from the first cleavage stages for experimentation by injection or embryological manipulation. The genome sequences of both species are known and there are impressive post-genomic resources available for data-led projects. Xenopus laevis has the advantage of producing larger embryos more suited to experimental grafting and cultured explants.

Xenopus tropicalis is diploid making gene inhibition protocols easier.

Typically, what will be done to an animal used in your project?

The embryos are used for experiments and destroyed prior to free-feeding and thus are not subject to Home Office regulations, however the adults that provide the embryos are. To procure embryos, a subcutaneous injection of human chorionic gonadotropin (HCG) is delivered to a female frog. This accelerates the natural process of ovulation. Frogs are induced to lay eggs no more frequently than once every 3 - 4 months, in order to allow the re-growth of follicles. Adults are used for no more than 14 spawnings, with at least 3 months rest in between.

What are the expected impacts and/or adverse effects for the animals during your project?

Normally, induction of ovulation by HCG injection has no ill-effects.

Occasionally, the female will suffer from post-induction egg retention which results in death from a swelling of the abdomen. If this happens, it happens within a week after induction and can be monitored by daily inspection for any visible swelling or bloating. When it occurs the animal is culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The subcutaneous injection of HCG is a mild procedure, inducing the natural process of ovulation.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to study how developmental biology works we need to have access to embryos. Frogs provide large broods of externally developing embryos. These animals are vertebrates: they have backbones, like humans do. This means studying embryos from these animals (rather than flies or worms) is best for understanding many aspects of human development. Frog embryos are excellent model organisms to study developmental processes that happen at the earliest stages of development, because these non-mammalian vertebrate embryos are accessible, developing outside the mother. Gene targeting and over expression methods are very effective in these models, allowing discriminating and informative experiments to generate new knowledge about the molecules being investigated.

Which non-animal alternatives did you consider for use in this project?

Some people study some aspects of development using stem cells that are cultured in 3D to mimic an embryo. These are called gastruloids, embryoids, or organoids. Some aspects of our project can be addressed in this way and we collaborate with another researcher to do this

Why were they not suitable?

The complexity of embryonic development cannot be modelled entirely by explants or stem cell cultures. Within 24 hours a frog embryo goes from an egg to an embryo with most of the body plan organised and most cell types established. This cannot be reconstituted in a dish of stem cells or as embryoids.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Female frogs of both species can be induced to lay eggs up to once every 3-4 months.

To generate sufficient X.laevis embryos for experiments, we induce 2 X.laevis per week during about 30 weeks of the year. 2 X.laevis x 30 weeks per year = 60 inductions per year. 20 X.laevis frogs are sufficient for 60 procedures because they can be induced 3-4 times a year. We estimate 30 animals in total over the project to allow for any death and replacement.

To generate sufficient X.tropicalis embryos for experiments, we use 4 Xenopus tropicalis per week for about 30 weeks of the year = 120 inductions/year. 40 X.tropicalis are sufficient for 120 inductions because we can use them 3- 4 times per year.

These estimates are based on the number of researchers using the animals and the amount of time they spend on animal experiments over the course of each year. Embryos produced from one spawning can support more than one researcher's experiments. The number of animals estimated allows for any death and procurement of new frogs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As a group, researchers in my lab coordinate when they do experiments so that when a frog provides a spawning of embryos lots of experiments can be done by different researchers using the same spawning. The embryos are not limiting, so statistically significant results can be obtained from a single spawning. Generating 3 biological repeats requires using eggs from 3 females, so somtimes 3 separate ovulations are needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Only frogs with a good record of providing high quality embryos are kept in our colonies. The optimal dose of HCG has been determined. The Xenopus community has an excellent platform (xenbase.org) to share best practice across the community using frogs as a model system.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Subcutaneous injection of hormone into female frogs, Xenopus laevis and Xenopus tropicalis.

This is a mild procedure that is carried out by trained staff with a personal licence from the Home Office.

Why can’t you use animals that are less sentient?

Using a non-mammalian vertebrate such as Xenopus to study developmental biology is the most appropriate as frogs produce hundreds of large, accessible embryos allowing many experiments from a single, mild procedure.

What we learn about development in frogs is highly related to other vertebrates including humans, whereas the kind of knowledge gained from studies using invertebrates like flies or worms is less closely related.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have refined our hormone injections into female frogs so that we inject lowest dose to induce ovulation.

We have reduced the density of frogs and fish in each tank which keeps them healthy and productive. We provide enrichment to the tanks, including tunnels and plastic lily pads.

We monitor animals daily for any sign of ill health.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The website Xenbase.org provides a wealth of information on use of Xenopus for the study of developmental biology. Experts from all over the world contribute to the content, which is up to date and trustworthy.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Facility manager alerts us of advances in 3Rs in emails and as part of our regular user fora.

The website NC3Rs.org.uk is useful for keeping up to date with advances relevant to Xenopus and animal work in general.

54. The Role of Human and Mouse Tissue Stem Cells in Development and Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Development, Cancer, Stem Cells, Breast, metastasis

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to better understand human and mouse tissue and tumour development, the cellular hierarchy of the cells (eg. stem and progenitor) which give rise to more specialised cells, and their interactions with the tissue microenvironment (ie. the environment surrounding the cells). These goals are relevant to human normal tissue development, to cancer progression and cancer spread. An increased understanding may lead to new targeted treatments for the cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK, for example in breast cancer, there are more than 55,000 new cases diagnosed each year and there are greater than 11,500 deaths from the disease. In other major tumour types, the mortality is similar, if not worse. Identification of the regulators of tissue and tumour cell stemness (stem and progenitor cells defined above) versus differentiation is important for understanding cellular signalling that could be targeted to regulate tumour development, progression and spread (metastasis). We believe the proposed pre-clinical experiments based on understanding normal and tumour development and in vitro cancer stem cell (CSC) colony formation and co-culture studies will lead to advances in our understanding of how to tackle cancer progression and its metastatic lethality in patients.

What outputs do you think you will see at the end of this project?

The overall purpose of the current project licence will be to further our understanding of human and mouse tissue development, the cellular hierarchy of stem, progenitor and differentiated cells and their interactions with the tissue microenvironment (ie. the environment surrounding the cells). In order to increase understanding of these biological processes and develop new targets for therapy, we have 3 major outputs:

(i) An increased understanding of the mechanisms and pathways regulating the growth and differentiation processes of normal human and mouse tissues, and their stem cells.

(ii) An evaluation of the role of the microenvironment and pathways such as developmental, cytokines (inflammatory factors) and growth factor signalling in the regulation of human and mouse tumour growth and in particular cancer stem cells (CSCs), their identity, dormant and active states, their regulation and targeting.

(iii) Knowledge of the role of CSCs contributing to the metastatic process (cancer spread to other body organs). The specific questions include: what is the role of the metastatic niche in regulating CSCs and how is the microenvironment altered by stromal and tumour cell signals?

This knowledge, which will be published in high impact peer-reviewed journals, will identify and/or aid development of new therapeutics which will be tested here to target stem cells and metastasis regulators in human cancer prevention and therapy.

Who or what will benefit from these outputs, and how?

The outputs will have a particular benefit for patients with breast cancer, though not exclusively, since this is the main focus of research:

1. We will determine how the tissue microenvironment and specific signalling pathways influence the initiation and development of tumours.

2. We will elucidate how the tissue microenvironment and signalling pathways influence the progression and therapy resistance of cancer.

3. We will demonstrate how the tissue microenvironment and signalling influence the initiation and development of metastases.

We will address these aims experimentally in years 1-5 of the project but dissemination of results and their impact will be fully realised beyond years 1-5 when we would anticipate their publication and their application in clinical trials and other confirmatory and validation studies.

Our data will influence clinical care of patients at high risk of breast cancer, for example those with high breast density (by radio-mammography), lifestyle or genetic factors that increase risk. We anticipate our results will lead to application in cancer clinical trials and other confirmatory and validation studies.

How will you look to maximise the outputs of this work?

Our findings will be communicated to other scientists through collaborations, invited seminars at other institutes and research centres, presentations at scientific conferences and meetings and publication in peer-reviewed journals. The establishment has a policy of ensuring that all publications from scientists are available with free access to all.

Species and numbers of animals expected to be used

- Mice: 1,325

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The work will be conducted in adult mice. These are suited to transplantation of tumour fragments and specific strains can be utilised for transplantation of human tissues without immunological rejection.

Typically, what will be done to an animal used in your project?

For example, this will typically involve the transplantation of human cells into immune-deficient hosts, monitoring growth and cancer spread, testing therapies usually administered by injection or gavage and aimed at interfering in stem cell regulation, tumour growth and overcoming resistance to current therapies. These novel approaches to

therapy may target the tissue or tumour itself or the supporting cells around the tumour implant with the aim of reducing growth or cancer stem cell activity that drives tumour initiation, recurrence and spread to other tissues. Typically, these experiments would be of a duration of several weeks for cell lines and up to 4-6 months for patient-derived tissues or tumour where growth is slow. Procedures might include transplantation of cells or tissue fragments with anaesthesia and pain relief, treatment with an anticancer therapy by mouth or injection, and imaging under recovery anaesthesia to determine growth and spread of the tumour.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals (over 95%) are not expected to show signs of adverse effects that impact on their general well-being apart from the development of tumours. The vast majority of the procedures will result in no more than transient discomfort and no lasting harm. However, some mice in which we are investigating the effects of treatments upon the spread and progression of tumours (<3% based on recent experience) might be unexpectedly found dead overnight when monitoring indicates that they are normal. This is due to a sudden impact of the spread of cancer cells from the original location to other body organs, which will be mitigated in future by improved imaging of tumour cells, daily monitoring for shortness of breath and mobility issues. Notwithstanding this, all the mice will be humanely culled at the end point of the experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on our experience of using these procedures and experimental models we anticipate about 40- 45% to experience Mild severity, 50-60% Moderate, and less than 1-3% a Severe one (Mild - no significant impairment of normal life; might have injection by needle; Moderate - procedures cause some discomfort and easily detectable disturbance of animals normal state. Loss of body weight, some level of discomfort after surgery; Severe - Animals found dead; Long term disease models where support in feeding is required; abnormal posture). Thus, the vast majority of mice are only expected to experience mildest to moderate clinical symptoms due to tumour growth before they are humanely killed. Some mice will experience the discomfort of repeated (daily) sub-cutaneous or intraperitoneal injections of therapeutic agents or oral delivery for up to 8 weeks. We will aim to utilise the least stressful route of administration wherever possible. However, effective therapies will lead to a reduction in tumour symptoms. There will be some procedures, such as tumour implantation or imaging of tumours that will require short-term procedures under recovery anaesthesia.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Transplantation of human stem cells into a mouse model is currently the gold standard for testing them in an in vivo microenvironment based on experience in the human blood and other tissue stem cell fields. In vitro culture models such as sphere or other colony assays that test stem cell activity exist but these lack the full tissue stem cell microenvironment. Tissue support cells from the microenvironment have important interactions with the stem cells and the developing tissue, the complexity of which cannot be fully modelled outside of an animal. Thus, there is a need for demonstrating stem cell capacity in mice, in order to test the efficacy of factors for stem cell-specific effects in the local environment.

Which non-animal alternatives did you consider for use in this project?

Use of animals will be minimised by using in vitro model systems, for example, colony assays and more complex modelling of tissues ex vivo, eg. using diverse tissue cells grown as artificial organs or whole tissues ex vivo in short term assays. We have published greater than 10 papers outlining ex vivo models and have more in preparation funded by several NC3Rs grants in the past 5 years.

Furthermore, there is a wealth of data analysis that can be carried out on previously generated studies that are publicly available (eg. GEO and c-bioportal) to precede, to guide or to complement in vivo studies.

Why were they not suitable?

These are not fully suitable because whilst progress has been made in the field of cancer research using in vitro models, there are a number of questions that can only be addressed using animal models of disease. For example: variability of disease onset within an animal and within a population (inter- and intra-heterogeneity), investigation of disease progression and therapeutic response, resistances and interactions with the immune system is most faithfully addressed using pre-clinical in vivo models such as mouse. For these reasons, studies on in vivo tumour models need to be performed, in which the benefits are weighted against the likely adverse effects, and humane endpoints utilised.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Number of animals to be used will be determined by the type of experiment and this will depend upon the observations of experiments performed in the lead up to these studies. The overall numbers to be used is based upon numbers used in similar studies on a previous PPL and knowing which studies will be required going forward.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments are designed using the principles outlined in the experimental design tool on https://eda.nc3rs.org.uk/ and reported following the ARRIVE guidelines.

Power analyses will be performed to ensure that we use the minimum number of mice to generate significant results. In cases where power calculations are not feasible, group size will be estimated using relevant statistical tests. Moreover, we involve those with statistical expertise, including our bioinformaticians, to ensure that we are using optimum groups sizes, and hence minimum number of mice, in our experiments, we use optimal procedures to reduce the number of mice. For each implantation experiment with a new tumour cell line, a small number of animals may be used in a pilot study to determine their tumorigenic potential and the required number of cells necessary to establish tumours so that the smallest number of animals can be used for the experiment itself.

By the use of stem cell colony and 3D organoid culture studies using normal and cancer cell lines and primary cells, the number of mice needed has been reduced over the course of the previous licence. All of our stem cell studies are started without using mice by using sphere colony assays, 3D organoids, ex vivo tissue fragments and cellular analysis to test effects of regulators or inhibitors on stem cell activity. We will continue this process in this proposed project licence by experiments to mimic tissue environments outside of animals but using the tissue of origin, eg. lung, liver, bone, brain, etc. where normal tissue and tumour cells grow in the body.

For determining the effects of the microenvironment, firstly, small scale pilot experiments will be performed to assess the size of the effect of a particular factor.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot experiments (using up to 4 animals) may be conducted to estimate the biological effect of an intervention (such as a drug) when not known or available in the literature.

We use optimal breeding strategies (conducted on a different licence) to reduce the number of genetically engineered animals.

We take care to ensure that each experiment is appropriately analysed and that the maximum amount of information is gathered thus reducing the need for experiments to be repeated. For example, at the end of each experiment, data is compared to previous studies by appropriate statistical methods (e.g. Kaplan-Meier plots of age at endpoint, Mann Whitney analyses using a two tailed distribution to reduce mouse numbers). We are keen to run experiments in parallel that can share a single control arm, which can sometimes represent a 25% reduction of animals within a given experiment. Where cell transplantation models are no longer needed, cells and / or tissue will be frozen to avoid unnecessary propagation of the model. In vivo experiments are preceded by relevant in vitro experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the appropriate species for transplantation of human normal and malignant cells since immune-deficient mice are able to host the tissues in a mammalian environment that models the human microenvironment in multiple ways.

We will continue to refine experimental protocols wherever possible, to minimize both the number of mice used and their suffering, in particular to refine and reduce the need for surgery by using needles including trocar and transplanting cells in a well tolerated location such as subcutaneously in the flank rather than the ventral region. We will consult statisticians including bioinformaticians in the design of our experiments. Throughout experiments, we will monitor tissue and tumour growth and the health status of transplanted mice with pre-defined frequencies. Any mice that have health related issues related to surgery, transplantation or experimental therapy will be given immediate attention with a view to alleviating symptoms or discomfort and will be killed humanely if adverse effects are considered too severe to be treated.

Why can’t you use animals that are less sentient?

Less sentient animals do not exhibit a similar tissue microenvironment and histopathological features to humans. Mice are far more similar to humans than other suitable and available animal models. This is critical both for using reagents like drugs developed for human targets and for translating findings to the clinic. Cancers develop

over many weeks to months, so use of terminally anaesthetised animals or immature animals is not possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal suffering will be minimised by making every effort to keep the tumour models employed at the subclinical levels. Wherever possible, this will be achieved by using non-invasive imaging modalities such as bioluminescence to monitor tumour growth and the development of metastatic disease. In addition, as detailed in the individual protocols, steps will be taken to minimise the severity of the procedures. Finally, we will ensure that all animals receive the highest standard of care, and preventative medicine (including anaesthesia and analgesia where required) will be used according to the general constraints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).

We will follow guidelines of good practice cited above as well as Morton et al. (Lab Animals, 35(1): 1- 41, 2001). Administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm. We will put into practice the guidelines for body condition score (Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23) and ageing mice will be monitored and managed according to Wilkinson et al (2020) (Laboratory Animals: 54(3): 225 – 238). We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature, participating in 3Rs workshops locally and nationally, and by our own National Council for the 3Rs (NC3Rs) funding for replacement and reduction of animal studies for our experimental work (we have held 3 NC3Rs grants in the last 3 years and have one shortlisted for funding). Through discussing refinements with our Named Animal Care & Welfare Officers (NACWO), Named Veterinary Surgeon (NVS) and Home Office (HO) inspectorate. We have regular institutional updates such as Annual Project Licence holder meetings.

55. Identification and Validation of Pathology-Related Antigens for Potential use in Immunotherapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, immunotherapy, new peptides

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our purpose is to identify and to validate new alternative targets of immunotherapies

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Immunotherapy is currently an innovative treatment approach getting more and more relevance in the fight against different immune system related diseases. One example is

cancer, a major cause of mortality in the UK, responsible for over a quarter of all deaths. Even modest improvements in treatment will benefit the lives of thousands.

In the last 5 years, the interest in unconventional peptides has grown rapidly with public and private groups investing resources in this field. In this way these animal experiments are part of a trending project.

This project will be useful to identify and to validate new targets for immunotherapies in mouse models with the aim to move them to the clinic afterwards. A key part of the project is the study of T cells, one type of blood cell of the immune system that play an important role in the immune response. We will focus in the response of these cells against specific peptides (proteins with short length).

What outputs do you think you will see at the end of this project?

The outputs from this work will include:

- Important information about the functional immune system response to new peptides.

- Spontaneous recognition of new peptides by T cells in patients will also provide important information for potential future steps towards translational application of this research programme. Indeed, therapeutic approaches, such as vaccination, could be preferable to Adoptive T cell Therapy (ATT) if we see a significant spontaneous response against these new peptide targets in patients.

- In practical terms, the new information generated will be shared via publications, research presentations at conferences (both national and international), and, if appropriate, the reporting of improved methods.

Who or what will benefit from these outputs, and how?

This work will benefit the basic research community by increasing our knowledge of rearranged peptides (peptide splicing) and the immune system reactivity to this peptides.

We anticipate that outputs of the proposed work could be translatable to cancer benefit and could be commercialised at the end of the research programme. For example, these kind of rearranged peptides could be used for adoptive T cell therapy and vaccination against melanoma, pancreatic adenocarcinoma (PDAC) and colorectal cancer; thus, they will likely be patented.

How will you look to maximise the outputs of this work?

A major mechanism to maximise the output of the work alongside the publication of primary research papers, will be presentation of the work at both big international meetings

and smaller more methods- oriented workshops. These latter formats have the advantage that details of approaches that were ultimately sub-optimal can be shared.

Our group already collaborates widely, and this provides another avenue to share details of approaches that were ultimately sub-optimal and how methods were improved.

Species and numbers of animals expected to be used

- Mice: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The key aims of this work are to identify and to validate pathology specific rearranged peptides as alternative targets of immunotherapies in cancer treatment. This necessitates a mammalian system that contains all the major cell types found in humans, and the mouse is the most appropriate mammalian model. The main cancer types that we study occur in adults, and occasionally, young adults. Therefore, we work with juvenile and adult mice.

Typically, what will be done to an animal used in your project?

Procedures will be performed that lead to the development of cancer in mice. This will be through injected cancer cells or in mice with genetic modifications that lead to tumour development. We will focus on melanoma and KRAS derived tumours (such us, but not limited to pancreatic adenocarcinoma PDAC). With this project we want to test the efficacy of adoptive T cell therapy using T cell clones specific for targets of interest in cancer.

We will use different approaches to identify and validate targets for immunotherapies. In the first case, mice will develop tumours following the injection of tumoral cells. We will treat the animals with modified T cells for tumour specific peptides. The mice will receive this T cells intravenously, and also, other agents intraperitoneally to improve the survival of this cells.

Other approach consists of immunizing mice with a tumour related peptide by injecting the peptide of interest subcutaneously. Then, we will isolate T cell clones specific for that peptide and use the components of that T cells to treat mice genetically modified prone to developed tumours in the same way that the previous model.

Advanced imaging methods (MRI, PET/MR, uCT, SPECT, Ultrasound, Optical Bioluminescence and Fluorescence imaging) will be used to monitor the spread of tumours

and how they react to therapies. Extensive post-mortem tissue analysis will be performed to maximise the information obtained from each animal.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will develop tumours. Initially, these have little effect on the mice, but as they become larger they might affect mobility. Further, animals can lose some weight (up to 15% compared with control age- matched mice). They can suffer a change of behaviour because the less mobility, they could be less active, and in advances stages of disease the can be tachypneic, this is breathing in a higher rate. The tumour could be up to 1.8 cm3, depending on the severity caused by the tumour, the duration of the adverse effect may range from a small number of days to 7-8 weeks (50 days).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity is expected for about a 75% of the animals. In the rest of the animals we expect less severity as the treatment of the disease is supposed to decrease the size of the tumours.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are interested in identifying and validating pathology specific new peptides as alternative targets of immunotherapies. Therefore, we need to work with systems where the cells are as similar to the human cells as possible, and also their tissue organisation. The latter point of accurate tissue organisation is particularly hard to recreate using non-animal systems. The mouse is well suited to this as it is a small mammal with relatively simple husbandry requirements. Further, well-established methods exist for genetic alteration in mice, which facilitate further analysis.

Which non-animal alternatives did you consider for use in this project?

Yes, we have considered and use alternatives for much of the work in our group. This includes extensive culture models, analysis of clinical material, and computational

modelling to improve the predictive power of our analyses. Our group has made extensive use of in vitro models (human and mouse) and in silico studies for determining the best peptide candidates and performing a preliminary screening of the efficacy of therapies using these candidates. Also, our group is planning to start the use of human and mouse organoids for melanoma and KRAS derived tumours. The organoids will be expanded from the original tumour and used for the identification of antigens presented on MHC/HLA class I. Through T cell co-culture we will investigate which antigen can be recognized by T cells. In the end, TCRs able to recognize presented antigens will be cloned in T cells and we will test the cytotoxicity against the organoids or different cell lines.

The use of organoids would also allow us to address the issue of the tumour microenvironment, but they can not replace the use of live animals because the microenvironment is not the same compared with a whole organism and the co-culture systems with other cell types are not firmly established. On the other hand, the use of organoids presents different benefits, such us they can be human derived representing human physiology, easier genetic manipulation, they can be specific from individuals.

Why were they not suitable?

It is currently not possible to replicate the complexity of mammalian tissue structures in culture models. A second issue is that the immune system only functions effectively in an organismal context with appropriate white blood cell movement and function within lymph nodes. Finally, we need a whole organism to test therapy failure or success. This is not achievable in simplistic non-animal models due to the differences in the immunosystem.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on several factors. First, we have taken into account the numbers of mice used in the previous experience. Second, we have taken into account the current number of researchers within the group. Third, we continually re-evaluate the numbers of mice required for each experiment using power calculations. This will allow us to determine the number of animals required per

experiment. By combining this with the group size and availability or resources for data analysis, we are able to estimate how many experiments we will run per year and therefore the numbers of mice required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design will employ suitable power calculations if prior data exists around the mean and the standard deviation of the metric in vivo. Ideally, experiments will be designed with α (level of significance) = 0.05 and power = 80. If the necessary in vivo data does not exist, then experimental design will be informed by a combination of prior in vitro data generated in the laboratory, existing publications, and the cumulative experience of years mouse tumour work. Experimental Design Assistant (NC3Rs) and PREPARE (Norecopa) will be used to assure best practice. And the experimental groups will be established in a way we can reduce the mice used as controls, for example, the same untreated animals could be use as control for different treatments.

We will perform systematic literature reviews to keep us up to date in the field and minimise the animals needed if data is already published.

On the other hand, regarding the breeding of genetically altered animals, the colony management team at the establishment reviews and manages the breeding of all colonies to minimise excess breeding and we also have tissue sharing to reduce wastage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We always aim to maximise the amount of data we get from each mouse, for example getting DNA, RNA, and freezing all the tissues for further analysis. Pilot studies will be done to establish the experimental conditions, for example to determine the amount of injected cells.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice in this project. The main focus is to identify and to validate pathology specific new peptides as alternative targets of immunotherapies. In the case of the use of immunotherapies in cancer treatment we will employ sub-cutaneous injections for the generation of tumours or genetically modified mice prone to develop tumours. Mice will receive therapies intravenously, followed by intraperitoneal administration of different

substances to improve treatment. Tumours will be expected to continue growing in the control group, tumours in experimental groups would be expected to stop growing, grow in a slower way or even decrease in size.

On the other hand, mice will be immunized in order to isolate T cell clones. Mice will be injected, for example, subcutaneously with a peptide able to activate the immune system. Mice will be immunized twice or three times with at least 1-week interval between immunizations. Seven days after the final immunization, the mice will be sacrificed and tissues taken for analysis. The main organs of interest will be spleen and lymph nodes to isolate T cells.

Rodents have been chosen as experimental animals as they have the lowest neurophysiological sensitivity while still having an immune system of comparable complexity to the human and are therefore the most frequently used animals in studies of human pathology/immunopathology.

The protocols used involve least pain, suffering or distress or lasting harm for the animals. None of the intended procedures reach beyond the moderate level of severity. Procedures reaching moderate severity arise from the induction of the disease model (cancer) and are thus inherent to the disease studied. Anaesthesia and analgesia will be administered to minimise discomfort and the animals will be monitored closely during all procedures and assessed regularly for any signs of distress. In all the proposed in vivo models, if animals display signs of distress, advice will be sought from the Named Veterinary Surgeon and, if distress cannot be alleviated, the animals will be humanely euthanized.

Why can’t you use animals that are less sentient?

We are interested in identify and to validate pathology specific new peptides as alternative targets of immunotherapies. Therefore, we need to work in systems where the cells are as similar as the human cells as possible, and also their tissue organisation. The latter point of accurate tissue organisation is particularly hard to recreate using reductionist non animal systems. The mouse is well suited to this as it is a small mammal with relatively simple husbandry requirements. Further, well-established methods exist for genetic alteration in mice, which facilitate further analysis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We try to minimise any possible adverse effects. Regular monitoring by trained staff is in place and we will use the available enrichment in the animal facility. Where appropriate we will also use suitable analgesia and other measures to minimise contingent harms by e.g. tube handling, single use needles, group housing, welfare assessments, adequate acclimatisation, aseptic procedures.

On the other hand, regarding the breeding of genetically altered animals, the colony management team at the establishment reviews and manages the breeding of all colonies to minimise excess breeding and they also have tissue sharing to reduce wastage.

We will also follow local veterinary advice in any moment on care and pain management to minimise any harms to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are aware of NC3Rs guidelines and we will also follow PREPARE, ARRIVE and Workman et al guidelines. We also discuss with colleagues in other research groups new improvements that lead to refinement.

The administration volumes and routes of substances is summarized in the animal experience section of each protocol and follows local advice at the establishment.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay up to date via regular communication with animal facilities and Named Persons at the host establishment, other scientists in the field and regular visits to the following website https://www.nc3rs.org.uk/3rs-resources.

56. Neural Basis of Tactile Behaviour

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

neuroscience, electrophysiology, somatosensation

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to investigate how neurons in the sensorimotor system operate during tactile exploratory behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The project addresses one of the fundamental general goals of neuroscience, which is to understand how neurons work to the point that we can accurately predict their activity during behaviour. This kind of discovery research is important not only for its own sake but also because improvement in our knowledge of how neural circuits work will facilitate the development of new treatments for neurological disorders in the future. Past discoveries in this area have led to the development of brain machine interfaces which are starting to become clinically effective.

What outputs do you think you will see at the end of this project?

New information on sensorimotor function, academic publications on the topic and data from the project to be shared with the scientific community.

Who or what will benefit from these outputs, and how?

The short-term benefit will be advances in our basic knowledge of brain mechanisms of sensorimotor function.

In the longer-term, there is potential for benefits both to human health (see above) and to Artificial Intelligence (machine learning) technology. Improved understanding of how neural circuits work makes it possible to 'reverse engineer' principles of how the brain works to suggest new directions for Artificial Intelligence. For example, past advances in our understanding of the brain chemical dopamine has led to important advances in a type of Artificial Intelligence called Reinforcement Learning.

How will you look to maximise the outputs of this work?

New knowledge will be disseminated primarily through publications in scientific journals and through presentation at scientific conferences. In addition, a relatively new trend is to share the data from scientific research with other scientists to a much greater extent than was done in the past. Data, including computer code, will be shared via websites such as github.com. This brings the potential for other researchers to obtain additional insight from the data and therefore for there to be increased benefit from the experiments.

Species and numbers of animals expected to be used

- Mice: 660

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the best species for this project since their brain is structured in a way that is broadly similar to the brains of other mammals (including humans). They permit the use of the most advanced and refined available research methods, whilst also having relatively low species sensitivity. This project concerns how the mature brain functions and hence focusses on adult mice.

Typically, what will be done to an animal used in your project?

Some mice will be implanted with microelectrode devices using aseptic surgical procedures under anaesthesia. Brain activity will be measured in response to sensory stimulation (eg whisker touch) after which these mice be killed.

Other mice will typically be implanted with microelectrode devices using aseptic surgical procedures under anaesthesia. After recovery, using these devices, brain activity will be measured whilst the mice freely explore their environment. In some cases, under anaesthesia, mice will: be injected with plasmids (small pieces of DNA) under anaesthesia, have their whiskers partially clipped, undergo sensory stimulation (eg whisker touch), have brain activity measured in response to sensory stimulation (eg whisker touch) or have minor repair of implants. Once the measurements are complete, these mice will be killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible adverse effects are: blood loss (avoided by choosing implantation sites away from major blood vessels); death under anaesthesia (controlled by monitoring of vital signs); post-operative pain (controlled by administration of analgesics and regular behavioural assessment); post-operative infection (controlled by aseptic surgical technique and treatment as advised by a vet).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity is moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The only way to address the aim of this project is to use animals. This is because the project requires the activity of neurons to be measured with cellular resolution in behaving animals.

Which non-animal alternatives did you consider for use in this project?

in silico modelling

Why were they not suitable?

We use in silico modelling in our research to derive hypotheses of how the brain operates, and such modelling informs the work in this project. However, the data we seek from the current project itself cannot be obtained from purely in silico modelling. This would require detailed knowledge of neuronal anatomy and cellular physiology that is far beyond the state of where neuroscience is today.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers have been peer-reviewed in a successful application for research funding and also have been reviewed by a statistician.

The numbers here have been estimated statistically in order to be confident that sufficient neural data will be obtained to meet our definition of satisfactory data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A useful refinement is possible by using the latest generation of high-density microelectrode arrays ("Neuropixels"). The current version of these devices consist of ~1000 recording sites and make it possible to record from 100s of neurons simultaneously from one animal. In this way, the number of animals required in order to obtain data from a given target number of neurons is substantially reduced compared to single microelectrode technology. New versions of Neuropixels are under development (but not yet publically available at the time of writing). Thus, we anticipate further reduction benefits to be achievable within the lifetime of this project

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of latest generation of microelectrode arrays, explained above.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice. To achieve the aim of the project requires measurement of neuronal activity at cellular resolution in freely moving animals. The way to achieve this that minimises pain/harm is to implant chronic microelectrodes into the brain using aseptic procedures and analgesic drugs, with careful monitoring for the possible adverse consequences, as detailed in the protocols.

Why can’t you use animals that are less sentient?

Mice are the least sentient appropriate mammalian species that are established as a model organism.

Our questions concern how the fully developed brain functions; hence study of animals at immature life stage is not applicable.

Our questions concern the neural basis of behaviour - this cannot be studied under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

An important refinement is that this project moves our research away from procedures requiring restraint and dietry control to increasing use of "free range" procedures where the animals can move freely, where their motivation is intrinsic, and where their dietry intake is ad libitum.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are using the most advanced microelectrode arrays (see above) and the most recent, refined, published methods for using them.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute is well-connected with UK 3Rs bodies and keeps scientists here up to date. In addition, the PI is well-integrated in the research community and is highly motivated to use the latest advances (see for example comments on Neuropixels technology above).

57. Myelination in the Central and Peripheral Nervous Systems

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

myelin, neuron, neuroinflammation, neurodegeneration, brain

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project focuses on understanding formation, maintenance and function of the nervous system's myelin and myelinated axons, together forming the nervous system's electrical wiring, under normal and disease conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the nervous system (brain, spinal cord, optic nerve and peripheral nerves i.e. those nerve connections that lie outside of the brain and spinal cord), nerve cell bodies are separated from each other, often over long distances. The way these spatially separated cells communicate with each other is through a network of ‘electrical wires’ called axons. This communication network is essential for neurological functions such as walking, sight, speech and thought. Axons (the electrical wires) are surrounded by an insulating material called myelin (similar to the plastic coating on an electrical wire) that speeds up the transport of electrically-encoded information along the axons e.g. from one nerve cell body in the brain to another nerve cell body at the base of the spinal cord, or from a nerve cell body in the spinal cord to a muscle in the foot.

The importance of the insulating myelin sheath is highlighted by the fact that humans and animals that cannot make myelin due to genetic mutations, fail to survive beyond infancy. More commonly, diseases that affect myelin result in abnormal myelin being formed (as in diseases termed leukodystrophies) or in myelin breaking down (as in multiple sclerosis). In both these cases, transportation of information (encoded as electrical impulses) along axons is slowed or halted. This usually leads to neurological symptoms such as blurred vision, incontinence, walking difficulties, altered sensation, or difficulty in swallowing. Long-term (chronic) abnormalities in myelin or myelin-forming cells lead eventually to degeneration (breakdown) of axons. Most axons cannot be repaired (as evidenced in spinal cord injury), so this causes permanent neurological disability where the individuals affected become wheelchair- or bed-bound. This happens for example in people with motor neuron disease or multiple sclerosis or leukodystrophy.

A variety of factors cause diseases of myelinated axons including gene mutations (e.g. some forms of motor neuron disease), reduced blood supply (e.g. stroke), physical injury (e.g. from breaking the spine), injury from exposure to toxins or viruses (e.g. polio) and abnormal immune reactions against the body's own cells (e.g. multiple sclerosis). Irrespective of the cause, injury to the myelinated axon is 'sensed' by neighbouring cells that belong to the body's immune system. The role of these cells is to help with repair, but if the injury is severe, these immune system cells can become 'activated'. Long term 'activation' of immune system cells changes them from behaving like 'defenders' to becoming 'attackers', thus causing further damage and speeding up the rate at which disease symptoms progress.

The work described in this project licence is important from a discovery science perspective and a clinical perspective. Only by understanding how nervous system cells develop, function and interact with each other, can we understand what goes wrong in diseases affecting the myelinated axon, such as multiple sclerosis, motor neuron disease and the leukodystrophies. This understanding is essential for treating and preventing such diseases, which each carry enormous financial and emotional costs.

What outputs do you think you will see at the end of this project?

Outputs will be new information that will be disseminated by publication in peer reviewed scientific journals. Outputs will further be disseminated in poster or oral presentation format at scientific conferences; in teaching; to the public at special 'lay person' events; and through social media. New information is expected to include ways to reduce animal use in the study of the myelinated nerve fibre (axon). This is based on a currently funded project from the National Centre for the Replacement, Refinement and Reduction of animals in research (NC3Rs) that aims to develop cell culture models to reduce and/or replace the use of animals to study diseases like multiple sclerosis (MS); a procedure involving induction of MS-like disease in animals, usually mice or rats. A further NC3Rs application is currently being prepared that aims to develop methods to reduce and/or replace the use of animals for imaging cells in the living nervous system, an invasive procedure usually done using mice; the alternative approach will involve using human and mouse cells grown in a dish, for similar purpose.

Who or what will benefit from these outputs, and how?

Members of the laboratory including research trainees, other researchers in the field, collaborators and funders. In the longer term, people with neurodegenerative diseases such as MS, motor neuron disease, periventricular leukomalacia and the leukodystrophies will benefit through improved understanding of the mechanisms of disease, hence through informed approaches to preventative and treatment measures.

How will you look to maximise the outputs of this work?

The applicant has collaborated for many years with colleagues nationally and internationally. Collaborative projects in which we are involved benefit from a wide range of expertise in diverse skills, maximising impact. We publish methods on open science platforms and share methods and approaches with others e.g. we currently provide training to colleagues elsewhere in establishing cell culture models of the nervous system in order to reduce the use of animals in research.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project uses mice with spontaneous (naturally occuring) genetic abnormalities or genetic modifications (where genes have been altered in the fertilised egg from which the mouse line is generated) to understand mechanisms and molecules involved in function, maintenance and disease of the myelinated nerve fibre (axon) such as multiple sclerosis, motor neuron disease and the leukodystrophies. In most cases, mice will be killed humanely for tissue collection or to generate cell cultures. We use mice principally because (i) as vertebrates, their nervous system is similar to ours with respect to myelination (lower species do not form 'compact' myelin i.e. the type of myelin found in the human nervous system), and (ii) because they are available with relevant genetic modifications, such as modifications that enable us to study disease or visualise cells.

Typically, what will be done to an animal used in your project?

Typically, mice will be bred, ear notched (a tiny piece of skin is removed from a specific site on one or other ear) for identification and genotyping (the skin cells are lysed to release the DNA, which is identical to the DNA in every other cell in the body), then killed by a humane method for tissue harvest. Disease models and controls or reporter mice (harbouring tagged cells or organelles) will be killed at postnatal day (P)3, P20, P40, P60, P90, P120, P180 and P365, with a minimum of 3 mice per genotype at each time point; averaging around 100 mice annually. Some disease models and reporter mice (with tagged cells and/or organelles) will be mated and killed at 13 days gestation to harvest mouse embryos. Typically, this will happen to 200 mice, annually. Some mice will receive injection with a substance that labels dividing cells or induces expression of a transgene before being killed for tissue harvest. Typically, this will be one subcutaneous injection and will involve approximately 50 mice annually.

Some disease models will receive a modified diet, designed to reduce the severity of pre-symptomatic disease pathology (harmful changes in cell and tissue that precede the onset of disease signs), and will subsequently be killed by a humane method for tissue harvest. Typically, mice will be killed at postnatal day (P)3, P20, P40, P60, P90, P120, P180 and P365, with a minimum of 3 mice per diet at each time point

What are the expected impacts and/or adverse effects for the animals during your project?

Administration of substances to the body's periphery (usually subcutaneously, i.e. under the skin), such as tamoxifen for gene induction or bromodeoxyuridine (BrdU) to label dividing cells, will be undertaken using a combination of volumes, routes, and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. Local guidelines will be followed for volumes and frequency of dosing when administering such substances.

Some mice with gene defects affecting myelin, axons or both, experience ataxia (loss of full control of body movements) and weight loss after approximately 10 months of age. These disease models will not be maintained beyond one year of age and will be

monitored daily once harmful signs become evident so that the stated severity limit (Level 1 or 2) is not exceeded. Weight loss of 20% or greater or evidence of incontinence or seizure lasting more than one minute or limb paralysis will indicate that the animal should be killed humanely for tissue collection prior to the predetermined end-point.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals will be killed humanely prior to the onset of harmful signs (90%). Some will experience mild (10%) or moderate (5-10%) severity harms, being ataxia, whole body tremor, <20% weight loss, seizure lasting less that 1 minute.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We aim to understand aspects of the human nervous system in health and disease, most particularly with respect to myelinated axons (the nervous system's electrical wires). Compact myelin is a specialisation of vertebrates (the term 'compact' refers to the tight wrapping of multple layers of cell membrane around the axon), therefore it is necessary to address scientific questions in vertebrate models, in which the gut, endocrine and immune systems impact the functions of brain cells.

Which non-animal alternatives did you consider for use in this project?

Whenever possible, we will employ partial replacement by using mouse-derived cell cultures, as in current and previous work funded by the NC3Rs. These will be generated from embryonic day 13 mice (occasionally from neonatal mice), meaning that pregnant mice will be used only for harvesting embryos i.e. they will not be used in other procedures. In some cases we will harvest tissue from postnatal mice that have received a dietary intervention aimed at ameliorating (i) pre-symptomatic pathology (cell or tissue injury) and/or (ii) mild or moderate disease signs.

We will review and incorporate alternatives throughout the project as they become available and/or if considered appropriate. For example, we aim to use human induced

pluri-potent stem cells (hi-PSCs) during this project and have established a collaboration for this purpose.

We aim to incorporate mathematical modelling into our work to explore how myelin wraps around the axon.

Why were they not suitable?

Mouse and/or human cell cultures cannot be used for all aspects of the project because they lack some physiological relevance that can only be provided by studying CNS cells in the context of the entire body including the blood-brain barrier and the gut, endocrine and immune systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on previous experience in breeding mutant and transgenic animals for similar work.

Our work uses compound mutants/transgenics, each of which is hemizygous/heterozygous or homozygous for at least two transgenes/mutations, meaning that only a proportion of offspring, ranging from one quarter to one eighth, will harbour the desired genotype combinations.

Many of the mice bred will be provide embryos or pups for cell cultures; others will be used for tissue harvest at a variety of ages; others will receive dietary intervention (aimed at reducing disease severity) and will subsequently be used for tissue harvest at a variety of timepoints post-treatment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3R's Experimental Design Assistant has been and/or will be used to help design robust experiments most likely to yield reliable and reproducible results, including group and sample size based on power calculations performed following collection of preliminary data.

Experimental design, choice of experimental groups, minimising confounding factors, careful handling and ensuring experimental rigour all impact on reproducibility and hence, on numbers of animals used.

Experimental design:

Experiments will be designed to obtain the maximum amount of information from the minimum number of animals e.g. by increasing the size of the control group, the size of the experimental group can be kept to a minimum.

Multiple tissues/samples will be collected from each experimental animal whenever it is possible and appropriate to do so.

Predetermined experimental endpoints (e.g. specific ages) will be adhered to, reducing variability between samples, except if an animal reaches a humane endpoint prior to that time.

Animals of both genders will be used except if there is a scientific reason to use only one gender. Breeding strategies will maximise the chance of obtaining relevant genotypes.

At the earliest stage possible, the experimenter and facilities staff will be blinded to the genotype/manipulation to avoid biased results.

Animals will be randomly chosen and assigned to experimental groups using a suitable randomisation method such as post-selection group assignation meaning that after an animal is selected, the treatment/intervention will be assigned from the random selection of two or more options.

By examining phenotypes across at least three-time points (ages), we will increase the confidence in our findings while keeping group sizes relatively small.

When looking at a new mutation, we will allow a small number of animals to age (usually to 12 months) before analysis, unless a humane endpoint is reached before that. This increases the chance of observing a phenotype if one exists and is much more efficient than examining large numbers of young animals where effects might be subtle or ambiguous.

Experimental groups:

These are usually wild type versus mutant/transgenic. Whenever the genotype allows, we will compare littermates to reduce inter-experimental variability.

Minimising confounding factors:

Where possible, siblings will be housed together and compared to minimise variation between experimental groups due to genetic and environmental factors.

To minimise stress, which can act as a confounding factor in studies of the nervous system, animals will be handled non-aversively (i.e. gently and carefully).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Multiple tissue types e.g. brain, spinal cord, bone marrow and spleen are routinely collected from individual animals and stored for future use if not required immediately. Non-nervous system tissue is routinely shared with other research groups investigating different cell/tissue types.

Efficient breeding practices (e.g. breeding heterozygous/hemizygous mice to generate control and knockout littermates) will be used to decrease variability between comparators and reduce numbers required to obtain statistically meaningful data.

Efficient breeding also includes replacing breeders before reproductive performance declines and replacing non-productive breeders as soon as possible.

Genotyping is carried out early so only suitable animals are maintained and bred; proven stud males will be reused to maximise breeding efficiency (keeping in mind genetic integrity).

Wild type and disease models on the same background strain will be housed together, where possible, prior to endpoint to minimise differences related to the housing environment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use wild type and transgenic/mutant mice to model health and disease in the human CNS. Experimental animals will be handled in a non-averse manner, according to local guidelines, which states "....all laboratory rodents should be handled using non-aversive methods...in all situations where a rodent has to be captured and removed from the cage. "

Specifically, we will use (i) mice with cells and organelles that are labelled with fluorescent markers (coloured tags that can be seen using a special microscope) to allow us to visualise and monitor these cells and organelles (ii) mice producing a protein that switches on genes in a cell- and/or time-specific manner (iii) mice with modifications in disease-relevant genes to study normal cellular processes, disease pathogenesis (mechanisms) and therapeutic approaches, particularly with respect to myelination and glial cell-mediated support of nerve cells.

In most cases, pain, suffering, distress or lasting harm will be avoided because most of the genetic modifications cause none of these. However, some gene modifications cause mild or moderate neurological signs in animals, usually aged 10 months or over. Mice with a harmful phenotype (e.g. signs of disease) will not be allowed to suffer. Such animals will be killed by a humane method when a

*humane endpoint is reached i.e. whilst neurological symptoms are mild or moderate (e.g. whole body tremor, mild incoordination, infrequent seizures of less than 1-minute duration).

*Welfare assessment protocols will be used to monitor adverse effects and determine when humane endpoints have been reached.

The only procedure apart from breeding and maintenance, to be applied to living animals is systemic administration of agent for cell labelling purposes or dietary intervention; the latter being designed to ameliorate (reduce) disease. Otherwise, experimental methods will all be applied to tissue or cells harvested from animals that have been humanely killed.

Why can’t you use animals that are less sentient?

We use mice to understand the human nervous system, most especially the myelinated nerve fibre. Only vertebrates produce compact myelin (meaning that myelin is formed by the oligodendrocyte process wrapping in multiple consecutive layers, tightly around the axon) like that in the human nervous system. Furthermore, mice are available with a variety of genetic alterations that allow us to study disease-relevant phenotypes and visualise cells and cell organelles. Mice are the least sentient vertebrate group, apart from Zebrafish, in which the myelinated nerve fibre can be studied in the context of understanding human nervous system. Zebrafish, whilst useful for studying several aspects of the myelinated nerve fibre, do not replicate all aspects of the human myelinated nerve fibre, in which we are interested e.g. they do express a gene that is mutated in one of the human diseases we study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be housed in an enriched environment (e.g. with nesting materials and/or play tunnels and/or burrowing treats), generally in small groups.

Observations and objective measurements will be used to identify endpoints and if and when reached, the animals will be killed humanely and tissue collected.

The applicant has 23 years of experience in the protocols described in the licence and will provide training and oversight of the use of animals.

Immune-compromised mice, that will be used to generate cell cultures to study e.g. viral infection of the CNS, will be maintained in barrier conditions to minimise the risk of infection.

Mice with neurological deficits will be killed by a humane method if they reach a humane endpoint prior to the predetermined endpoint of the study.

The NACWO and NVS will be consulted regularly and kept abreast of our work.

Routine, careful handling by Biological Services' staff minimises stress when animals are handled in preparation for Schedule1 kill/perfusion fixation.

There might be instances where we need to singly-house animals for scientific reasons, for example, when :

-we have stud males for our breeding program and they fight when kept in social groups.

-only a single male or female is available for experimental intervention that requires specific housing conditions such as a specific dietary intervention.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE guidelines are adhered to as indicated in previous publications from my group and routinely required by the peer reviewed journals in which we publish our work.

Percie du Sert et al - The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research (2020). PLOS Biology https://doi.org/10.1371/journal.pbio.3000410

Sharing and archiving of genetically altered mice will be conducted as described in 'NC3Rs news', December 2021. This procedure has been routinely used in my lab for ~20 years.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Project Licence holder and members of the research team will ensure continued professional development in the 3Rs area through regular attendance at meetings/workshops such the Animals in Science Regulation Unit (ASRU) annual meeting, 3Rs workshops/symposiums held at local or national Research Institutes, and also attendance at local training workshops organised by the NTCO. The NC3Rs webpage

(https://www.nc3rs.org.uk/) is one we visit regularly. We receive regular updates from NC3Rs through their mailing list.

58. Genetic and Chromosome Instability in the Germline

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

germ cells, spermatogenesis, oogenesis, meiosis, gametogenesis

Animal types	Life stages
Mice	embryo, juvenile, neonate, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how chromosomes are kept stable in developing eggs and sperm, and why eggs from older mothers often pass the wrong number of chromosomes to the next generation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Problems with keeping chromosomes stable during egg and sperm development in humans typically cause infertility, miscarriage and a range of inherited genetic diseases including Down syndrome.

These errors typically happen when developing eggs and sperm go through a specialized cell division known as meiosis that reduces the number of chromosomes in each cell. These errors are particularly common during egg development, and strongly increase with maternal age. Understanding how eggs and sperm normally keep chromosomes stable during their development, and how ageing affects chromosomes in eggs, will help design strategies that might be able to prevent these errors.

What outputs do you think you will see at the end of this project?

This project will primarily generate outputs in the form of peer-reviewed publicly-accessible research publications in scientific journals.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries of this project will be scientific researchers working in this field. These impacts are likely to be continuous throughout the life of the project.

Medium-to-long term impacts beyond the timeframe of this project include better predictions of whether some types of inherited mutations will or will not cause infertility and related disorders, which has potential to impact on patients.

Longer term beneficiaries might potentially extend to wider human populations affected by changes in fertility, miscarriage and inherited aneuploidy associated with maternal ageing.

How will you look to maximise the outputs of this work?

Output visibility will be maximized through open-access publications and publicity through conventional and social media channels. Outputs will also be maximized through presentation of data and results at scientific meetings and conferences in this research field.

Raw and processed data will be made available on public databases to allow other researchers to study and build on this work, and to identify any links that we might not have been able to find ourselves, potentially using approaches or techniques developed subsequently.

Genetically altered lines developed in this project will be made available to other researchers, and genetically altered lines that are likely to be in high demand will be deposited in appropriate repositories (e.g. MRC Harwell hub of the European Mouse Mutant Archive).

Dissemination of new knowledge that has potential to be translatable to human oocytes will be achieved through collaboration with clinical colleagues associated with IVF clinics.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse is a good model to study chromosome behaviour in the germline given the large volume of genetic and molecular knowledge in this area, well-defined descriptions of pathways and identification/analyses of genes involved in these pathways in this species, and the availability of reagents such as antibodies that are used to study this process. The ease of genetic manipulation of this species, and the relatively short generation time are also advantageous. Notably, age-dependent changes in chromosome structure and chromososome segregation in oocytes has already been described in this species.

This work will use mice containing genetic alterations in genes that affect genetic and chromosomal stability in developing eggs and sperm. These animals will allow us to uncover and understand how developing eggs and sperm try to keep their chromosomes stable, and which molecules can be used to influence this process. Non-genetically altered animals will also be used as controls, and to assess age-dependent chromosome changes that happen normally in developing germ eggs.

The choice of life-stages used is mainly determined by the way that eggs and sperm develop in animals and life-stage at which specific events in chromosome segregation happen. Most of the work in this project will be done on adult animals where all stages of meiosis are happening in males, and later stages of meiosis are happen in females. Some work may be done at earlier stages of development to access earlier stages in meiosis in females (mid-late gestation embryos), or to access the first synchronous wave of spermatogenesis in males (prepubertal post-partum pups).

Typically, what will be done to an animal used in your project?

Most (>80%) of the animals used in this project will be used in breeding and maintenance procedures to generate mice with the desired genetic modification. Animals will typically be killed using a schedule 1 method, then post-mortem tissue dissected for subsequent analysis by molecular techniques.

Some mice (~20%) will experience interventions prior to killing and tissue collection e.g. intraperitoneal injection with hormones to induce superovulation up to 48 hours prior to ovarian tissue collection.

A small number (~1%) of mice may experience ageing beyond 15 months and up to 24 months to allow effects on age-dependent effects on chromosome segregation in oocytes to be studied. These mice may also experience intraperitoneal injection with hormones to induce superovulation up to 48 hours prior to ovarian tissue collection.

What are the expected impacts and/or adverse effects for the animals during your project?

Eggs and sperm are not needed for the health of an animal, and though the genetic modifications that will be used in this project might result in subfertility or infertility, this typically will not cause distress or suffering.

The majority (>70%) of animals used for this project will experience breeding and maintenance protocols but will not experience adverse effects given the nature of the genetic modification.

Some animals (~10%) will experience mild adverse effects due to the nature of the genetic modification (e.g. mild intra-uterine growth restriction that does not impact on the ability of the animals to feed or drink, or detectably alter their movement or behaviour).

Some animals (~20%) will experience transient mild threshold pain during intraperitoneal injection of hormones to induce superovulation due to the injection itself.

A small number of animals (~1%) may also experience mild adverse effects associated with ageing to 15 - 24 months.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (>70%) of the mice used in this project are expected to experience sub-threshold levels of severity.

Some mice (~30%) used in this project are expected to experience mild levels of severity (mild phenotypes associated with genetic alterations, intraperitoneal injection of hormones for superovulation, ageing).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The specialized chromosome segregation events that happen in meiosis in developing eggs and sperm are currently not accurately modeled in cell lines. Non-animal models such as yeast have provided significant insight into how these events happen in those species, but some of the pathways that operate in this process in mammals are mammal-specific (e.g. Prdm9-dependent regulation of recombination site distribution, Tex19.1-dependent regulation of chiasma maintenance).

Human eggs arrest their development for decades and need to maintain their chromosomes during their arrest. Age-dependent changes in chromosomes during that arrest are thought to underlie age- dependent chromosome segregation errors in eggs, but this is not modeled in yeast or in many non- mammalian species such as nematode worms or fruit flies that use stem cell systems to provide more consistent supplies of developing eggs as they age. Therefore animal models are needed to study mechanistic aspects of this process.

Which non-animal alternatives did you consider for use in this project?

Cell-free in vitro models, cell line models, yeast, nematode worms and fruit flies were, and will continue to be, considered during the course of this project. Notably, some of the mechanisms that will be studied in this project build on information obtained from work from some of these alternative systems, but incorporate mammal-specific components that have a role in preventing chromosomal instability in mammalian germlines.

This project is part of a larger programme of work that will incorporate structural protein predictions, biochemical analysis of purified proteins, and clinical data from infertility patients. The animal use within this larger programme will model and validate key findings from in vitro experiments and clinical data.

Why were they not suitable?

Cell line models do not accurately replicate the chromosome segregation events seen in developing germ cells, and age-dependent changes in chromosomes during a mammalian egg's prolonged developmental arrest are not well modeled in non-mammalian species such as nematode worms or fruit flies that use stem cell systems to provide more consistent supplies of developing eggs as they age.

In vitro biochemical models reconstituting protein complexes involved in this process provide some insight but likely still lack key components and are restricted in scope.

We have previously used animal models to test the in vivo relevance of mechanisms predicted from in vitro biochemical models, and have used discrepancies between our in vivo observations and in vitro models to identify missing components and interactions from in vitro models.

Though cell line, non-animal and in vitro models in isolation are not particularly well suited to addressing this biological question, the animal use in this project is part of a larger programme of work incorporating iterative cycles of testing findings from these models in vivo, and using in vivo observations to develop modelling mechanisms that are relevant to the in vivo physiology.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based on similar projects currently undertaken on an existing project licence that is due to expire

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The majority of the animals used in this project are used in breeding and maintenance protocols to generate experimental animals of the desired sex and genotype.

I have consulted with a statistician to determine appropriate sample sizes and experimental design to associate genotype with phenotypic effects in these cohorts of experimental and control animals. Data from previous phenotypic analyses were used to generate estimates of data distributions and effect sizes to facilitate those sample size calculations.

I have evaluated technical improvements in superovulation (HyperOva) as a potential route to reduce number of animals used during analysis of oocytes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have been able to use the increased efficiencies associated with CRISPR/Cas9 transgenics to perform some phenotypic analyses on F0 founder animals, significantly reducing the number of animals used in breeding and maintenance protocols. Though this approach is not optimal for all experiments within this project, experiments designed to

analyse cell-autonomous effects on chromosome behaviours in meiosis in male germ cells are well-suited to this approach.

Cell line models, structural predictions, and biochemical assays will be used where possible to design and test specific types of genetic alteration, or to test functionality of fusion proteins, to identify the key genetic alterations to introduce into mice. This will reduce the number of mice used by limiting the genetic alterations studied to those that are likely to be most informative.

Efficient breeding strategies will be used to limit the number of animals used. Genetically altered lines will be cryopreserved to facilitate sharing and distribution of these lines, and to limit breeding and maintenance once all experimental cohorts have been collected.

Multiple phenotypic assays can typically be performed on tissue isolated from each animal, and some material frozen for use in multiple molecular assays over long time scales, reducing the number of animals needed to generate significant mechanistic insight.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most of the animals used in this project (>70%) will experience breeding and maintenance protocols, but will not experience any additional procedural intervention, and will therefore experience minimal distress or harm. The genetic alterations typically involve genes and pathways involved in genetic and chromosomal behaviour in the germline - though these can cause infertility this does not cause pain, suffering or lasting harm to the animals. The genetically altered tissue that will be obtained from these animals will be obtained post-mortem after killing by a schedule 1 method.

Some animals will experience additional procedural interventions (e.g. hormone injections to induce superovulation) prior to killing by a schedule 1 method and tissue collection. This is expected to cause mild and transient discomfort, but is not expected to cause lasting harm to the animals.

Superovulations are used to synchronise the oestrus cycle in female mice and allow more oocytes to be collected from each mouse, improving the quality and quantity of research data collected from each mouse.

Why can’t you use animals that are less sentient?

The life stages used for these experiments are largely dictated by the way that eggs and sperm develop: experiments involving analysis of chromosomes during meiosis in males and in later stages of meiosis in females must be carried out on post-natal animals as this is when meiosis occurs during spermatogenesis; analysis of chromosomes in early meiosis in females must be carried out in mid-late gestation embryos as this is when these events occur during oogenesis.

Animals that are less sentient (e.g. nematode worms, fruit flies) do not use the same developmental strategy for oogenesis as humans/mammals, and do not use some of the mechanisms, pathways and molecules under investigation in this project.

Most of the animals used in this project (>70%) will experience breeding and maintenance protocols, but will not experience any additional procedural intervention. The genetically altered tissue that will be obtained from these animals will be obtained post-mortem after killing by a schedule 1 method, therefore terminal anaesthesia does not provide significant benefits.

Superovulations can't be performed on terminally anaesthetised animals given the amount of time that needs to pass between the hormone injections and the tissue collections.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The majority of the animals (>70%) will only experience breeding and maintenance protocols. Refinements associated with this protocol include environmental enrichment, and implementation of non-aversive mouse handling.

Intraperitoneal injections (e.g. during superovulation) will be refined by implementation of non-aversive mouse handling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs - Responsibility in the use of animals in bioscience research https://nc3rs.org.uk/3rs-resources/responsibility-use-animals-bioscience-research Medical Research Council - Guidance on research proposals involving animal use https://www.ukri.org/councils/mrc/guidance-for-applicants/proposals-involving-animal-use/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Annual PIL refresher courses run by the establishment will help keep me, and other PIL holders implementing this project, informed about advances in 3Rs.

Experimental interventions (e.g. superovulation) will be authorised locally by the Named Veterinary Surgeon at the establishment through a time-limited Experimental Request Form (maximum duration 1 year), which will allow timely implementation of 3R advances in these regulated procedures.

59. Transgenic Rat Somatic and Germ Cell Gene Mutation Assay

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Transgenic, Risk assessment, Reproductive cells, Mutation, Genotoxic

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to conduct the Transgenic Rodent (TGR) assay to detect gene mutations in rats in accordance with regulatory guidelines. These studies play a key role in determining the actual risk a test chemical poses to human health and the environment, when non-animal data show that the test chemical could cause DNA damage.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Testing chemicals in this assay will assess whether they are considered safe for use in humans and/or exposure to the environment, or whether they can cause a change (mutation) within the genes of the rat and would therefore be classified as genotoxic. Chemicals which cause gene mutations are potentially very dangerous to humans as they could cause for example, genetic disorders, harm to unborn children and serious illnesses such as cancer.

What outputs do you think you will see at the end of this project?

There are two outputs for this project:

The first will be the use of dose-range finding (DRF) studies for the generation of dosing information that will be used to determine appropriate and scientifically relevant dose levels for use in the main TGR gene mutation test. The maximum tolerated dose (MTD) for a test chemical in the rat will be determined. The MTD is defined as the highest dose that will be tolerated without evidence of study- limiting toxicity, relative to the duration of the study period, but not death or evidence of pain, suffering or distress necessitating humane killing.

The second will be evidence of whether a test chemical is able to cause genetic mutations in any tissue of the body and an understanding of whether this could occur in humans. This knowledge is gained by carrying out the TGR gene mutation test in transgenic rats that have had their DNA modified to be able to detect mutations in any tissue.

Who or what will benefit from these outputs, and how?

The conduct of this assay will be at the request of regulatory authorities, or to meet a regulatory requirement, to confirm that a test chemical does not cause gene mutations in any cell type and is safe to be taken by humans (eg, in the case of new medicines, or food additives), or not toxic to the environment (eg, in the case of weed killers, fertilisers and other chemicals).

The TGR gene mutation test will be conducted in a live animal, where the responses seen after 28 days of dosing will be dependent on how the animal processes the test chemical (eg, how organs like the stomach and liver break down the compound, how the individual cells of the body may be damaged and how that damage might be repaired). Therefore, short-term this enables an accurate assessment of whether the test chemical causes mutations in a living animal and whether it could potentially cause the same mutations in humans.

The TGR gene mutation test enables gene mutations to be seen in any cell type of the body allowing for mutations that could cause cancers or other non-cancer diseases to be detected early and prevented. Germ cells (cells involved in reproduction) can also be assessed, so it is also possible to check if there is likely to be a risk of passing a genetic disease onto an unborn child.

Long-term, if a test chemical is found to cause gene mutations, it will not be approved for sale and its development halted. This is to protect humans and the environment from chemicals which are potentially harmful to human health, which may lead to the development of cancer or other genetic diseases, or be highly toxic in ecosystems.

How will you look to maximise the outputs of this work?

As this test will be conducted as a service, the ownership of the data will belong to the Study Sponsor. Data generated will be sent back to the Study Sponsors by way of a formal study report, which they will use as part of their regulatory package of work to be submitted to the regulatory authorities. Regulatory bodies will then make a decision as to whether the test chemical is safe for approval for use.

Any work that may be conducted on non-Sponsor owned test chemicals will be shared with the wider scientific community through publication.

Species and numbers of animals expected to be used

- Rats: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats have been used historically in safety evaluations and genotoxicity studies and are recommended by regulatory agencies. The wild-type strain used to make the transgenic rats will be used to determine the MTD.

The use of the transgenic rat has been extensively reviewed by regulators and is identified as being appropriate to use when investigating the potential for a test chemical to cause mutations in any tissue of interest.

Regulatory guidelines specify that rats need to be sexually mature adults aged between 8 and 12 weeks old at start the of dosing.

Typically, what will be done to an animal used in your project?

In the DRF phase, small groups of wild-type animals will be treated daily with the test chemical for a number of days (typically 7 days) in order to establish the highest dose to be used in the TGR gene mutation test. The test chemical will be given either orally, or by injection in to the blood stream. Blood samples may also be taken from these animals to measure, for example, the amount of test chemical in the blood. Animals will be killed humanely at the end of the DRF phase.

In the TGR gene mutation test, animals will be treated, using the same route of administration as used in the DRF phase, with the test chemical daily for up to 28 days. Blood samples may also be taken from these animals to measure, for example, the amount of test chemical in the blood. At the end of the study animals will be killed humanely and the required tissues taken for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that up to 60% of animals in the DRF phase will experience adverse effects following repeat dosing. These could include changes to breathing (increased or decreased), body weight loss (up to 15%), occasional changes in normal appearance (e.g. fur may stand up, animals may have discharge from the eyes and nose, or animals may hunch up), changes in normal behaviour (e.g. animals may not interact with their cage mates) and moderate pain or discomfort.

Animals may be restrained for the purpose of dosing or blood sampling into/from the tail vein, which may cause momentary distress. Minor pain or discomfort may be felt when the blood is sampled or test chemical injected.

In the main gene mutation test approximately 80% of animals should not experience any adverse effects, but some in the highest dose group may experience, at worst, moderate adverse effects for a short duration as described above. Any adverse effects will be closely monitored and should not exceed a moderate degree of suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- mild: 60%
- moderate: 40%

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is necessary to conduct the TGR gene mutation test, as it allows time for mutations to occur in any cell of the animal, to fully assess a test chemicals potential to cause mutations in the DNA before giving it to humans or exposing it to the environment. At the moment there is no non animal test available that the regulators will accept for this evaluation.

Which non-animal alternatives did you consider for use in this project?

Prior to animal testing, computer programs which analyse the chemical structure of the test chemical are used to assess how the molecule will interact with the DNA. Cell-based tests are also performed to assess the test chemicals potential to cause gene mutations and DNA damage. These tests are very useful and provide a good indicator of the test chemicals potential to cause mutations in the DNA.

Why were they not suitable?

Computer programmes and cell-based tests are not able to fully represent how a chemical is altered in a live animal system in terms of absorption, distribution, metabolism and excretion by the animal's organs and tissues, nor do they assess whether a mutation has the potential to be passed on to children by occurring in the reproductive cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is based on the number of studies expected to be conducted over the 5 year period, the number of animals required in each treatment group and the number of treatment groups required to enable a statistically significant increase in mutant frequency to be detected.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments will be designed in accordance with the regulatory test guideline adopted in 2011 and updated in 2013 and 2020. The guideline includes the latest advancements in

technology and ethical practices to ensure the tests are being conducted properly, using the least number of animals. The number of animals per study group has been shown, using statistical methods, to be the minimum number required to detect a doubling in mutant frequency between non-dosed and dosed animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Dose range finding work will be carried out in small groups of animals so that a dose that can be safely administered for 28 days can correctly be selected for the TGR gene mutation test. This will ensure that the risk of having to humanely kill animals over the 28 days, and potentially having to repeat work in extra animals, is kept to a minimum.

Blood sampling to determine blood levels of the test chemical or other genetic markers identifiable in the animal will be carried out in the DRF and TGR gene mutation test animals, where possible, in preference to using additional groups of animals, or running separate studies, for this sole purpose.

Once an adequate positive control tissue bank and historical database have been established, concurrent DNA would be extracted from tissues in the tissue bank, thus replacing the need to dose a separate positive control group and reducing the total number of animals required on each study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The DRF phase will be conducted in the Fischer 344 rat. This animal has been used for over 50 years in toxicology and cancer studies and was the strain used to generate the transgenic rat, which is used in the TGR gene mutation test. Using the transgenic rat means that gene mutations can be assessed in any tissue from this rat. This model allows the cancer risk of a test chemical to be assessed over a much shorter period of time (typically 1 to 2 months) when compared with conducting 1 to 2 year cancer studies in animals, potentially causing less pain and suffering in fewer animals.

Blood micro-sampling to determine blood levels of the test chemical will be done where possible in preference to collecting larger blood volumes from the tail vein, which could cause bruising and pain, or using additional groups of animals for this sole purpose.

Animals will be humanely killed, and all tissues will be removed post-mortem.

Why can’t you use animals that are less sentient?

The life stage of the animals to be used in this test is specified in the regulatory guideline. Animals are required to be sexually mature adult animals that are 8-12 weeks old at start of treatment.

The preferred rodent species for regulatory toxicity testing and use in cancer evaluation studies is the rat. The Transgenic rat gene mutation detection model is therefore considered the least sentient rodent model that will allow for the data obtained to be correlated with other regulatory toxicity studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be allowed a minimum of 7 days to acclimatise to their new environment following transfer. Animals will be housed in groups and provided with environmental enrichment items as agreed with NACWO. Animals will be regularly monitored for health and welfare and routinely handled by fully trained and competent staff.

During the DRF phase and TGR gene mutation test, animals will be carefully monitored to assess for the onset of any potentially adverse clinical signs. Particular attention will be paid to the animals around the expected peak exposure time to the test chemical. Any observations will be closely monitored until they have subsided, or if necessary, animals will be humanely killed if the humane endpoints are reached.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experiments will be conducted in accordance with The Organisation for Economic Co-operation and Development (OECD) regulatory guideline. In addition, guidelines issued by the Laboratory Animal Science Association (LASA) and guidance from the NC3Rs on best practice in rodent studies will be followed, as appropriate. In addition, the PREPARE and ARRIVE guidelines will be followed, where applicable.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Although the experimental design is highly prescribed in the regulatory guideline and literature, regular reviews of the latest scientific publications in the field and the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs)

website will be conducted in order to identify and refine any procedures or processes which could be improved upon.

60. Genetic and Environmental Impacts on Hearing

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Genetics of deafness, Progressive hearing loss, Cochlear pathology, Diagnostic tools, Therapies for deafness

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project are to use genetics to identify critical molecules required for normal hearing, determine the pathological mechanisms underlying hearing loss, develop

diagnostic tools for different types of auditory pathology, and investigate potential therapeutic approaches to preventing the progression of hearing loss or reversing it.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Hearing impairment is very common in the population and can begin at any age. Childhood deafness affects one in 1000 children born and with age this number increases until over half of adults in their 70s have a significant hearing loss. Hearing impairment isolates people from society, is often associated with depression and cognitive decline, and is a major predictor of dementia. The only remedies currently available are hearing aids and cochlear implants, but these do not restore normal function. There is a large unmet need for medical approaches to slow down or reverse hearing loss. This project will provide the scientific underpinning for the development of new treatments.

What outputs do you think you will see at the end of this project?

The outputs will include improved knowledge and understanding of the pathological mechanisms that lead to hearing loss, novel ways of diagnosing different types of dysfunction within the inner ear, molecular pathways that are good targets for development of medical treatments for hearing loss, and proof-of-concept that some types of hearing loss may be reversible.

The knowledge will be published in scientific peer-reviewed journals and discussed at scientific and clinical conferences.

Who or what will benefit from these outputs, and how?

The primary beneficiaries will be people with progressive hearing loss, as we build our knowledge of the mechanisms underlying their hearing which will underpin the development of new treatments. This will be a long-term output.

Clinicians will benefit from these outputs because it will allow them to offer improved services to hearing-impaired patients who currently do not benefit from hearing aids.

The research field will grow as a result of this research, allowing synergy and faster progress towards treatments. The short-term outputs of this project will include this increased knowledge and understanding of the pathophysiology of hearing impairment.

How will you look to maximise the outputs of this work?

All outcomes from the planned research will be published, including findings that do not fit our original hypotheses because these may change the way that researchers build their research plans.

We will continue to collaborate with other researchers in the field including those in the UK, USA, Southern Africa and Asia. These collaborations build a common understanding of the mechanisms involved in hearing loss and spark new ideas.

I will continue to engage with hearing-impaired people, often through my close links with the charity Royal National Institute for Deaf People (RNID). These interactions are inspiring and important in keeping the goal of understanding and treatments in focus.

I will also continue to interact with researchers working in industry because we have a lot to learn from each other about how to develop treatments.

Species and numbers of animals expected to be used

- Mice: 37,700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use the mouse because it is a mammal, and to understand the biological basis of human hearing loss we need to study mammals. Other animals have very different structural specialisations to enable good hearing, and so would be of limited use in understanding human deafness.

The ages of mice that we study are determined by the progression of hearing loss in each different mouse mutant. We aim to analyse the earliest age at which any changes in auditory function can be recorded, so that we can find the primary, or earliest, abnormality that leads to progression of hearing loss. For some of the mouse mutants we study this means analysing them from 12 days old onwards while for others with later onset and slower progression we need to follow their hearing loss up to a year old or more.

Typically, what will be done to an animal used in your project?

Most of the mice we study (over 85%) are culled humanely and their tissues taken for analysis. This minimises the harm they may experience. For the remaining mice, some are injected with drugs to modify the progression of hearing loss and others are anaesthetised, their auditory responses to sounds recorded using methods similar to the human newborn baby screen carried out in hospitals, and then the mice are allowed to recover. Surgery

with recovery is used very rarely when it is necessary to achieve the goals of the project, and every care is taken to minimise any pain or distress.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect any adverse effects for the mice beyond mild stress due to being taken out of their home cage and handled or injected. Occasionally certain mouse mutants may show a predisposition to seizures when stressed, and if this happens and the seizure is more than mild and transient (like freezing) then we will immediately cull the mouse to avoid any suffering. Rarely we may need to carry out surgery on a mouse, and in these cases the mouse will be fully anaesthetised and treated with analgesics for pain relief after the operation. When we need to keep mice beyond a year old, we need to watch carefully for signs of frailty, pain, reduced mobility, growth of tumours, skin lesions, and weight loss. Any mice showing such signs will be treated if possible or culled humanely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the mice (over 99%) will experience no more than mild severity.

Fewer than 1% of the mice used may experience moderate severity, including any mice used for surgery with recovery.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no other way of investigating the development and function of hearing apart from using a living animal. We investigate humans with hearing impairment to discover candidate genetic mutations that may explain the deafness, but animals carrying the same genetic mutation are needed to confirm the role of these genes and for understanding the ways in which the auditory system fails, leading to deafness.

Hearing loss is often a progressive disorder and using a mouse we can study the early stages of the dysfunction and identify the main part of the ear affected, but this level of intrusion would never be possible in a human. We need to know the primary site of dysfunction in order to select and assess suitable drugs. It is possible to make some recordings in cultures of samples from the inner ear, but these are not helpful in explaining how the system works as a whole and still require breeding of a mouse to provide the sample to study. It is possible to expose these samples to drugs to test their effects, but this does not tell us anything about the ability of the drug to cross into the inner ear – for this a whole living animal is required

Making observations on other impacts of a mutation on other features in an animal can give us important insights into the pathological and molecular mechanisms involved in hearing loss.

Which non-animal alternatives did you consider for use in this project?

We investigate the genomes of humans with hearing impairment to discover candidate mutations that may explain the deafness. However, animals carrying the same gene mutated or same mutation knocked-in are needed to confirm the role of these genes and for understanding the pathological mechanisms leading to deafness.

Human inner ear samples are available through established repositories, but these are donated after death and usually represent the end-stage of a long ongoing pathological process so often do not tell us why the person had hearing impairment earlier in their life. Using human samples we can only look for correlations and cannot carry out the genetic manipulations to determine the cause of deafness as we can in animals.

We make extensive use of data available on the web, such as protein interaction data to build molecular networks. We work with computer modelling, such as modelling the sources of components of the Auditory Brainstem Response (ABR) to localise the possible site of the malfunction, but generally computer modelling is not helpful because we do not have the necessary information to feed in.

With the help of our collaborators, we make recordings from explanted samples of tissues from the inner ear, but as mentioned above, these have limitations in interpreting the impact upon hearing as a whole because the explants are maintained in such an abnormal environment outside of a living organism with blood circulation.

Other research groups are working on organoid development, and cell lines derived from inner ear tissues are available. However, these have not yet been shown to develop mature sensory hair cells and they have the same limitations as cultured explants from inner ears of animals because they are not in the context of a whole living organism with a blood supply.

We continue to monitor alternatives and will use them when they allow us to answer key questions about hearing loss.

Why were they not suitable?

The non-animal alternatives that we use are useful in some respects, especially the details of genome variants in humans associated with deafness, but, as listed above, these alternatives cannot lead to understanding of the pathological processes (cellular, molecular, electrophysiological) underlying hearing loss. To understand how and why people have hearing loss we need to ask specific scientific questions to establish the causes and mechanisms involved, and these questions can only be addressed by carrying out experiments in animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The total number of mice we expect to use is based upon our experience in carrying out these sorts of research projects previously. The number includes approximately 40% that will be used directly in experiments and 60% that are needed to maintain the breeding colonies of mice each carrying different genetic mutations but not used in experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the minimum number of animals to give us a robust and statistically-valid result based on our previous experience of how variable the results are likely to be. For most experiments, we use 6 mice of each genetic type and age or sex. We adjust the number needed if the variability is larger than we expected. We also consider size of the effect. Small effects (minor worsening of hearing) require large numbers of mice, so we focus upon larger effects on hearing to enable clear interpretation. We minimize environmental influences on findings by studying control mice raised in the same litter as the mutant mice. For drug treatments we use control mice that have undergone the same procedure but without the drug. We collect samples at the same time of day, as daily rhythms can influence the results. Whenever possible we test animals before disclosing the genetic status, to avoid any experimenter bias. Minimising variability in the results means we can use fewer mice to get a statistically-sound result. Some measures can be recorded in the same mouse at different ages, reducing the number of animals we use and allowing tracking of progressive hearing loss in the same mouse.

For statistical testing, we consult experts and websites that give guidance to the appropriate test to use. We consult the NC3Rs Experimental Design Assistant for general guidance.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When we start a new project involving a new mouse mutation, we firstly test the hearing of a pilot set of mutants compared with littermate controls at several ages to establish the rate of progression of any hearing loss, which allows us to select the optimum age for further analysis. We initially test mice carrying either one or two copies of the mutant gene as well as mice with only a normal version of the gene to determine whether we need to analyse all three types in further experiments or whether just mice with two copies can be compared with their normal littermates. For each mouse mutant we study, we set up breeding pairs carrying the correct combination of mutations to produce the maximum number of offspring that can be used in experiments to improve efficiency.

For efficient colony management we use guidance from ASRU (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773 553/GAA_Framework_Oct_18.pdf) as well as advice from the NC3Rs (https://www.nc3rs.org.uk/3rs- resources/breeding-and-colony-management). We regularly cryopreserve samples to allow us to remove the colony from the shelf temporarily and we always archive new mutations we generate via the European Mouse Mutant Archive. Details about breeding performance of each mutant colony are maintained through our electronic mouse tracking database, MCMS, which facilitates identification of key features of breeding colonies and highlights any subviable genotypes.

For new projects involving drug delivery or collection of samples for new analyses, we always read previous published reports describing the methods used and talk with other researchers who have used similar drugs to determine the optimum doses and sample collection methods before planning the experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use the mouse because the inner ear of mammals has unique structures involved in progressive hearing loss that are not found in other vertebrates like birds or reptiles. The mouse is the most suitable mammal for the genetic manipulations we need to carry out and there are many existing mouse lines available avoiding the need to use additional animals to generate new model systems.

Most of our experiments (over 85%) involve humane culling of the mouse using approved methods to minimise any chance of pain, suffering, distress or lasting harm to the mouse followed by detailed examination of inner ear samples from the mice. Some experiments include testing auditory responses to sounds under full anaesthesia prior to humane culling while the mouse is still anaesthetised.

A small proportion of our experiments involve testing of hearing under anaesthesia followed by recovery of the mouse, or injecting drugs. Mice used for recovery experiments are observed until they recover fully from anaesthesia to ensure there are no signs of distress. Pain relief will be provided as needed. Surgery will be carried out in only a very small number of mice, and will cause minimal pain or distress but we will monitor this and adapt procedures as necessary to reduce potential suffering.

In the case of new mutations introduced into mice, any possibility of suffering is minimised by daily inspection of new mutants and breeding potentially affected mutants only when needed for experiments.

Why can’t you use animals that are less sentient?

In order to study hearing processes that are most relevant to human deafness we need to study a mammal and the mouse is the optimum mammal to use. Non-mammalian vertebrates and other animals have quite different inner ears and mechanisms for hearing so are not suitable in most cases for analysing the range of abnormal functions that can lead to hearing loss in a mammal.

We carry out some of our measurements of auditory function in fully anaesthetised mice that are not allowed to recover. However, we have adapted some of our recording techniques to allow recovery of the mouse which has the advantages that we reduce the total number of mice needed and we can track the progression of hearing loss in an individual mouse by repeated measurements.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We keep all protocols under continual monitoring to minimise the risks of any harm to our mice. In the case of new mutations introduced into mice, any possibility of suffering is minimised by daily inspection of new mutants and breeding potentially affected mutants only when needed for experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE guidelines are useful reminders of the factors to consider, and we are aware of the recent revision of these guidelines as published by Percie du Sert et al in 2020. We also refer to the PREPARE guidelines published by Smith et al in 2018, the guidance on administration of substances published by Morton et al. 2001, and the LASA guidance on aseptic surgery issued in 2010. For efficient colony management we use guidance from ASRU (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773 553/GAA_Framework_Oct_18.pdf) as well as advice from the NC3Rs (https://www.nc3rs.org.uk/3rs- resources/breeding-and-colony-management).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have access to regular lectures and other resources from the NC3Rs. We have useful feedback from the Animal Welfare and Ethical Review Boards (AWERBs), and several people with responsibilities to inform users about welfare considerations such as the Named Vet, Named Animal Care and Welfare Officers, Named Training and Competency Officers, etc. Occasional circulars from the Home Office, highlighted by regular newsletters from the animal care facility, also are useful in keeping up to date with advances in the 3Rs.

If any of the advances we hear about would improve animal welfare while allowing our research to continue, then we will implement these changes.

61. Vitamin B3 Driven Signals and their Impacts upon Steroid Hormones

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

PARP1, Metabolism, NAD+, Molecular biology, Glucocorticoids

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to better understand biology by the study of a molecule called Nicotinamide Adenine Dinucleotide (NAD+). NAD+ is supplied to our bodies through vitamin B3 in our food. In our tissues, NAD+ is the activator of important factors, all of these are potentially critical regulators of health and aid normal hormonal function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Each organ in our body has very specific and different nutritional and hormonal requirements. These conditions can change during periods of health and illness.

When these demands are not met the organs function is impaired and our health can suffer. However, we currently do not understand the exact demands each organ has for the moelcule NAD+. Moreover, we have only a very simple understanding of how NAD+ levels impact our endocrine systems.

Improved appreciation of these interactions will allow us to identify diseases where hormonal response and NAD+ status might be an important clinical feature.

What outputs do you think you will see at the end of this project?

Outputs of this project will include:

- Datasets providing new information on how the factor PARP1 detects and use vitamin based molecules important to our health and how this factors activity impacts our hormones and varies in different tissues (for example muscle, liver, heart) - these will be shared on publicly available online repositories.

- Publications on the topics of cellular biology and mammalian metabolism. These will give new knowledge on nutrient regulated factors that control health and crosstalk with hormonal systems
  - publications will be in open access journals in the fields of biological research.

- Dissemination of information. Presentations to audiences will be on the topics of vitamin B3 metabolism, molecular activity regulated by NAD+ controlled PARP1 and the interplay between this nutrient driven molecule and hormone systems - findings will be disseminated at national and international conferences.

Who or whatwill benefit from these outputs, and how?

This project may generate new knowledge and information that can be used by other researchers studying human health. Also these findings can be utilised by translational researchers to generate new studies aimed at evaluating treatments surrounding diseases such as muscle physiology (medium term (5years)).

Moreover, it can inform healthcare providers in their treatment of metabolic pathologies that currently lack effective strategysuch as type 2 diabetes, and cardiovascular diseases (long term (10years)).

Longer term studies will be a part of a subsequent PPL.

The projects work will be published in peer reviewed open access journals. Preprints of papers will be published on preprint repositories.

How will you look to maximise the outputs of this work?

This work will be carried out as part of ongoing collaborations with other research groups. Data will be disseminated both at national and international conferences. Unsuccessful

approaches will also be published in journals and shared with relevant communities as technical notes.

Species and numbers of animals expected to be used

- Mice: 1000 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The majority of the current understanding surrounding both NAD+ biology and steroid hormones was generated in the mouse. Mouse genetics and genome engineeering is uniquely advanced (as opposed to fish or fly) and there is a wealth of understanding of murine physiology making mice a most suitable mammalian model.

Adult mice of the strains mentioned within this project have been chosen to avoid any developmental issues that can be seen when treating younger mice.

Typically, what will be done to an animal used in your project?

Mice will be bred using natural mating and may have genetic modifications which are not expected to be harmful. They will be given various substances by injection or in food or water which are not in themselves expected to be harmful. Mice will be humanely killed at the end of the experiment

Typically, under this project animals will experience:

- Tissue collection for genotyping (ear clip).
- Administration of a compound to activate genetic construct. Typically, via intraperitoneal injection, altered diet or altered drinking water.
- A diet with altered constituent for example a diet composed of 60% kcal fat (high fat diet). Food withdrawal for upto 16 hours.
- Administration of a compound to modulate metabolism by the intravenous, oral or subcutaneous routes (typically glucocorticoids).
- Metabolic assessment by using the Sable Systems Promethion home-cage system.

What are the expected impacts and/or adverse effects for the animals during your project?

It is anticipated some animals may experience minor transient discomfort during this project, resulting from the administration of substances, food withdrawal and

acclimitisation in the Promethion metabolic assessment home-cage system. It is expected that some animals will experience minor transient discomfort during this project as a result of administration of compounds and fasting. Withdrawal of food may cause hunger for up to 16 hours but it is not expected than animals will lose weight as they will be able to eat following food withdrawl.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 80% of mice will undergo combined procedures (examples include, diet of altered energy constituent and glucocorticoid drinking water treatment or a diet with altered content, administration of compound to alter cellular metabolism and metabolic cage assessment or administration of a compound to alter energy metabolism or typically, glucocorticoid treatment and metabolic cage assessment). Individually, these steps are considered mild but as there are multiple steps this protocol will be classified as moderate severity.

The remaining 20% of mice will not experience combined procedures and be classified as mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The physiology of a mouse is very similar to human. The mechanisms and hormones controlling tissue metabolism are likewise similar to humans. This makes the mouse an important animal that can help us understand and develop treatments for human diseases.

In addition, studying a mammalian animal allows us to improve knowledge surrounding the impact of disease. This means we can identify how one tissue (e.g. skeletal muscle) influences other tissues (e.g. liver, fat, heart etc...) and the body as a whole.

Which non-animal alternatives did you consider for use in this project?

Laboratory based In vitro experiments using human and mouse cells are used to underpin and expand findings from this study. They are also used to validate the use of ligands and compounds used to alter cellular metabolism (typically, NAD+ precursors and

glucocorticoids), this better informs us prior to our in vivo work. These elements help reduce our reliance on the animal model as well as informing our planning of animal experiments.

Why were they not suitable?

The use of mice in this work is important to help understand how changes in one tissue (usually skeletal muscle) impact the on the whole body system which is not possible in a laboratory based in vitro model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates are derived from previous studies undertaken by myself and my previous research group. In addition published works by groups studying the similar areas.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Colony size is determined for the number of animals required to meet their scientific goal and we will calculate the number of breeding animals required using known breeding data. Prospective sample sizes for experiments have been generated in consultation with biostatisticians using appropriate statistical software in combination with the Experimental Design Assistant (NC3Rs) for generation of power calculations. Animal numbers will be recorded and under constant review to prevent excess animals being generated. Genotyping will be carried out rapidly to minimise animal numbers held under this licence.

Experimental design is based upon our extensive experience and performing pilot studies. Using appropriate power calculations, we have determined that between 6-10 animals per experimental group are required for these studies. Prior to each study, we will outline a protocol for each experiment carried out to identify those objectives for the study, description of the experiment and methods, animal numbers and their identifications to be used as well as experimental grouping allocation and expected outcomes. The PPL holder has experience in statistical analysis and use of statistical software to design experiments with sufficient power analysis. All experiments will be blinded where possible to treatment and planned in accordance with the ARRIVE guidelines.

Typically, indirect calorimetry analysis will require n=8 following experimental intervention (post hoc power analysis n=2; cohens d = 1.66) to reach statistical significance. And for

example altering cellular metabolism with the NAD+ precursor nicotinamide riboside will require n=6-9 following experimental intervention (post hoc power analysis n=2; cohens d = 1.68) to reach statistical significance (recent study of skeletal muscle elevation of NAD+ using nicotinamide riboside experiment: Control=100%

±2.10 vs treatment =126%±4.20 Two way ANOVA p<0.05, n=5).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding will be performed on a minimal basis to reduce surplus mice. Both sexes will be used in studies. Consideration may be given to the use of ex-breeders for the use of tissue collection and analysis.

Pilot studies can be performed to assess the efficiency of genetic recombination and optimal route of administration before moving onto a main study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Models used:

This project will use mice of both wild type and genetically modified backgrounds.
Methods:

- Administration of a compound to activate a genetic construct. Activating compounds are well tolerated and commonly used, doses will be inline with existing publications. Food and water intake will be monitored. Pilot studies will be carried out to ensure we reduce and minimise pain suffering or distress.

- Administration of diets composed of altered nutrient content. Cages will be monitored for cleanliness as in particular high fat diet can crumble onto cage floor. Cages will be cleaned or changed with increased regularity as required. Softer bedding will be used to reduce the chance of excessive grooming.

- Withdrawal of food for up to 16hours. Food will be in place after 16 hours allowing animals to feed as required. Animals will have access to water during these 16 hours. This time period is sufficient to achieve the balance of minimising suffering and generating a metabolic state that is required to better understand fuel source utilisation

during fasting periods, in response to PARP1 deletion and glucocorticoid excess. response to PARP1.

- Administration of compounds to alter cellular metabolism. These compounds (typically glucocorticoids and NAD+ precursors) have been used extensively in the scientific literature and will be used at the lowest dose possible to induce the pharmacological effect required in our mouse lines. The compounds used to influence metabolism are well tolerated and have minimal effects on welfare, and in general terms can often promote metabolic health.

- Mice will be housed in a home cage located in a Promethion indirect calorimetry analysis unit for up to 14 days. Whilst in this system mouse movement, food intake and water intake will be monitored. This replicates the homecage environment and thus minimises any distress.

Why can’t you use animals that are less sentient?

Mice are the least sentient species that will allow us to achieve our objectives. Not all steps to minimise suffering are available to this project. For example use of anaesthesia would impact the biochemical turnover of reactions and the metabolic rate of the animal. This would negatively impact the quality and robustness of the experimental datasets. Also, animal use at a different life stage as a mode to further reduce suffering is unachievable as younger mice are weaning (milk has a high vitamin B3 content, this would negatively influence our data) moreover our objectives are unachievable using mice in in utero.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

High welfare standards, good animal husbandry, and environmental enrichment will be employed. Mice will be carefully monitored and if adverse events are observed, steps will be taken to alleviate them including analgesia, or the affected mice will be humanely killed.

The route, volume and frequency of the administration of substances is reviewed and selected in order to ensure the scientific question can be answered with the least impact on the welfare of the animal.

Where a procedure has an unexpected impact on the welfare of an animal the frequency of monitoring clinical signs and bodyweight assessment will be increased.

Mice will be carefully monitored and if adverse events are observed, steps will be taken to alleviate them including analgesia, or the affected mice will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to experimentation the PREPARE guidelines (PREPARE: guidelines for planning animal reearch and testing) are used to better support the preparation of animal stuides.

The ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments), NC3R's and LASA Good Practice Guidelines are also tobe incorporated.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Literature searches will be routinely performed, I will attend appropriate seminars, symposiums and conferences to find out about new technology and new approaches that can be implemented.

The ARRIVE guidelines will be adhered to. I am subscribed to the NC3R's newsletter and also receive updates from my institutions named information officer.

Close interaction will be maintained with NACWO, NTCO and NIO.

62. Targeted Therapies for Inflammatory Diseases

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Inflammatory diseases, Inflammation biology, Drug discovery, Antibody-based therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new medicines to provide better and safer treatments for inflammatory diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inflammatory diseases include a vast range of conditions and disorders, including Crohn's disease, ulcerative colitis, rheumatoid arthritis (RA) and psoriasis. These are characterized by an unbalanced immune response, with a vast proportion of patients that do not respond to standard treatments or stop responding over time. Unresolved chronic inflammation has also been associated with the development of cancer, and with different stages of tumour progression and metastasis.

The burden of these diseases is not only detrimental for human health but also brings a notable financial burden to individuals, their families, and society. The work performed under this project licence will help to develop novel therapeutics for the treatment of inflammatory conditions and the diseases associated.

What outputs do you think you will see at the end of this project?

The main outputs of this project licence will be the development of novel therapeutics to rebalance immune and inflammatory responses that drive chronic inflammatory diseases.

Our pipeline is focussing on novel approaches in the pursuing of potential treatments for inflammatory diseases, with some new drugs currently being tested in clinical trials, and several in pre-clinical development. The studies performed within this project will help us to validate molecular targets and test different drug formats.

This project will also help us to identify which diseases can be targeted with these drugs and what other therapeutics could be used in combinations to have a stronger anti-inflammatory effect.

Who or what will benefit from these outputs, and how?

Inflammatory diseases can cause pain and reduce quality of life, by disrupting normal activities and affecting social and psychological wellbeing.

None of the current available drug treatment are curative and in many cases the disease continues to progress, leaving some patients without alternative treatment options. In the short term, this project will provide data that will help identify novel targets and therapeutic strategies. In the longer term, the data generated will support the development of novel therapeutics that will benefit patients either as stand- alone therapies or in combination with other agents, increasing response rates and ultimately being able to bring about effective disease control in a greater number of patients. This would benefit not only individual patients, but it will also help to relieve the burden placed on communities, workplaces, and national health systems.

How will you look to maximise the outputs of this work?

Data generated in this project, including any unsuccessful approach, will be disseminated within our organisation and it will benefit several programs of work.

Findings will be presented at national and international scientific conferences and meeting as posters and talks, and eventually published as scientific articles and patents.

The results of the potential accompanying clinical trials will be included in the entries to the ClinicalTrials.gov and/or published in the scientific journals.

Species and numbers of animals expected to be used

- Mice: 5350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project, we are developing antibody-based therapeutics against inflammatory diseases.

Mice are used to model inflammation because of the relative ease of manipulation of the immune system and well understood genetics. We will be using young adult mice (typically 6-14 weeks old at the start of the study), with a fully mature immune system.

Typically, what will be done to an animal used in your project?

In this project, mice will be challenged with a stimulus that will induce an inflammatory response. The administration of the stimulant could be done locally (e.g. in a subcutaneous pouch) or systemically (e.g. via intravenous injection). When using inflammatory bowel disease models, the inflammation will be induced in the gut. Some of these animals will also receive an injection of a colonic carcinogen to induce the formation of inflammation-associated carcinoma.

Mice will be treated with novel anti-inflammatory drugs, mainly antibody-based therapeutics dosed generally 2-3 times a week for up to 3 weeks , but on some occasions, treatments may be administered more often. During the study mice will be observed, weighed and sometimes imaged, usually 2-3 times a week. The studies will be terminated when enough data on the effects of the tested treatments have been collected and no additional scientific knowledge could be obtained within welfare guidelines.

What are the expected impacts and/or adverse effects for the animals during your project?

Induction of local or systemic inflammation may cause mild pain and some behavioural changes, including decreased peer interaction. Body weight loss may also be observed. Mice will be regularly monitored, and symptoms alleviate whenever possible, for example with provision of food supplement on the cage floor.

When using colitis models, mice will experience intestinal inflammation, with expected adverse effects including the presence of blood in the faeces, mild abdominal pain and mild to moderate weight loss.

Most of the animals used in this project will be dosed with antibody-based treatments. Antibodies are usually very well tolerated, but their administration could lead to temporary mild adverse effects such as weight loss or piloerection. These effects usually resolve within 2 days from appearance.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the individual procedures performed under protocols 1, 3, and 4 are expected to result only in mild discomfort. However, as studies run under these protocols will include several procedures, this will result in a cumulative level of severity likely to be moderate for most of the animals. We estimate that around 50% of the mice in Protocol 1 and 70-80% of the mice under Protocol 3 and 4 will experience cumulative moderate severity. For the remaining mice used under these protocols we estimate mild severity.

Mice used in Protocol 2 (IBD model) are expected to experience moderate severity due to the induction of colitis (>80%)

Most mice used under Protocol 5 will experience procedures only under terminal anaesthesia, thus they are expected to be classified as non-recovery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Inflammation is a process that involves many immune and non-immune supportive cells, including macrophages, neutrophils, T-cells, fibroblasts and endothelial cells. All these different cell populations communicate between each-other through complex positive and negative feedback loops of inflammatory mediators. This intricate interaction can only be modelled properly in an animal setting.

Chronic inflammatory conditions have also been associated with the development and progression of malignancies. Studies performed under this licence will allow us to

investigate the anti-inflammatory properties of our novel therapeutics and their ability to counteract the process of inflammation- associated carcinogenesis, process that could not be modelled without the use of animals.

Which non-animal alternatives did you consider for use in this project?

It is possible to model some properties of inflammatory diseases by expanding and stimulating human tissues in vitro or with 3D cell cultures such as spheroids or organoids from human or animal organs.

It is also possible to study inflammatory processes from tissue resections from the patients, for examples from surgical residual material or biopsies. However, these can be very difficult to obtain.

Why were they not suitable?

The current 2D and 3D in vitro culture systems are very simplistic, as they include only few cell types, they can't recapitulate the complex interaction between the several immune cell populations. However, these remain a useful resource and we and others are working towards more refined 3D culture systems.

Patient explants are more relevant models, but they cannot be maintained in culture for more than just a few days. Some aspects of the inflammatory process take a long time to fully develop and therefore cannot be studied in this system. Also, the limited amount of these types of tissue can restrict the number of conditions/treatments that can be tested.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals we will use in this project based on the number of targets and drug candidates we plan to test yearly during this program.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure we use the minimum number of animals, experiments will be carefully designed, taking into account the expected outcomes and statistical analysis of the data. An estimation of the animal being used in this project was done through power and sample size calculation, for example, to compare two means (e.g. control vs treatment), a sample

size of n = 5 mice per group will allow to detect a Cohen'D effect size of 2 (large, acceptable for data with low variability), using a two-sided t-test analysis with a type I error of 5% and a power of 80%. Data previously generated in the literature, together with pilot experiments, will help to have preliminary information that will be used in each individual experimental design. Power calculations will be performed using the NC3R's Experimental Design Assistant, Gpower3.0 or other relevant software.

Sources of variability (cage identity, sex, age, operators etc.) will be controlled. Stratification may be used to guarantee balance between the groups, and animal assignment to experimental groups will typically be randomized. For models with a confirmed sex bias (e.g. sex differences in experimentally induced colitis), only the sex with the desired phenotype will be used. Alternatively, experiments will be performed on comparable numbers of male and female mice whenever possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All our antibodies and related molecules undergo extensive characterization of their activities in a suite of cellular and tissue assays in vitro. Only a small number of selected candidate molecules (usually less than 5) is used in animal experimentation.

To further reduce the number of mice used, we will maximise the amount of data obtainable from each single experiment. Whenever possible, for example, we will obtain preliminary information on the levels of the drug in the mouse blood post injection while testing its general tolerability or during pilot studies. This may allow us to identify any dose-related issues with a specific molecule and guide us in the optimisation of the dosing regimens.

We routinely use the micro-sampling technique for blood collection from tail vein for plasma isolation. Using this method, we can collect blood from the same animals over multiple time points and generate data using a reduced number of animals compared to standard blood collection methods. We are also planning to implement live imaging for the longitudinal analysis of the pharmacodynamic activity of our drug, which will help reduce the number of mice needed.

Additionally, collecting mouse tissues and performing ex vivo experiments will allow us to further reduce the number of live animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use commonly used mouse models of inflammation, such as localise inflammation (air pouch model), systemic inflammation model and disease-specific model (inflammatory bowel disease).

These models have been widely used to strengthen our understanding of human immunology and to help define the pathophysiology of immune-induced inflammatory diseases. The large body of literature available on these animal models will help us define the most efficient means of obtaining scientific data while causing the least harm to the animals.

Why can’t you use animals that are less sentient?

In this project, we will investigate therapeutic interventions that modulate the immune system. Many of the targets for these interventions (both particular cell types and proteins) are not present in non- mammalian species. For this reason, mice with their very well understood genetics and immunology, plethora of well-established inflammation models, and developed technologies to manipulate their genome are currently the species of choice for modelling inflammatory diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be housed in a state-of-the-art animal unit where a high standard of environmental enrichment is usually provided to animals. Animals will be housed in groups to allow for social interaction. However, when required for animal husbandry purposes, they might be housed singly and enhanced environmental enrichment may be provided.

When appropriate, suitable analgesia and anaesthetic regimes will be used to minimize animals suffering. Where novel agents are administered, the duration and frequency of monitoring will be increased to ensure that no animal will suffer unduly. Humane endpoints will be continuously evaluated for each model and refined wherever feasible.

All studies will be reviewed internally by the Project Licence holder and the personal licence holders involved before commencing to ensure that experiments are aligned with the Licence and reflect the implementation of best practices.

All the compounds used in animal studies will undergo extensive quality control checks and where possible, we will use drugs sourced at clinical grade.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The PREPARE guidelines will be used to assist with the planning of experiments and the LASA Diehl guidelines Guidance on dose level selection for regulatory general toxicology studies for pharmaceuticals. The “Guiding Principles for preparing for and undertaking aseptic surgery” (LASA 2010) guidelines will be followed for surgical procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All staff involved in the design and implementation of animal experiments in line with this project licence will be encouraged to participate in relevant inflammation modelling conferences, courses and workshops to stay on top of current trends in the field.

Additionally, they will register on the NC3R mailing list to ensure communication of best practices. Periodical reviews will occur internally and in consultation with the named people to ensure best practice is implemented at all times.

63. Efficacy Testing of Antiviral Compounds and Vaccines for Emerging RNA Viruses

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

virus, vaccines, antiviral, therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop improved vaccines and drugs for the prevention and treatment of disease caused by emerging viruses

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The COVID-19 pandemic has emphasised the need for continued efforts to develop effective antiviral drugs and vaccines against emerging viruses, particularly viruses with an RNA (as opposed to DNA) genome. Effective antiviral drugs are an important first line of defence against an emerging virus until a vaccine is developed. The plasticity of RNA viruses means that they can evolve rapidly to resist inhibition by viral-acting drugs or evade immune responses developed in response to vaccination.

There is therefore an increasing focus on compounds that act against proteins in host cells that are hijacked by viruses to support their replication. These host-acting compounds carry less risk of development of drug resistance and are usually broader acting (i.e. effective against unrelated viruses) than viral-specific drugs. Although effective COVID-19 vaccines were rapidly developed, further improvements to vaccines against RNA viruses such as COVID and influenza would be the generation of immune responses that are not compromised when viral variants arise. Furthermore, a challenge for developing vaccines against respiratory viruses is the induction of immune responses at the respiratory mucosal surfaces to block infection early. Despite the rapidity with which COVID-19 vaccines came into clinical use and decades of vaccine research, there are still some viruses for which safe and effective vaccines are not yet available. In particular, development of vaccines against flaviviruses including dengue and Zika has faced the challenge that it is possible to generate an inadequate immune response that can lead to more severe disease on subsequent exposure to the virus due to a phenomenon referred to as 'antibody-dependent enhancement'.

What outputs do you think you will see at the end of this project?

The project is likely to generate publications in peer-reviewed journals and provide proof-of-concept data to enable additional funding to be secured for the further development of antiviral drugs and vaccines. The expected outputs for objective 1 are data demonstrating the immunogenic potential of novel vaccines. Results will include titration of antibodies in serum samples and measurement of T-cell activation (e.g. using ELISpot assays). Outputs expected for objectives 2 and 3 are demonstration that novel vaccine formulations are effective at protecting against respiratory viruses or antiviral drugs are effective at preventing or treating infection with respiratory virus. This will be demonstrated by a reduction in clinical signs between treated and untreated groups, reduction in virus replication (measured by titrating infectious virus in nasal washes or lungs collected post mortem and reduction in lung damage (detected by histological examination of lung tissue).

The project will provide proof-of-concept data about vaccine formulations and aniviral compounds that will form the foundation for further development towards clinical application in both the human and veterinary medicine fields.

Who or what will benefit from these outputs, and how?

The academic community via publications arising from the studies. This will likely be in the medium to long term.

Individuals (both human and animal) affected by disease caused by emerging RNA viruses may benefit from new antiviral treatments and vaccines in the long term.

How will you look to maximise the outputs of this work?

I have a strong track record in disseminating findings from my research via publication in scientific journals and lay articles and presentations to both scientific and lay audiences. I am engaged with industry and have experience of the requirements for licensing antiviral drugs and vaccines and also collaborate extensively nationally and internationally.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used because of the long history of antiviral drug and vaccine development in the mouse model. This means that experiments to demonstrate efficacy of antiviral drugs and vaccines have been refined to the greatest extent in mice. Adult mice are used for vaccine immunogenicity testing because a mature immune system is required to generate antibodies and cellular immunity to vaccines. Testing the efficacy of antiviral drugs and vaccines requires that infection of untreated animals exposed to infectious virus produces measurable outputs (such as clinical signs of disease, virus replication) in order that a reduction in these outputs can be observed in treated animals.

Typically, what will be done to an animal used in your project?

The majority of animals will have either an antiviral drug or a vaccine administered by one of several routes. The administration of vaccines or drugs is unlikely to impact adversely on the animals as this would not be acceptable in the final product. The principles for protocols of minimal severity will be followed. For most vaccines, one or two 'booster' immunisations are required, and antiviral compounds may require repeated administration over several days. The level of circulating antibodies in the blood (the antibody titre) in response to vaccination will be monitored by blood sampling at appropriate time points.

The typical experience of animals undergoing a non-recovery protocol for the collection of blood and tissue at the end of experiments would be exposure to an anaesthetic gas or the experience of an injection of an anaesthetic drug. The anaesthetic agents would be administered in such a manner as to minimise the risk of panic and the animals would gradually lose consciousness and enter a stage of deep surgical anaesthesia. At this point blood and/or tissues would be collected. The loss of blood during the procedure would ensure that the animals would be unable to regain consciousness; however humane killing would be completed and confirmed according to Schedule 1 of the Act.

Some of the mice will be experimentally infected with a respiratory virus. This will be done by dripping a small volume of infectious viruses into the nostrils of the mice.

The longest experiments (up to around 8 weeks) will be those in which two or three immunisations of a vaccine are required to generate sufficient immune response followed by inoculation with virus to test the efficacy of the vaccine.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will experience mild and transient effects when antivirals and vaccines are administered, the extent of which may depend on the route of administration with intramuscular or intravenous administration requiring a needle and syringe. Intradermal administration using a ‘gene gun’ may also cause transient pain; intranasal administration is less painful but may cause some discomfort. Vaccine immunisation may lead to a period of mild lethargy for typically up to 24 hours. The recognised and characterised adverse effects of the adjuvants used to stimulate the immune system may result in localised redness and inflammation for a period of typically 3 to 5 days. In some cases, a subsequent non painful sterile abscess or granuloma will form at the injection site. These may not resolve during the time scale of the immunisation protocol but will be monitored by the Named Veterinary Surgeon.

When animals are blood sampled in a conscious state, use of refined techniques in line with LASA and NC3Rs guidelines will ensure that any pain is mild and transient in nature. On rare occasions (<5%) a bruise or swelling at the site of blood sampling may form, which should typically subside within 3 to 5 days.

Challenge infection with infectious respiratory virus will cause control animals (i.e. animals that did not receive an active vaccine or drug) and possibly also treated/vaccinated animals to experience clinical signs typical for that virus in mice. As the mouse is not a natural host for respiratory viruses affecting humans and/or livestock or companion animals, the clinical signs experienced by mice are typically mild. There are some strains of influenza A virus (e.g. ‘PR8’) that have been adapted to cause more severe disease in mice so that the benefits of vaccination or antiviral treatment are more obvious.

Rather than develop fever, mice can become hypothermic when infected with PR8. They typically

develop anorexia and demonstrate behaviours consistent with physical discomfort or lethargy, such as huddling, hunching, and fur ruffling from lack of grooming and dehydration. Mouse-adapted influenza strains can cause a fatal primary viral pneumonia. Therefore, mice challenged with these strains will be killed 4 or 5 days after infection (before they are severely affected) and virus infection confirmed by analysing the lung (and potentially other tissues such as nasal turbinates) to detect virus or virus damage using histochemistry and titrating infectious virus. For respiratory syncytial virus, clinical illness is only seen in older mice, manifested by ruffled fur, reduced activity, and weight loss.

For animals undergoing blood sampling and/or tissue collection under terminal anaesthetic, the deep surgical anaesthetic plane will prevent animals feeling any pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity experienced by animals during administration of vaccines or antivirals while conscious will be mild. This will apply to all animals on such protocols.

The expected severity experienced by animals undergoing blood sampling while conscious will be mild. This will apply to all animals on such protocols.

The expected severity experienced by animals after virus infection will be moderate. The actual severity experienced by individual animals will depend on on the virus strain used and dose, and whether animals are in non-treatment groups and/or the efficacy of the experimental vaccines or treatments.

The expected severity of this work is non recovery for all animals from which blood is sampled under terminal anaesthetic.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Efficacy testing of vaccines and antivirals intended for use in humans or veterinary species involves the whole complexity of the immune system of higher order animals.

Which non-animal alternatives did you consider for use in this project?

Due to the complexity of the immune response to viral vaccination and infection, non-animal alternatives are not yet available for this project. However, laboratory work will be undertaken before moving into animal studies (e.g. to achieve optimal expression levels of protein from DNA vaccines).

Why were they not suitable?

See above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers to be used are estimated by projecting the likely number of studies to be performed during the five year duration of this licence from the current demand, which is likely to be at a peak due to the current COVID-19 pandemic situation. Typical experiments will have at least one, possibly up to three treatment groups and a control group with up to around 10 mice per group a likely maximum.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals being used over the course of this project was estimated following a literature search for experiments typical of those to be performed. Prior to designing individual experiments to be performed under this licence, in conjunction with using the NC3Rs Experimental Design Assistant, a systematic literature review will be performed (I have undertaken systematic review training) to identify relevant studies (e.g. studies using a similar vaccine presentation or involving challenge infection with the same virus) in order to obtain the best data possible on effect sizes (for example) to inform study design and power calculations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where animals remain naïve at the end of an immunogenicity study (i.e. control animals), the possibility of sharing tissues with research colleagues will be explored. The facility electronic distribution list and internal intranet notice board can be used to alert colleagues in advance of the availability of fresh tissue for ex vivo use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Adult mice will be used as they are widely used models of viral infections with a broad range of reagents available to measure immune responses to vaccination and infection.

Why can’t you use animals that are less sentient?

Animals at a more immature life stage, species that are less sentient or animals that have been terminally anaesthetised are not appropriate alternatives because immunisation requires a fully developed and functional immune system for the development of protective immune responses and efficacy studies require clinical disease to be manifested in control animals to demonstrate a reduction in infection in treated or vaccinated animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The welfare costs to animals will be minimised by the provision of group housing with environmental enrichment, bedding and or nesting material as standard. Animals will be handled and restrained with the minimal effective restraint - the use of the tail for handling and restraint will be minimised.

The potential for pain and inadvertent infection will be minimised by use of single use sterile needles of the appropriate size for the procedure. Local or general anaesthesia will be applied, where appropriate, under the direction of the Named Veterinary Surgeon. Injection sites will be clipped or shaved and cleaned ahead of injection to minimise the risk of contamination and to allow regular monitoring of the injection site after the procedure. Veterinary intervention will be promptly sought as required and appropriate humane endpoints applied in the unlikely event that adverse effects develop and cannot be controlled. Full records of procedures undertaken, daily monitoring and veterinary requests

will be maintained using both an established electronic facility management software and / or hard copy records.

All licensees and animal care staff will be trained, supervised and signed off as competent for the procedures they will undertake.

Where necessary, supportive husbandry will be provided for mice that have been infected with virus, for example mash and additional warmth and nesting material for mice that become lethargic and/or inappetant.

For studies involving infection with a strain of virus not previously used, a preliminary study will be conducted with enhanced monitoring to characterise the time course of adverse effect progression to ensure that appropriate monitoring and application of humane end points can be applied at a point that minimises the risk of avoidable suffering. This will include out of hours monitoring if required as a result of rapid progression of infection.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA and NC3Rs best practice guidelines will be followed in respect to refining blood sampling and injection techniques. The NC3Rs grimace scales will be used to monitor mice for potential signs of distress. Home Office and FELASA severity information will be used to ensure that the actual severity experienced by the animals can be recorded and limits within this licence adhered to. Body condition score charts specific to the mouse will be used.

Home Office Code of Practice will be used to ensure animal care and housing is appropriate. This guidance will be used in conjunction with the advice available in the NC3Rs Resource Hub for both housing and handling of animals.

The NC3RS Procedures with Care resource will inform personal licensees of refinements in the conduct of the minor procedures undertaken in this licence.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive regular e-mail updates from University colleagues including the Named Training and Competency Officer (NTCO). I am registered for alerts on the NC3Rs website and follow @NC3Rs on Twitter, this alerts me to the latest developments, for example in non-aversive mouse handling. I will continue to communicate with colleagues at the University and other institutes that are conducting similar studies to find out about the latest refinements they have introduced.

64. The Development and Plasticity of Functional Properties of Brain Cells

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Brain, Functional cellular properties, Neurons and glia, Development, Plasticity

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this programme is to gain new knowledge about how the functional properties of a brain cell are established during development and how these properties might change as a result of brain activity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurological disorders, such as epilepsy, autism and schizophrenia, are associated with alterations in the functional properties of brain cells. These functional properties are crucial in determining how individual brain cells transmit information to one another. In the case of neurons in the brain, important functional properties include the type, number and strength

of synaptic connections that the neuron forms with other neurons, plus the electrical properties that determine how the neuron transmits action potentials. In the case of glial cells such as astrocytes, key functional properties include intercellular communication via gap junctions, plus intercellular chemical signalling that regulates the local cellular environment.

Alterations to functional properties of brain cells can result from aberrant events during development, changes to brain cells during a person's lifetime, or a combination of both of these processes.

Therefore understanding the mechanisms by which brain cells establish their functional properties is crucial if we are to understand disease processes and generate new avenues for effective treatments. To advance our understanding, we require a much greater understanding of how the functional properties of brain cells are controlled by their genetic information (i.e. cell intrinsic information) and how much is influenced by ongoing signalling between cells as the brain is developing (i.e. cell extrinsic information). The current work is therefore important as it will provide new knowledge about how the functional properties of brain cells are hard-wired during development and how these properties can change as a result of the brain’s activity.

What outputs do you think you will see at the end of this project?

- The output will be the advancement of scientific knowledge about the genetic and environmental factors that control how the functional properties of brain cells are established and can be altered by activity within the nervous system. The project will produce the following outputs:
- Publications describing novel findings on the functional properties of brain cells that are pre- determined during development.
- Publications describing novel findings on the functional properties of brain cells that are plastic and altered by the brain's activity.
- Datasets on functional properties of brain cells that can be incorporated into computational models of normal and abnormal brain function.
- Advances in understanding of how environmental and genetic factors may influence brain cells in individuals with neurological disorders such as epilepsy, autism and schizophrenia.

Who or what will benefit from these outputs, and how?

In the shorter term:

- The outputs and advances in our understanding of brain cell properties will benefit a large national and international community of researchers working on mammalian brain development and plasticity.

- The outputs and advances will also be of interest to an even wider community of researchers in neuroscience, pharmacology, psychology and psychiatry, including those researching the causes and consequences of neurological disorders.

- The outputs will also benefit computational scientists, who are aiming to produce realistic simulations through which they can better understand brain function in health and disease.

In the longer term:

- The outputs and advances in our understanding of brain cell properties will benefit parties (e.g. the pharmaceutical industry) that wish to identify molecular targets for new products that could improve neural functions in neurological disorders.

- Also, they stand to benefit clinicians who seek to treat patients, or better explain disease processes to patients and their carers.

How will you look to maximise the outputs of this work?

- By publication of the resulting data on "preprint" servers and in peer-reviewed international journals.

- By contributing to the UK knowledge economy through timely publication of high-quality research accessible to academics and clinicians.

- By sharing the data (published and unpublished) through presentations at conferences, as well as at specialist user groups (e.g. clinicians, industry).

- By sharing the raw data and computer code on publically-available repositories.

- Through public engagement activities, such as school outreach and public-facing events.

- By maintaining and developing existing links with the pharmaceutical industry.

- By contributing to the economic competitiveness of the UK through enhancement of researcher career development and the training of young scientists.

Species and numbers of animals expected to be used

- Mice: 19600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

- This research programme will use mice across a range of life stages (from embryo to adult) for the following reasons:

- The mouse brain is a simple model of the human brain, but significant advances in our understanding of neurological disorders are underpinned by studies on small animals.
- The anatomy and physiology of the mouse brain is well described, and previous work provides an important foundation for the research.
- The experimental methods that will be used have been specifically designed for, and successfully used in, mice.
- The project will use a range of life stages, from embryo through to adult, because a large proportion of the project is to study the development of brain cells. Most brain cells are generated before birth, their functional properties emerge as the animal grows during the late embryonic and early postnatal stages, and then their functional properties reach maturity during later postnatal stages.

Typically, what will be done to an animal used in your project?

Mice used in this research programme will experience the following:

- Genetically altered animals will be bred, which is not expected to cause any harm.
- On occasions, animals will be treated for up to two weeks with drugs, the majority of which will have proven tolerability and safety in animals and humans.
- To study early brain development, some embryos will have minute amounts of substances delivered to their brains. This requires a surgery to be performed on a pregnant female under general anaesthetic, and the offspring are typically monitored for up to six weeks as part of the experiment.
- Some animals will have substances delivered to the brain or have miniature recording devices placed on, or in, the brain. This requires a surgery to be performed on the animal under general anaesthetic, and the animals are typically monitored for up to four weeks as part of the experiment.
- Some animals will have their heads temporarily fixed in place for brief periods of time, so that their brain activity can be monitored whilst they are awake. Mice are continuously monitored during these sessions, which typically last no more than three hours. The mice are fully habituated to the apparatus beforehand and would typically experience either one session, or five sessions over a week.
- At the end of experiments, animals may be recorded under terminal anaesthesia, will be killed by humane methods, and cellular measurements will typically be performed in post-mortem tissue. This is not expected to have any welfare impact on the animals.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice in this research programme may experience adverse effects that include the following:

Animals that undergo surgery are expected to experience some pain and discomfort, but recovery is expected to be uneventful. All surgical procedures are carried out under aseptic conditions and with analgesia always provided during the surgical procedures and continued until all signs of discomfort have disappeared.

Animals that have their heads temporarily stabilised might initially experience brief periods of frustration (over minutes), but this is only expected to have a minimal impact upon wellbeing and the animals will be continuously monitored and carefully habituated to the apparatus.

Some animals may experience a modest decrease in body weight, due to a change in sleep-wake pattern or due to administration of an agent that regulates gene expression. These animals will be frequently monitored and weighed, and offered additional palatable food, as required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

60% sub-threshold

10% non-recovery

17% mild

13% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed to achieve the aim of this project because they provide the best way to study the functional properties of brain cells. The functional properties of a brain cell depend heavily upon the type of cell, its developmental lineage, where the cell is

positioned within the brain, how the cell interacts through electrical and chemical signals with other cells, and the brain's activity patterns. The brain's activity reflects a combination of internally- and environmentally-generated signals and animals offer the only way to examine the importance of how the brain's activity changes over the course of an animal's lifetime and varies depending on the brain state, such as sleeping and waking states.

Which non-animal alternatives did you consider for use in this project?

- Computational models of the development and plasticity of brain cell functions.
- Cultured cells, comprising either immortalised cell lines or brain cells derived from induced pluripotent stem cells.

Why were they not suitable?

- Although computer models can provide insights into the behaviour of individual neurons and simple networks of connected neurons, the models lack the complexity to address the key research objectives here.
- Whilst important for some types of investigation, cells grown in culture are either unable to exhibit, or fail to acquire, many of the key functional properties of brain cells. Cultured cells lack tissue organisation, exhibit abnormal interactions with one another, and the patterns of activity in cultured cells do not recapitulate those observed in the intact brain. In the case of brain cells derived from induced pluripotent stem cells, these lack the normal connectivity and activity of the intact brain, and are known to lack mature functional properties.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based upon extensive experience of the technological approaches and experimental design required to address the scientific objectives, which has been acquired by performing related projects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Steps taken to reduce the numbers of animals in this project include:

- The use of experimental designs that incorporate statistical analysis and randomised, blinded experimental methods.

- Pre-emptive use of power calculations to establish the minimum number of animals required to achieve a meaningful result.

- Wherever possible, statistical sensitivity will be increased with experimental designs that compare experimental and control cells from the same animal. This statistical 'pairing' can be used with more powerful statistical tests, which can reduce the number of animals.

- Multiple recordings will be performed to maximise the number of data points per animal. Previous evidence indicates that data from different cells in the same brain can be treated as independent values, which is critical for the application of parametric and non-parametric statistics.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- The use of well-managed and conservative genetic mouse breeding strategies and the use of both male and female mice, as well as heterozygote mice where appropriate.

- The use of methods that detect the activities of multiple brain cells in a single animal, thereby reducing the number of animals required, and at the same time generating large biological datasets to capture the complexity of the neural circuits.

- The use of extensive literature searches to avoid replication of experiments and pilot experiments before embarking on full-scale studies.

- The incorporation of data into computational models to aid further hypothesis development and prediction testing.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- The use of genetically altered mouse lines represents a refined method for selectively labelling and manipulating specific populations of brain cells. These mouse lines are not associated with any adverse effects.

- The delivery of substances to the brain during either embryonic or postnatal life, represents the most refined method to investigate brain cells with a defined lineage, at a specific time point in development, and without complications from causing changes to other parts of the nervous system or organism. This method alleviates the need to

generate new and complex transgenic mouse lines, which requires breeding many generations of mice.

- The use of miniature devices and periods of head stabilization, represents the most refined method for monitoring and manipulating brain cell function in the non-anaesthetised, intact brain. The activity of brain cells is measured using fine microelectrodes and minimally-invasive imaging fluorescence microscopy techniques. This approach is also compatible with the most refined methods for targeting/manipulating genetically-defined populations of cells, using techniques called optogenetics and chemicogenetics.

Why can't you use animals that are less sentient?

Animals that are less sentient:

- Do not have the complex neural tissue, brain cell types and connectivity that are representative of the mammalian brain.
- Do not follow common principles of brain development that is characteristic of mammals.
- Generally have nervous systems that are much less studied, and so there is not the knowledge foundation or databases to support the current project.
- While some questions can and will be addressed using terminal anaesthesia, certain aspects of brain cell function can only be studied if the animal is awake.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will be refined through the following general approaches:

- Health monitoring of adverse effects with humane endpoints, and in a manner that minimises cumulative effects of experimental steps.
- The use of peri-operative analgesia, which will continue after surgery for as long as required to alleviate any pain.
- The optimisation of experimental parameters to produce reproducible effects with the minimum intervention.
- The use of the existing literature and databases to aid selection of cell labelling and manipulation reagents.
- The incorporation of advances and refinements in technologies, including recording devices.
- The use of feeding regimes that reduce post-operative weight loss and speed post-operative recovery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experiments will follow best practice guidance from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (https://nc3rs.org.uk) and from the Laboratory Animal Science Association on aseptic surgery and the administration of substances (https://www.lasa.co.uk).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The primary establishment creates several forums for sharing advances in the 3Rs, in the form of departmental animal welfare meetings and the Animal Welfare Ethical Review Body (AWERB) meetings. Represented at these meetings are the vets, NACWOS and the regional programme manager for the 3Rs, all of whom provide updates and advice on refinements.

65. Nervous System Modelling, Protection and Repair

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

(i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

peripheral nerve, CNS cell culture, tissue engineering, advanced therapies, nerve repair

Animal types	Life stages
Mice	adult, neonate, embryo, juvenile, pregnant
Rats	adult, neonate, embryo, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To improve understanding of how the nervous system responds to damage and disease and to develop and test new ways to treat patients with nervous system injuries. This involves developing tissue engineering, cell, drug and gene therapies and creating advanced cell culture models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Nervous system damage due to injury or disease can be debilitating, causing physical disability and pain as well as impacting on personal and societal interactions for those affected. Understanding damage and promoting repair in the nervous system are key areas of biomedical research. Recent advances in regenerative medicine and the combination of physical and biological sciences to understand tissue damage and repair mean that this field is advancing rapidly. Translation of new nervous system repair technologies to the clinic requires laboratory models to understand cellular and molecular mechanisms underpinning damage and repair, both in vitro and in vivo. To progress new treatments, regulators require a comprehensive set of experimental data to support the application.

Our work involves the discovery and development stages of new treatments for nervous system damage and depends on the availability of robust in vivo and in vitro models.

What outputs do you think you will see at the end of this project?

The overall benefits of the project are:

1. Improved understanding of nervous system damage

2. Identification, testing and development of therapies to treat nervous system injury

These benefits are likely to include new knowledge, publications and treatments and will be achieved through (1) the use of in vitro CNS models to explore cellular responses to damage and to screen potential therapies, and (2) the use of the nerve repair model to develop and test new approaches to treat nerve injury.

The benefits will directly contribute to improving the understanding of nervous system injury and the development of therapies. The cell culture aspects also serve to provide innovative new tools for neuroscience research, screening and testing which are likely to be adopted by other users such as industrial and clinical researchers. An established non-animal approach in our lab is the use of mathematical modelling to simulate new nerve repair interventions, so an additional output from this work is to inform and parameterise in silico models which are powerful tools to accelerate development of therapies and reduce reliance on experimental models.

Long term consequences are likely to include improved clinical treatments for nervous system injury and disease, improved functional outcomes, reduced reliance on nerve autografts, fewer side effects, novel neuroprotective treatments and accelerated development of new therapies.

Who or what will benefit from these outputs, and how?

In the long term the people who will benefit from better treatments for nervous system damage are the patients affected by these injuries, their families, friends and colleagues. Our engagement with patient communities has identified the current lack of effective

treatments to improve outcomes after injury as being a priority to improve their health and wellbeing. Improved treatments will enable injuries to be treated more effectively with fewer side effects, better outcomes, faster return to work, reduced mental illness and reduced cost to those affected and the healthcare and welfare systems.

Clinicians and other healthcare workers will benefit by having more effective treatments to offer patients, improving outcomes, reducing disability, shortening rehabilitation times and reducing complications and side effects.

In the short and medium term, researchers working on the project will benefit from improved training and understanding, career development, and acquisition of advanced transferable skills. The wider research community will benefit through increased understanding of the progression and treatment of nervous system damage.

How will you look to maximise the outputs of this work?

Data will be shared directly with our academic and clinical colleagues, published and disseminated through conferences and networking and will underpin future collaborative projects with other research groups, industrial partners and clinicians.

Open-access publication will make the scientific outputs available freely to all.

Datasets from in vivo experiments will be made available to the global nerve injury research community via an open source data repository.

New therapeutic approaches that show promise will be taken forward for clinical development using our established translational pipeline involving institutional support structures for IP protection, engagement with regulators, clinicians and patients, and commercialisation.

Species and numbers of animals expected to be used

- Mice: 400
- Rats: 2900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice are used because they are the most appropriate least sentient option that have the required anatomical and physiological features for this work.

For CNS cell culture the brains from neonatal animals will be used because these provide a viable source of mammalian cells at an appropriate stage of development for use as in vitro models.

For nerve injury models in vivo adult rodents tend to be used. That is because they recapitulate the key features of adult human nerve injury and regeneration. The nerves in the hindlimb of a rat are of similar dimensions to the nerves in human hands, which means they can be used to model clinical microsurgical repair scenarios directly using equivalent approaches and instruments.

Typically, what will be done to an animal used in your project?

For CNS cell culture, animals will be killed and then brain tissue removed to provide a source of living cells.

For nerve injury, typically an animal will be anaesthetised then a nerve in one hindlimb will be exposed, damaged (e.g. crushed or cut), then repaired microsurgically. A treatment being investigated (or appropriate control) will be applied and then the skin will be closed and the animal will regain consciousness and be returned to its home cage and maintained for a period of a few weeks to months. The duration will depend on what is being studied, for example initial responses to damage may be measured in the first few days, neuronal growth through the injury may be measured after 2-4 weeks and recovery of function can take 3-4 months. During that time the animal will be monitored for signs of adverse effects and the recovery of nerve function may be measured. At the end of the experiment the animal will be placed under terminal anaesthesia and nerve regeneration assessed using electrophysiology, then tissues removed post mortem for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

For the nerve injury model the impact on the animal is loss of sensation and movement in one hind paw. Depending on the injury/treatment, this functional loss will gradually recover during the weeks following the experiment. Animals recover consciousness within minutes following anaesthesia and are able to move around their home cage and can eat, drink and interact normally.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For all animals in the nerve injury experiments the expected severity is moderate. For the animals used as a source of CNS cells the expected severity is mild.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

(1) Before a nerve injury treatment can be considered for clinical use it is essential to assess it in a living mammalian system. Initial development can be conducted using non-animal systems, but it is not possible to progress a new treatment to the clinic without conducting tests in animals. There are currently no alternatives which model all the body systems that would potentially influence outcome.

(2) Cells derived from freshly culled animals are essential for CNS models, however, it is important to note that the resulting cell culture systems are an alternative to live animals in many experiments. Alternatives include fresh human cells, cell lines and various stem cell sources, but in some cases these options are not suitable; cell lines and differentiated stem cells can fail to resemble natural brain cells, and fresh human brain cells are difficult to obtain and grow in culture.

Which non-animal alternatives did you consider for use in this project?

(1) We use non-animal alternatives to model nerve injury wherever possible and these include sophisticated computational and in vitro approaches, including 3D cell culture and engineered tissue models.

(2) Alternatives to rodent CNS cells include fresh human cells, cell lines and various stem cell sources.

Why were they not suitable?

(1) Our computational and in vitro models are good at predicting some of the outcomes of injury and treatment but currently they cannot integrate all of the different body systems that are likely to have an influence.

(2) Non-animal cell sources are used wherever possible but in some cases these options are not suitable; cell lines and differentiated stem cells can fail to resemble natural brain cells, and fresh human brain cells are difficult to obtain and grow in culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to

design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are estimated based on experience of similar work conducted by the research group over the course of previous projects. Each experiment is designed to provide scientifically robust data from the minimum number of animals. Most of the animals included in these numbers are used for breeding approximately (1300 rats and 200 mice) with smaller numbers used in nerve injury approximately (900 rats and 100 mice) and CNS cell culture approximately (700 rats and 100 mice) over the course of 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

(1) For nerve injury, extensive rounds of in vitro and computational modelling are conducted in advance, allowing treatments to be developed to an advanced stage before testing in animals.

Where appropriate, power analyses are performed to determine the minimum number of animals in each experimental group required to provide statistically significant results. This is facilitated by previous datasets that provide an indication of the standard deviation and the relevant effect sizes for the outcome measures. Tools such as the online Experimental Design Assistant (NC3Rs) can be used. The research team is skilled in power analysis and experimental design and where more specialist expertise is required the advice of a statistician is available on site. Randomisation and blinding are incorporated into the design of experiments to reduce bias.

(2) For CNS cell culture, these are prepared only when specific experiments are undertaken and animal numbers can be calculated based on the number of cells required. Typically up to a litter of pups would be culled at one time and their cells pooled and used for multiple experiments to maximise data and minimise variability

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Multiple outcomes are investigated in the same animal and our methods for sensitive quantification of neuronal regeneration enable significant data to be obtained from small numbers of animals per group. Where possible, additional information about the time course of regeneration will be obtained using repeated measurements on the same animal. This further reduces the number of animals required by avoiding having to set up multiple groups with different end point times. Results are compared between groups, normalised against contralateral controls, and compared to other devices or controls. The

standardised nature of the approach means results can be compared directly with previous datasets, minimising the need to include additional groups.

Computer modelling will be used to simulate specific nerve injury and repair scenarios where possible and the outcomes from these models will be used to optimise any subsequent experimental approaches. Where breeding is required, an efficient approach will be used to minimise the number of animals required. Because nervous system damage can affect both sexes, male and female animals will be used in experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

(1) Nerve repair in rats and mice under general anaesthesia is the least severe procedure that enables a reliable assessment to be made in an environment that resembles the human repair situation. Various animal models have been used for peripheral nerve repair research and the rat has become established as the species of choice for gap repair while mice are used where genetic alterations are required. These models are designed to minimise animal suffering and provide valuable preclinical data. The sciatic nerve is the biggest nerve in the animal and is readily accessible with minimal disruption to surrounding muscles; it is the only easily accessible nerve with a long enough section suitable for gap repair; in rats it is very similar in terms of size to human digital nerves enabling devices of clinically relevant dimensions to be tested; loss of function in a limb does not excessively reduce the ability of an operated animal to feed and drink or move around.

(2) For CNS cell culture, rats and mice are the lowest vertebrates whose CNS cells have been characterised thoroughly and show a similar response to damage as the human (e.g. glial scarring). Furthermore, the availability of genetically altered animals with markers such as fluorescent proteins increase the value of using rats and mice for this work.

Why can’t you use animals that are less sentient?

The animals chosen are the least sentient option for the required experiments. More immature life stages and less sentient species are not suitable for use in these studies

because they do not recreate key features of the adult human nervous system aspects needed to be present in the models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Surgical procedures are accompanied by administration of analgesia and regular monitoring to detect any signs of pain associated with the procedure.

In some experiments it may be possible to reduce severity further through transecting and repairing one of the distal branches of the nerve rather than the main nerve trunk, or through transient crushing of the nerve rather than complete transection. These approaches are used when appropriate to reduce the extent of damage caused by the injury.

Where it is beneficial to reduce a potential immune response to an implanted material (e.g. containing human cells) then animals can be immunosuppressed using drugs, or alternatively immunocompromised strains will be used to minimise the potential harm caused by the additional handling and injections associated with drug administration.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Licensees will be directed to published best practice available via the NC3Rs resource library when planning experiments. Relevant available guidance includes topics such as welfare assessment, anaesthesia, aseptic technique in rodent surgery and administration of substances, as well as the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.

PREPARE guidelines (norecopa) provide a useful checklist to be used when planning new experiments and ARRIVE guidelines will be followed during reporting of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The researchers will remain actively involved in the 3Rs research community and will attend workshops and symposia and monitor the NC3Rs gateway and e-newsletters and new literature to stay informed about advances in the 3Rs. Opportunities that are identified for further refinement will be discussed with the Named Persons and animal unit staff as well as within the research group and, where it is appropriate for an approach to be changed, this will be communicated to all licensees by the PPL holder.

66. Motor Neuron Development and Disorders

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Motor neurons, Axon guidance, Zebrafish, Motor neuron disease, Congenital Cranial Dysinnervation Disorders

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, adult, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The single main purpose of this project is to elucidate mechanisms that guide the axon growth and connections of motor neurons, and to unravel how abnormalities of these mechanisms can lead to disorders. The study will incorporate detailed description of the ways in which axons project to their target muscles, as well as manipulations of gene and protein functionto elucidate the molecular mechanisms that underlie axon guidance. Genetic models will be used to identify how particular mutations lead to motor neuron disorders and the effects on neuroanatomy and behaviour will be analysed.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The mechanisms by which axons grow and find their targets are poorly understood. Motor neurons are a key neuronal group that are responsible for locomotion and other animal behaviours. Gaining insight into the mechanisms of axon guidance and its molecular underpinnings will allow us to elucidate the aetiology of disorders. The manipulations of genetic and molecular function that we propose will give insight into the role of genes during normal processesof axon guidance and connectivity. As well as illuminating developmental processes, these models will provide insights into neurodevelopmental and neurodegenerative disorders of motor neurons.

What outputs do you think you will see at the end of this project?

The project outputs will be scientific papers and conference presentation. We will share data with relevant other research groups and collaborators and data and technical insights will be shared on platforms such as ZFIN. Any reagents or transgenic lines will be shared with the research community via relevant repositories after publication of our findings.

Who or what will benefit from these outputs, and how?

Beneficiaries of the work will be immediate colleagues within our establishment and those in the neuroscience and developmental research community. This includes basic researchers interested in mechanisms of axon guidance and the genes involved, and those interested in how insights into the genes and proteins studied can translate into other systems. Other beneficiaries include clinicians and scientists studying neurodevelopmental and neurodegenerative disorders that affect motor neurons. In particular, our work has direct implications for studies of eye movement disorders, which are relatively common in the human population with squint having a prevalence of 1%. Whereas squint is not a life- threatening condition, it produces difficulties for sufferers, and can be very debilitating. We will share our findings with clinicians in this area, which provide insights for screening of patient DNA, and for approaches to therapies. We also plan to work on mechanisms of causation of motor neuron disease (MND: incidence ~2.5 persons per 100,000). Unravelling the contribution of several genes to MND would eventually benefit patients through improved diagnosis and treatments.

How will you look to maximise the outputs of this work?

The outputs of our work will be datasets consisting of imaging data defining phenotypes in the developing zebrafish. Behavioural assays will also be used to analyse eye movements and locomotion. These data will be shared with other scientists in our University, nationally and internationally, published in peer-reviewed journals and presented at conferences. We will also share information with clinicians to improve patient care and to inform clinical studies to identify mutations in human populations

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 13,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish will be used for this project and the majority of our analyses will involve experiments performed on larvae before the 5 dpf timepoint at which these animals become protected. Moreover, zebrafish have a large number of advantages for studies of nervous system development and disorders. They can be imaged readily, are genetically tractable and exhibit measurable behaviours from 2 or 3 dpf, and a number of transgenic lines are available. In the case of studying motor neurons, the motor systems have similar properties to those of humans, including the ocular motor system and the segmental arrangement of spinal motor neurons. Hence studies in the zebrafish can provide very useful information about genetic function and the aetiology of motor neuron disorders in humans. We will examine various wild type and transgenic zebrafish lines. We will breed adult fish and collect naturally spawned embryos in order to analyse phenotypes in larval stages, typically 1-5dpf. Zebrafish have several advantages over other model organisms. Large numbers of embryos can be obtained from each breeding pair, larvae can be treated using water soluble pharmaceutical agents for high- throughput drug screening and are translucent making them easy to image and analyse.

Typically, what will be done to an animal used in your project?

We will maintain various wild-type zebrafish lines, lines carrying mutations and transgenic lines. We will use cutting edge techniques, such as CRISPR/Cas9, to generate genetically altered models of neurodevelopmental and neurodegenerative diseases. Most breeding of freshwater teleost lines is undertaken by natural spawning following pairing of male and female fish, but in some cases frozen sperm and in vitro fertilisation will be used, yielding embryos which are then allowed to develop.

Skin swabbing or fin-clipping will be used in some cases. This is because, for some of the transgenic or mutant lines received or produced by this project, identification of carriers from outcrosses is only efficiently achieved by PCR amplification of DNA extracted from surface mucus/a small tissue sample. This is routinely done in zebrafish by swabbing the skin or section of a small portion of the caudal fin of young adults, under sterile conditions and light anaesthesia. A shortened caudal fin does not affect the swimming abilities of the fish and regenerates extremely well.

In order to analyse alterations in nervous system development, function or viability, behavioural analyses will need to be performed. In the majority of cases this will involve non-injurious filming of juvenile or adult fish in environments where they arepresented with

specific visual stimuli, or in which their swimming patterns in response to certain stimuli are monitored.

What are the expected impacts and/or adverse effects for the animals during your project?

In the vast majority of cases, the mutations and transgenes carried by the adult fish are unlikely to have any harmful effects (subtle morphology changes which have little or no effect upon viability and health). However for some mutations, the fish may develop defects in neural development, which might lead to behavioural abnormalities. In other cases, fish models of motor neuron disease might lead to compromise of axon development and neuronal death. This could in turn lead to muscle atrophy and loss of movement. Whereas these changes would entail adverse effects on the larvae, we plan to analyse the animals before 5 dpf. Adults would not be kept as genotypes which are likely to yield such adverse effects.

Any viable transgenic animal that shows harmful abnormalities such as inability to feed or swim will be culled by schedule 1 methods as soon as the abnormality is apparent. This also applies to juveniles and larvae.

Immobilisation of fish for eye movement or neuronal activity analysis may cause minor distress or discomfort but most tests are likely to only last a few minutes and fish will be killed by schedule 1 procedures at the end of the testing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities of the majority of procedures (95%) to be undertaken is mild. However, for a few transgenic lines (5% or less), there is a possibility that some genotypes will develop neurodegeneration leading to a severe assessment.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals is necessary for this project as the axon guidance of neurons, formation of neural circuits and analysis of motor neuron degeneration requires insights in

the intact animal, including the interaction of neurons with their environment. The zebrafish is an optimum model for our approaches due to its huge advantages for imaging and genetic studies. Our procedures our unlikely to generate pain or distress. In the rare event that the fish need to be kept at the end of a procedure, it is first monitored for sign of pain/distress (lack of activity, appetite or sexual behaviour). Any individual presenting any sign of pain or distress that is not rapidly curable will be killed under schedule 1.

Which non-animal alternatives did you consider for use in this project?

Recent work has been undertaken to elucidate the mechanisms required to differentiate ocular motor neurons from stem cells in rodents, which could potentially give an in exhaustible source of experimental material. Thus far, these protocols are inefficient and generate very few relevant cells. However, the majority of our work over the years has focussed on early stages of development, before these species are protected. We have used in vitro approaches, which although they involve the culling of animals to generate neurons, can give very large numbers of datasets from a single animal, in order to identify mechanisms and molecules that are involved in axon guidance processes and disease. Only then do we perform analyse in whole animals (larvae) in order to perform critical experiments, e.g. transgenesis that involve an intact environment.

Why were they not suitable?

As mentioned above, we are not yet able to use cell lines because they are not available or reliable. However, we have sought to reduce our animal use as much as possible in our projects as outlined below, by performing only the most critical experiments in intact animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The principle of reduction is applied for all procedures used. Number of embryos and adults used are defined statistically as the minimum required to ensure results. An indication of these numbers isgivenby starting numbers of embryos in most protocols being 100-150. Microinjection of these embryos would be followed by incubation to later developmental stages, with mortality of around 10%. Staining and imaging procedures would yield a sample of around 30 fish with 15 giving good images. The experiment would be repeated 3 times per condition. These procedures should yield a

sample size of around 45 per condition, with statistical analysis using non- parametric tests (Mann-Whitney).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Creating stable transgenic zebrafish lines is by itself a way to reduce number of animals used. This method allows us to test the effects of gene manipulation readily, reducing the number of animals which need to be bred for analysis, as transient gain and loss of function approaches require many more animals. In addition, transgenic fish with fluorescence for analysis of axon pathways minimise the need for staining protocols.

In studies over several years, we have optimised analyses of neuroanatomy and behaviour in order to reduce the number of animals needed. For example we are able to extract multiple metrics from images of axon pathways in order to achieve significance.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The minimum number of wild-type and transgenic zebrafish required for optimal breeding will be maintained. This will be determined from our extensive experience using this model organism. We will perform initial pilot studies, such as using transient genetic alteration techniques on small numbers of animals to determine their relevance in modelling either neurodevelopmental or neurodegenerative disorders. This will allow us to determine which genetic modifications to establish as stable zebrafish lines, and therefore optimise the number of animals to be used in the project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish as a model for neurodevelopmental and neurodegenerative disorders in this project. Most experimental procedures to be undertaken are unlikely to cause distress or harm to the animals. It is possible that some genetic alterations may affect the ability of larvae to swim freely. All animals will be closely monitored for signs of pain/distress and culled using schedule 1 methods if the effects are not rapidly curable.

For some of the transgenic or mutant lines received or produced by this project, identification of carriers from outcrosses is only efficiently achieved by PCR amplification of DNA extracted from a small tissue sample. This is routinely done in zebrafish by section of a small portion of the caudal fin of young adults, under sterile conditions and light anaesthesia. A shortened caudal fin does not affect the fish swimming abilities and regenerates extremely well.

In order to analyse alterations in nervous system development, function or viability, behavioural analyses will need to be performed. In the majority of cases this will involve non-injurious filming of juvenile or adult fish in environments where they are presented with specific stimuli, such as presenting fish with a rotating drum with vertical stripes and filming their eye movements, in order to measure the optokinetic reflex.

None of these procedures cause pain, suffering or distress to the animals, apart from in a very low proportion of animals when using models for motor neuron disease, as explained above.

Why can’t you use animals that are less sentient?

We will use zebrafish as they are a less sentient model organism compared to other vertebrate species. The majority of procedures will be restricted to larval stages of development (1-5dpf), in order to further reduce the sentience of the model used. Certain protocols, such as examining the optokinetic reflex or startle responses require intact and fully conscious organisms. However, where appropriate, other procedures, such as imaging, will be performed following terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For some of the transgenic or mutant lines received or produced by this project, identification of carriers from outcrosses is only efficiently achieved by PCR amplification of DNA. We have optimised all protocols including DNA extraction following fin-clipping to maximise yield and remove the smallest piece of fin possible. Where appropriate, we will transition to using skin swabbing as a more refined method for genotyping following optimisation. Animals are monitored following the clipping procedure. Fish are checked each day (2 - 3X) and monitored for any changes or signs of ill-health. Animals embedded in agarose for behavioural tests are culled immediately after testing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to engage with the most relevant literature using zebrafish as model organisms for disease to ensure that the numbers of animals used are in line with, but do not exceed, those publications. We will continue to consult the information available

through the NC3Rs to ensure that our animals receive the highest standard of care and can implement any required changes to our animal welfare practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular updates from the NC3Rs which we will engage with and look to implement any relevant changes to our animal welfare/facilities. Our establishment has introduced a yearly award to encourage research into the 3Rs and their implementation. We will continue to work closely with our animal technicians and NACWO to ensure that our zebrafish experience the highest standard of care.

67. Exploring the Mechanisms of Tertiary Lymphoid Organ Formation

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Salivary Gland, Inflammation, Autoimmune, Tertiary Lymphoid Organs

Animal types	Life stages
Mice	juvenile, adult, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to examine the role of tissue resident fibroblasts in the formation and maintenance of tertiary lymphoid organs in chronic inflammation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inflammation is the process by which the body's own immune cells enter a target tissue, such as the salivary gland, gut or skin for example. This process occurs in response to infection, injury or where the body's immune system reacts to healthy tissue in a process called autoimmunity. When inside the tissue these immune cells can aggregate together in structures called tertiary lymphoid structures or organs (TLOs). We see these structures in

the tissues affected in certain diseases such as Sjogren's Syndrome. How and why these structures form and their exact role in inflammatory tissue pathology is poorly understood. If we can understand why and how these structures form we may be able to develop novel drugs to treat this disease.

What outputs do you think you will see at the end of this project?

We anticipate that this project will lead to the generation of novel data which will give rise to mechanistic insights into diseases with a significant unmet clinical need.

Project outputs will include:

- advances in scientific knowledge on the role of fibroblasts in autoimmune salivary gland and joint inflammation.
- scientific and lay publications of our findings and methodology.
- presentation of our data and/or methodology to the wider scientific community through conference oral and poster presentations.
- identification of novel therapy targets or agents which can be taken forward to develop new therapies.

Who or what will benefit from these outputs, and how?

Short-medium term

Scientific developments and innovations leading to our enhanced understanding of the role of immune effector fibroblasts on the formation of tertiary lymphoid structures will have an immediate impact on the ongoing projects at the host organisation, and also further afield upon dissemination. Moreover, the project aims to improve our understanding of the processes driving pathology in chronic disease, specifically disease pathways mediating the formation and persistence of tertiary lymphoid structures.

Medium-long term

We will disseminate our findings at national and international scientific conferences with the view of fostering further collaborations based on the concepts and ideas incorporated in this proposal. We envisage that these collaborations will occur during and following the completion of this project, and therefore represent a medium to long-term impact of this work. Using these collaborations, we will develop the infrastructure needed to translate these findings into clinical trials and ultimately, clinical practice, therefore fully exploiting the translational potential of this work.

Long-term

Clinical academics, pharmaceutical companies and patients directly will benefit from advances in our understanding of disease pathology along with identification of novel targets which can be taken forward to develop new therapies. We will develop collaborative networks to realise the translational potential of our findings over the subsequent 5-10 years following the completion of this project.

How will you look to maximise the outputs of this work?

Dissemination of information:

We will work with the relevant teams within our establishment to facilitate communications and resulting impact. We plan to use several routes to disseminate our findings to the wider scientific community and the public that will facilitate end-user engagement, namely:

(a) Peer-reviewed publication: we aim to publish high impact papers based on the findings generated from the research grants funding this project licence. In addition, our group has a strong tradition of publishing methodology papers and negative data to ensure that groups do not unnecessarily repeat experiments that either technically are flawed or biologically yield the null hypothesis.

(b) Presentations: we and our collaborators will present data at internal seminars along with national and international conferences, such as British Society of Rheumatology, European League Against Rheumatism Annual Congress and American College of Rheumatology.

(c) Dissemination via international societies: we and our collaborators are active members of various scientific societies including: European Workshop for Rheumatology Research and British Society for Rheumatology, allowing our findings to be disseminated to the wider scientific community in societal magazines and training workshops.

Enhancement of public understanding and engagement with research:

We will take advantage of several events organised by the Public Engagement Working Group at our organisation and local charities to facilitate the public's awareness of our research:

Lay Resources: we would develop lay resources, in collaboration with our patient/public research partners (PRP), for publication of Atlas of Science. Additionally, we will continue to involve patients and the public in the delivery and dissemination of research generated from this project.

I actively engage with our rheumatology patient research partners in all stages of our research including research strategy and planning, as well as dissemination to lay audiences. I also work closely with our CLUSTER consortium (https://www.clusterconsortium.org.uk) parent champions who are parents of children with

childhood onset arthritis. These partnerships are pivotal in developing our ongoing research strategy and ensuring our work is disseminated to lay audiences.

Clinical networks and translational collaborations:

My team and I are active members of several multi-institute research centres and will be able to present our findings at least twice annually at ongoing Centre seminars. We will also attend clinical conferences (e.g. European League Against Rheumatism, American College of Rheumatology, British Society of Rheumatology) where we will present our data and foster collaborative opportunities for translational research across the fields of rheumatology, ageing and chronic inflammatory diseases. As a team of both clinicians and scientists we have access to unique patient cohorts and therefore the expertise and ability to translate findings rapidly to early clinical studies.

Species and numbers of animals expected to be used

- Mice: 3000 over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the best vertebrate model for the study of persistent disease because:

1. the main components of their immune system are shared by humans; this is essential where immune responses as opposed to the function of individual genes is being studied and thus will produce satisfactory results.

2. a wide range of wild type and genetically manipulated strains of defined genetic make-up are available

3. an extensive range of reagents is available for analysis of the cellular and molecular interactions occurring during immune responses

For the cannulation experiments we will use mice aged 8 weeks onwards. This is to ensure that their salivary glands are well developed and physically possible to cannulate.

Typically, what will be done to an animal used in your project?

Breeding and maintenance protocols:

Animals will be grouped or paired, mated and subject to such other non-painful procedures as may be required for the conventional breeding and maintenance of animals with specific genetic alterations or harmful mutations. Animals may be marked and genotyped

by appropriate husbandry methods which cause no more than momentary discomfort. Specifically this includes ear notching or the withdrawal of a very small amount of blood. Some animals will be humanely killed via a Schedule 1 method with tissues taken for analysis.

For cannulation experiments:

Whilst part of an experimental cohort, animals may be given substances via intraperitoneal, subcutaneous or intravenous injections, or by oral gavage. Blood samples may be taken according to recommended published guidelines via the saphenous vein (on a weekly basis) or via cardiac puncture under terminal anaesthesia. For the cannulation procedure, mice will be anesthetised using an injectable reversible anaesthetic. Once sedated, the opening duct of the salivary gland will be cannulated with a substance delivered directly into the gland. Cannulation may be repeated up to four times with animals humanely killed up to 28 days post-cannulation. Animals will be humanely killed via a Schedule 1 method or following a larger bleed performed under a terminal anaesthetic at the end of the experiment with tissues taken for analysis. Procedures will be undertaken using the most appropriate anaesthetic and analgesia will be given where appropriate. Any new substances or route of administration will be tested in a small pilot study and the mice monitored daily for signs of adverse effects.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may experience pain and discomfort from administration of substances or blood sampling, but the discomfort is expected to be minimal and not long-lasting. Cannulation will result in localised pain and discomfort, so mice will anesthetised and analgesia given where appropriate. some weight loss is expected as the animals may refrain from eating and drinking after the procedure. This is expected to last for only one day after which a full recovery and return to normal intake is expected. Any animal showing deviation from normal behaviour as judged by body weight, body condition, general and coat appearance, gait or behaviour will be treated with pain relief (only if the adverse effect is considered to be due to pain) and further monitored. Before adverse effects exceed a moderate severity level, animals will be killed to prevent any ongoing pain or suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity limit on this licence will be moderate. Approximately 80% moderate and 20% mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to study the inflammatory response three components need to be examined; time, place and cell type. While place (organ) and cell type (leucocyte or stromal) can be examined relatively easily in humans, it is difficult and in some cases unethical to perform multiple biopsies and adoptive transfer experiments in human patients with chronic diseases such as Sjogren's Syndrome (SS) without underpinning preclinical data that support therapeutic utility. Furthermore, manipulating cells as a therapy has the potential to impact on the normal function of the individuals immune system. We will need to determine therefore, whether manipulating these cells as a therapy could affect an individuals ability to also fight infection. We therefore need to examine these diseases in models with a fully functional immune system analogous to humans. Small rodents are the lowest mammals that can be used to recapitulate the response of the human immune system to localised inflammation. Mice at a more immature life stage cannot be used due to their salivary glands not being fully developed. The model requires the use of live animals since our aim is to track changes in the immune response over a course of hours to weeks, therefore terminally anaesthetised animals cannot be used.

Which non-animal alternatives did you consider for use in this project?

We considered a range of co-culture models and organoid experiments as non-animal alternatives, using patient samples and archived tissue. These techniques will supplement where possible animal experimentation and therefore reduce the overall number of animal experiments needed.

Why were they not suitable?

We and our collaborators have pioneered a range of in vitro co-culture models that have furthered our understanding of leucocyte-stromal cell interaction in chronic inflammation. However we have now reached a point where we cannot proceed to test our ideas without resorting to animal models of inflammation. A key strength of our work is that it combines both human and animal models so that each can be used to inform the other and therefore minimise an over reliance on mouse models of disease. While there are no in vitro alternatives to this work, we will use cell culture experiments and target validation experiments on human samples alongside the program of work explained in this licence to support and validate our findings. We are confident that this approach will prevent us from developing a large program of work in vivo that is void of a functional relevance in human disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used specific mathematical calculations based upon previous studies and the likelihood of our interventions producing positive results to estimate the number of animals we will use in our study. For all experimentation, the lowest possible number of animals will be tested whilst ensuring that the experimental result is robust.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A key strength of our work is that it combines both human tissue work and animal models so that each can be used to inform the other and minimize an over reliance on mouse models of disease. This will give us the option to stop the line of research at any stage where our findings fail to show any significant increase in our understanding or therapy potential in Sjogren's Syndrome.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our previous work has mapped the specific time points in this model that are critical for the analysis of TLO development. This work will allow us to limit the number of observations and therefore animals required in each experiment, as we can now focus on specific time points depending on the objective of any specific experiment. To maximise the information gained from a single animal, we aim to perform multiple analyses on tissue obtained from each individual animal.

New interventions will first be tested for efficacy using in vitro models prior to use in vivo. Where new routes of administration or new interventions are being examined, pilot studies will first be established in 2-3 mice prior to full experiments. Subsequently these pilot data will be used in the specific mathematical calculations described above to ensure that we use the minimum number of animals needed to obtain statistically significant results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Building upon previous work, we will use a well-defined and published mouse model of Sjorgrens Syndrome (a disease of salivary gland inflammation). We will induce salivary gland inflammation in mice by administration of a non-harmful virus into the submandibular salivary gland via a procedure that directly cannulates the salivary duct.

1. The procedures listed in this licence have been optimised to minimise discomfort for the animals. All cannulations are carried out under anaesthesia with analgesia provided both before and after the procedure, and as required over the days following virus administration. The virus administered has been altered to be non-harmful and does not result in widespread infection only local inflammation at the site of injection. Our experiments are short-term, taking place over hours or a few weeks, with very clearly defined humane endpoints. Mice that undergo procedures and/or mice with uncharacterised genetic mutations will be monitored closely and appropriate action taken if they demonstrate adverse effects. Animals will be humanely culled unless, in the opinion of the NVS or NACWO, suffering can be remedied promptly and successfully using no more than minor interventions, such as pain relief and hydration.

2. We have refined the protocol to immunise mice by single subcutaneous injection in the upper surface of the paw and not in the foot pad so as to cause less discomfort.

3. When using genetic mouse models we will, where possible, use inducible models where genes are switched on conditionally. This will limit the duration of any potential harm or suffering to the mice affected by a change in expression of that particular gene.

4. Where possible we will use established reagents and protocols that we have developed and refined to treat the mice. The lowest doses of agents that are well tolerated and effective will be used.

5. Where necessary, male mice transgenic for the gene of interest will be mated with WT females in order to exclude indirect effects on the progeny derived from gene overexpression in the pregnant female.

Why can’t you use animals that are less sentient?

Less sentient animals do not possess the same sort of salivary gland structure, and often their vascular tree and immune system do not fully represent that of humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have already heavily refined the cannulation protocol and the associated peri- and post-operative care. We will continue to seek advice from the NVS regarding best use of anaesthetics and analgesics, particularly for any mouse strains which have never been previously cannulated. Any strain which has never been cannulated will receive increased post-operative monitoring following the procedure. We will have to use injectable anaesthetic rather than inhalation anaesthetic due to needing access to the animals mouth. We are currently planning a pilot study in cooperation with the NVS on refining the procedure to use a shorter acting injectable which allows for faster post-operative recovery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animal welfare is a key consideration in all of our protocols, and we will be guided by our NACWOs and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.

If undertaking a systematic review, we will use SyRF (the free online platform for researchers) to perform a systematic review and meta-analysis of animal studies. This will allow us to keep up to date with any improvements in protocols and techniques which may reduce or replace the use of animals.

Finally, we will follow the LASA guidelines Guiding Principles for Preparing for and Undertaking Aseptic Surgery (www.lasa.co.uk/wp-content/uploads/2018/05/Aseptic-Surgery.pdf) and by the Home Office Minimum Standards for Aseptic Surgery (www.procedureswithcare.org.uk/ASMS2012.pdf) when undertaking aseptic surgery and providing analgesia. We will also follow the PREPARE and ARRIVE guidelines for our planning and reporting of our experimental findings.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I or a member of my research team will attend the 3Rs regional workshops that run at our establishment on a regular basis and sign up to the NC3Rs newsletter. We will also be reviewing the literature on regular basis in our journal clubs and through this network we will discuss any refinements that could be applied to our own work.

68. Determining Mechanisms of Tumour Development and Relapse Following Treatment

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Chemotherapy, lymphoma, neuroblastoma, drug resistance

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand why cancer develops and how it changes in response to treatment, in particular, to determine why some cancers become resistant to therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is one of the major causes of death worldwide with at least 1 in 2 people developing this disease in their lifetime and only half of these surviving. It is therefore clear that we must conduct more research to understand not only why cancer develops in the first place but also why treatment is not successful for many.

What outputs do you think you will see at the end of this project?

This research will lead to new information regarding the mechanisms of cancer development as well as the reasons for resistance to therapy. This work will be published in the scientific literature as well as presented to both lay and scientific/medical communities at research conferences and meetings. In particular, through interactions with clinical communities as well as pharmaceutical companies to enable the translation of the research findings into real clinical impact. This could be in the form of the development of new therapeutic targets and drugs and/or clinical assays that can be used to determine whether a patient will have a good outcome following treatment. Alternatively, this research may facilitate clinical decisions such as whether their treatment needs to be altered due to a lack of response to the therapeutic protocol.

Who or what will benefit from these outputs, and how?

In the short term, the outputs of this research will benefit those in the medical and scientific communities to facilitate future research activities. In the medium-term, we these findings will be applied to the design of clinical trials and associated biological studies to learn more about cancer in the real world, outside of the lab. In the long term, it is hoped to develop new treatment strategies that may include new drugs or different combinations of existing drugs to improve cancer outcomes.

How will you look to maximise the outputs of this work?

This research is part of many ongoing collaborative research activities, including Europe-wide and international research initiatives. In particular, both established research networks and clinical trials groups will be engaged whereby these data will be presented at network-wide meetings towards clinical application and to inform future research opportunities. In addition, via a Europe-wide training network, this research will also contribute to the training of fledgling research scientists and clinician scientists in order that this future generation will be better informed and will be able to take forward the findings of this research to real clinical application. The research conducted under this licence will also be applicable to patient groups globally including those residing in low-income countries that are affected by the cancers that will be studied. Important collaborations with such populations will enrich the work.

In all cases, the work conducted will be published in the scientific literature, disseminated to both lay and scientific audiences at meetings and conferences, and communicated to interested parties such as pharmaceutical organisations to initiate collaborative research activities.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our research uses mice to understand why cancer develops, in particular mice that have been genetically modified to express proteins suspected to cause cancer. This work is necessary as a mechanism to prove that certain changes to the DNA code drive cancer development. Furthermore, to determine whether inhibition of the activities of these proteins will be effective in the treatment of people with cancer. We also use mice that have no immune system so that we can grow human tumours in the lab. If the mice have an immune system, they will reject the human tumour. Adult mice with no immune system host human tumour cells and allow them to grow. We can try to cure them of the disease.

Typically, what will be done to an animal used in your project?

We will breed mice that have no immune system so that they do not reject the human tumours. However, an immune system is necessary to enable some drugs to work, in particular drugs called 'immunotherapeutics'. To study these drugs, we will develop 'humanised' mice. Humanised mice are mice that do not have their own immune system are instead injected with human blood cells to create a human immune system. Mice are reconstituted with human immune system cells (humanised mice) by intravenous (iv) injection. Tumour cells are grown under the skin (sub-cutaneous) of these mice so that tumour growth can be easily monitored by measurements with a type of ruler called a calliper, and by feeling the mouse at the site of injection. On occasion, the sub-cutaneous environment cannot support tumour growth and so we also attempt to culture the primary tumour cells at other sites in the body such as in the abdomen (intraperitoneal) or in the blood (intravenous).

Treatment of the mice with investigational drugs starts once the tumours reach a certain size (as determined by calliper measurements, or in case of intravenous/intraperitoneal growth, by looking for tumour cells in blood samples and using imaging techniques such as magnetic resonance imaging (MRI) scans). In order to better mimic the human scenario, whereby tumours are generally diagnosed when they are relatively large (preventing normal bodily activities leading to symptoms and subsequent diagnosis),

treatment commences when the tumours reach 0.5-1.0 cm at their widest point. Mice are humanely killed at the pre-defined study endpoint, which is either the end of the treatment regimen, or when the tumour reaches the maximum recommended size of 1.5 cm in any one dimension. In some cases, the tumours are allowed to reach 2 cm when more cells are required for downstream analysis (particularly when analysing tumour cell subsets such as the very small populations of cells that remain after therapy, so-called treatment persister cells, or cancer stem cells). In these cases, the mice for these studies are clearly identified before commencing the project and are monitored closely for side- effects of tumour growth (e.g., paralysis). Drugs are administered by the most appropriate route according to how drugs are metabolised by the body (so-called pharmacokinetic/pharmacodynamic parameters). This can be through the mouth, intraperitoneal (into the abdomen), sub-cutaneous (under the skin) or intravenous (in the blood) or via a mini pump implanted under the skin. In the past we have dosed mice with the drugs for a maximum of 30 days, but it has become apparent that this is not enough time – when the drug treatment has completed, despite it looking like the tumour has disappeared (even when using high resolution devices such as MRI scans), the tumour returns. As such, we would like to have more flexibility in drug delivery schedules allowing us to give the drug with a variety of treatment schedules (e.g., metronomic dosing (on, off, on, off drug etc), drug holidays (on, off for a long period of time, on etc.) and co-administration of different drugs over longer periods of time. In all cases, mice are closely monitored for any clinical signs that might indicate that the drugs are toxic, for example by monitoring the weight of the mice daily.

Genetically altered (GA) mice (mice that have had their DNA code altered) will largely be used for ex vivo (outside the body) studies of tumour cells. These mice express cancer-causing genes, so-called oncogenes, in certain parts of the body, and develop tumours at these sites. For the most part, the GA mice we use produce tumours of the immune system and therefore develop tumours at sites of immune system components such as the thymus (an organ that sits above the heart), spleen and lymph nodes. Tumours are detected by regular palpation (massage) of the mice, and we will incorporate imaging, such as MRI scans, at key timepoints and on presentation of clinical signs to allow early tumour detection to minimise suffering. To allow tumour growth, the GA mice are aged, sometimes as long as 15 months of age. The GA mice are also used to examine how tumours develop and, in these cases, the mice are killed by a humane method shortly after genotyping (checking the DNA code) for analysis of tumour cells outside of the body. We may breed GA mice to incorporate other genetic elements into our studies. For example, clonally expressed T cell receptors (e.g., TCR transgenic mice), the 'flags' on the surface of immune cells that recognise invading pathogens, to see if these also contribute to tumour growth.

To assess the effects of potential secondary events on tumour development, i.e., environmental factors that might contribute to the development of cancer, GA mice might also be administered stimulatory agents to assess the rate of tumour development and incidence in comparison to control groups. For example, TCR transgenic mice expressing

oncogenes in immune cells might be dosed with agents that activate the immune cells. This might include ovalbumin protein or components of this, called peptides. We will also examine the role of other environmental agents such as microplastics that are shed from a range of plastics and polymers. These agents may be delivered by the routes previously described for drug administration but might also include delivery through the nose, perhaps in an aerosol.

Typically, work conducted under this licence allows mice to live under standard conditions until tumours develop. As soon as tumours are detected, the mice are humanely killed, and the tumours harvested for studies conducted in the lab and outside of the body (ex vivo).These tumours do not grow without a host biological system and the mouse provides the least sentient being that can facilitate tumour growth. However, at all times we attempt to grow the tumour cells in the lab in plasticware and as technologies evolve that facilitate this, we will incorporate this more into our research approach.

In the case of human tumours grown in mice with no immune system, the tumour cells are typically injected and grown under the skin on the hind flanks of the mouse. In some cases, for example if we are studying leukaemias, cancers of the blood, the cells may be injected into a blood vessel or at another site that is more representative of where the tumours grow in humans, such as the abdominal cavity. The mice are monitored continuously for their well-being, and should the tumours prevent their normal activities such as feeding and moving, the mouse is humanely killed, and the tumour harvested for ex vivo studies or re injection into a new host mouse. In some cases, we treat the mouse bearing the tumour with different drugs to determine if these are good options to cure the tumour and prevent its continued growth. In these cases, the mice are again closely monitored for any clinical signs, not just those that might be caused by the physical presence of the tumour, but also those that might be due to the drug being administered. If any of the mice show clinical signs, they are immediately humanely killed. However, this is a rare occurrence as we monitor tumour growth not just by eye, but also using imaging modalities such as MRI scans and ultrasound so that tumours are harvested before they impact the wellbeing of the mouse. Drug treatment experiments are typically conducted over periods of months with the initial months being the period in which the tumour grows and in the subsequent time, the mouse is being treated. If the treatment approach is not successful and the tumour continues to grow, the mouse is humanely killed before the tumour reaches a size that would impact on the wellbeing of the mouse. On some occasions, when we think the mouse has been cured as we cannot detect any tumour cells in the body, the mouse is allowed to survive in case the tumour relapses or returns, so that we can study the tumour cells at this point to understand why they have grown back. To prove that the cells which grow back are truly resistant to the drugs, we may also treat the mice again with drugs to see how the tumour responds.

What are the expected impacts and/or adverse effects for the animals during your project?

In general, the mice do not experience any adverse effects from tumour growth as we carefully monitor their health status. We do not allow tumours to grow in size to the extent that they affect the wellbeing of the mouse. However, should the tumours affect the wellbeing of the mouse, it is normally due to growth of the tumour near to the hind limbs which can cause paralysis. Affected mice are humanely killed immediately. As the mice are checked daily, at most, a mouse would experience paralysis for no more than 24 hours.

Some mice can experience weight loss due to the effects of the therapy, as do people with cancer undergoing treatment. However, whilst on the protocol, the mice are weighed daily to observe any changes that might trigger humane killing such as weight loss and lethargy. Should a mouse show any clinical signs, they are immediately humanely killed.

On rare occasions, a new drug being tested can have unexpected adverse effects. However, to minimise this possibility, we search the literature for existing and known toxicity data for a given drug before use. If such data does not exist, we start experiments with low doses of drug in one or two mice as a pilot project and scale up dependent on the results. As the mice are checked daily, at most, a mouse would experience paralysis for no more than 24 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mouse: moderate 20%
- Mouse: Mild 80%

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer is a complex disease that requires a number of host factors to be 'just right' for growth and propagation. For the most part, as a scientific community we do not know what these factors are, but they likely involve food and nutrients provided through the lymphatic and blood circulation as well as locally provided compounds such as growth factors and

messengers produced by the immune system and the cells providing the structural support of the tumour. Until the conditions required for tumour growth can be emulated in vitro, we need to continue to use the mouse to host tumour growth and to be able to examine the tumour as essentially, a new organ. Secondly, how a tumour responds to treatment can vary depending on how the body as a whole reacts to administration of a drug, specifically, how the body processes the drug. Drugs are normally given to a patient orally or via the blood stream - these routes of administration can affect how a drug is metabolised and therefore its efficacy in the body. Therefore, to fully assess the activity of any given drug in affecting tumour growth, in vivo studies are ultimately required.

Which non-animal alternatives did you consider for use in this project?

In vitro growth of tumour cells as single layers of cells or as organoids.

In vitro drug screens on established cancer cell lines.

Why were they not suitable?

Our experience shows that the tumour cells do not grow in these in vitro systems. It is clear that they require the environment of the mouse host to survive, likely due to the requirement for some, as yet unidentified growth factors.

For drug studies, whilst established cancer cell lines can be informative in determining the efficacy of a drug, the effects of bodily systems on the metabolism and, in some cases, activation of the drugs, must be determined in vivo. In addition, the established cell lines have evolved in the lab to become less representative of the tumours that were first removed from the patient to establish these cell lines, i.e., the cell lines have evolved and adapted to growth in a petri dish and no longer truly represent the genetics of the original tumour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In the previous project licence, we used 800 mice in the first 4 years of the project. I anticipate that we will continue to use mice at this rate as this current application is a continuation of the prior work.

However, in the last project period, our research was inhibited by the pandemic, and we had not secured sufficient funding to complete all of the proposed work. We now have

secured considerable research funding for all aspects of the research proposed and do not anticipate interruptions due to global pandemics. As such, I expect that are usage will triple over the 5 years of the project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We follow PREPARE guidelines in our experiments. In particular, in the design of drug studies, we perform Power calculations to make sure we use the minimum number of mice to reach significant results and are assisted in this with the use of the NC3Rs experimental design assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have developed in vitro methods for tumour cell growth using feeder cell lines to conduct drug screens with patient-derived material. Where cells cannot be grown in vitro, we perform experiments with primary cells ex vivo. Ultimately, drug studies have to be conducted in vivo, particularly when in vivo drug activation is necessary.

We have also begun to use imaging techniques in our studies so that tumour development in vivo can be monitored more easily. In particular, we have used MRI to assess tumour growth and will apply this technique more in the future. We will also use ultrasound in this manner.

If a drug has been tested before in mice for the purposes we intend, we search the literature first for previously conducted toxicity studies, if available, to identify LD50 doses (the dose that has been shown to lead to the death of 50% of the animals in that study). We then conduct control experiments starting with low doses and incrementally increasing them whilst monitoring mice for any clinical signs before progressing to each higher dose. These pilot studies allow us to assess the tolerability of the drug and the amount of drug required to kill the tumour cells.

If a drug has been tested in vivo before, we assess the literature to decide on the best drug dose for our studies rather than repeating efficacy studies.

Mice are randomly assigned into treatment groups and are blindly administered drugs, the identity of which are unknown to the administering technician.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice:

NSG immunodeficient mice

Transgenic mice including strains expressing oncogenes predisposed to developing cancer

Techniques:

Sub-cutaneous, intraperitoneal or intravenous injections of tumour cells: these routes of tumour delivery are conducted by fully trained personnel without anaesthesia and have very minor and transient effects on the mouse. The mice are closely monitored after the procedure for any clinical signs.

Intraperitoneal, intravenous, oral and sub-cutaneous mini-pump delivery of drugs: these routes of drug delivery have transient and mild effects on the mice when conducted by trained personnel. They are conducted without anaesthesia but by fully trained individuals. Surgery to implant sub-cutaneous mini pumps is conducted under sedation or brief general anaesthesia from which the mouse is monitored closely for a full recovery. The mini pumps, when inserted correctly, have no effect on the wellbeing and normal activity of the mouse.

Imaging - MRI, ultrasound and PET/CT: allows us to monitor tumour growth when they are not detectable by palpation alone, preventing 'unseen' tumour growth to continue to the point where clinical signs ensue. Mice undergo sedation to improve their comfort during the procedure.

Why can’t you use animals that are less sentient?

In order to study the development of cancer it is important that we consider the roles of the whole body in order to better model the scenario in humans. This requires components of the extracellular matrix, stromal cells, immune system components and a blood supply, factors that at present are not possible to fully mimic in vitro. In addition, a defining feature of cancer is the ability to invade surrounding tissues and to metastasise - these can only be truly modelled in vivo. As such our research to investigate origins and development of tumours will continue to be performed in vivo with GA mice. We will also continue to use mice as we have a plethora of GA mice that have previously been developed and characterised available to us. In order to conduct experiments assessing established tumours, we employ patient derived xenografts (PDX) as the least sentient system in which to grow primary human- derived tumours. With our PDX models we attempt to grow the tumour cells in vitro after each passage through the mouse but have had limited

success even with 3D culture conditions. We continue to refine these in an attempt to establish non-animal alternatives and reattempt in vitro culture at each stage.

When short term culture is sufficient, e.g., for determination of early chemotherapeutic sensitivity, we conduct initial experiments in vitro to determine active drug concentrations. However, due to effects of bioavailability, experiments are then conducted in vivo to predict the potential consequences in human patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will add enrichment to the home cage (such as tunnels) and conduct non-aversive handling (tunnel and cupping), habituation and acclimatisation, e.g., if mice ordered in from an external supplier, will be allowed a habituation period of at least 1 week so the mice can settle into their new environment.

When performing dosing, mice are first acclimatised to the handling technique leading up to the day of dosing, (such as scruffing), so as not to overwhelm the animal all at once.

We will employ immunodeficient mice to propagate human tumours and wild type congenic mice to propagate tumours derived from GA mice. Both models will be used to assess the impact of chemotherapeutic treatments on tumour response and clonal tumour evolution. The most appropriate site for tumour propagation in vivo will be determined based on experience and will largely constitute sub-cutaneous growth of solid malignancies and intraperitoneal or intravenous for liquid tumours. All of the techniques we use are already well established and result in minimal suffering to the mice. We perform all sub-cutaneous injections with two trained animal researchers so that the procedure is quick and accurate (one to hold the mouse, the other to inject). We also capture mice using non-tail handling techniques prior to scruffing for injection (the NSG mice are very placid and respond well to handling). All trained animal researchers are also regularly assessed in their use of techniques by experienced animal technicians in the unit. We also attempt, when possible, to employ the services of animal technicians within the unit who regularly perform these techniques and are therefore very experienced resulting in minimal suffering to the mice. When performing injections, we suspend the reagents in the smallest volume possible to reduce the time taken to undertake the procedure although this is dependent on the solubility of the compound. Tumour growth is monitored by calliper measurement or palpation of internal tumours and liquid tumours by blood sampling. When attempting to grow a new tumour for the first time, the mice are carefully monitored using a staging system for clinical signs until we can establish the growth properties of that tumour. We also employ imaging techniques such as MRI and ultrasound where possible to monitor tumour growth. In this manner, tumours can be monitored, and the mice culled before overt clinical signs manifest.

Our mice are expected to develop tumours and therefore in order to minimise suffering we use an in- house designed Excel database to record experiments and severity levels

reached. We also check our mice for tumour development by palpation and observation of clinical signs on a daily basis. Sub- cutaneous tumours, once established, are measured using callipers on a daily basis to ensure the size limits are not exceeded. At the same time, the mice are monitored for any clinical signs and any issues with the grafted tumour; in particular, tumours are monitored for ulceration, any growth that limits movement and general condition. Mice experiencing any issues with grafted tumour humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Advice on experimental design will be sought from the statistical services unit and by using the NC3rs experimental design assistant (www.nc3rs.org.uk/experimental-design-assistant-eda). Factorial design of experiments will be considered where necessary to minimise animal usage and for quantitative experiments, power calculations will be used to determine sample sizes generally using a significance level of 5%, a power of 80% and a least practicable difference between groups of 25%. However, we will also plan experiments based on our prior experience of working with the described model systems and dependent on experimental limitations, for example, the number of cells that can be isolated from a human tumour and therefore propagated in the mouse; we expect treatment group sizes to consist of between 6-8 mice, but this may be less. Each experiment will be conducted following the development of a study plan whereby a statement of the objectives of the experiment, a description of the experiment, covering such matters as drug dose, frequency of dosing, number of mice per group, experimental endpoint, data analysis and the experimental material are described. Mice will be randomly assigned to treatment groups and attempts will be made to blind studies. In essence, we will conduct all experiments according to the ARRIVE guidelines in accordance with NC3rs procedures in order that data can be disseminated by publication in the peer reviewed scientific literature. We will also consult the 'Guidelines for the welfare and use of animals in cancer research' published by Workman et al., British Journal of Cancer, 2010.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly monitor the scientific literature for advances in the modelling of human cancer, in particular paying attention to advances in the development of in vitro organoids and 3D bioprinting and will review journals such as ATLA (Alternatives to Laboratory Animals) Journal: https://journals.sagepub.com/home/atla. As these techniques improve and are better able to mimic the human tumour microenvironment, we will apply for funding so that we can adapt our research to these technologies. We will also regularly refer to the LASA Guidelines: https://www.lasa.co.uk/current_publications/ and to the RSPCA website (http://science.rspca.org.uk/sciencegroup/researchanimals).

We also subscribe to the local 3Rs email enquiry list that provides regular updates on advances in the 3Rs and their implementation and signposts the reader to important and

relevant resources. We also regularly consult the local 3Rs search tool. We also subscribe to the NC3Rs webinar series and will attend these events as appropriate as well as consult the NC3Rs Gateway (https://f1000research.com/nc3rs).

69. Establishment of Patient Derived Xenografts from Biopsy Samples

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Xenograft, Patient biopsy, Tumour Microenvironment, Biobank

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to establish Patient-Derived Xenografts (PDX-man-to-mouse tissue graft)from a variety of human tumour biopsy samples and to identify those elements of the environment in which the tumour grows (Tumour Microenvironment-TME) that are critical to ensuring that mouse xenograft tumour models optimally represent the human disease. As part of this process, we aim to generate sufficient tissue for use in laboratory-based drug development assays or other projects and to freeze and store samples in a Biobank.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer directly affects 1 in 2 of the population during their lifetimes and despite significant progress being made in the last two decades, it still remains a major cause of mortality meaning improved therapies are required.

Despite advances in transgenic (genetically modified) technology, use of new species such as zebrafish and the availability of new strains of rodents, there still remains a level of disconnect between laboratory evidence of effectiveness and toxicity of new anti-cancer agents and the outcome of their trials in the clinical setting with drugs tested. Thus, there is currently a drive to determine ways of ensuring animal and laboratory models of cancer are more predictive and a number of areas are being focused on including:

- Use of ‘close-to-patient’ tissue
- Humanisation of the Tumour Microenvironment (TME)

Therefore, the main purpose of this licence will be to establish xenografts derived from fresh patient samples, incorporating elements of the TME if appropriate, to provide close-to-patient tissue to use in our experimental animal and laboratory models, which we hope will be better able to represent the variety between and within patients and will, consequently, be more clinically relevant.

Given the variety of cancers which affect the population, we will investigate a number of different tumour types, namely

Colorectal Gastric Pancreatic

Oesophageal Brain

Lung Cholangiocarcinama Prostate

Ovarian Breast

What outputs do you think you will see at the end of this project?

These finding will directly feed into both our cell based and experimental animal based projects, by enabling us to produce more accurate "human-like" models, supporting cancer drug discovery pipelines.

Data and findings generated under this project will be published in peer reviewed journals and disseminated at national and international meetings by several members of the group.

The establishment of a Biobank of frozen tissue will provide a valuable resource for future studies.

Who or what will benefit from these outputs, and how?

The main beneficiaries will be scientists working on developing clinically-translatable drugs and imaging agents who will use the models in their research. In the longer term the beneficiaries will be patients as the models will enable development of more clinically-effective, affordable drugs and imaging agents which will improve cancer diagnosis, treatment and outcomes.

During the lifetime of this project, this will arise from the generation of superior ‘humanised’ cancer xenograft models incorporating human cell components, derived from patient tissue, which are more representative of the patient’s tumour in terms of biology and response to treatment than standard xenograft models. They can also be used to establish flat (2D) and 3-Dimensional laboratory-based model systems in order to reduce/replace animal use during the early stages of drug discovery. These would provide better, more robust models that are more predictive of individual patient response, and will therefore, provide more accurate results in drug development research which can be used both by ourselves and our collaborators. This may result in the development of more effective drugs that do not fail when they reach the clinical phases of drug development, reducing the numbers of animals used in developing drugs that are unlikely to be clinically useful and the costs and time associated with this process. Hence, ultimately this will also benefit patients by reducing disease burden and mortality through development of better drugs.

Longer term, through the establishment of a bank of frozen PDX samples, we will secure and develop a valuable resource for future use by, not only us, but also shared with other collaborators whose projects would also benefit from this technology, which, in turn, will reduce the overall numbers of animals needed to generate tissue for their experiments.

We also aim to be able to capitalise on knowledge gained during the above processes to further develop our cell based models and develop methods to produce "close-to-patient" cells in the laboratory, reducing/replacing the use of animals for this purpose too.

How will you look to maximise the outputs of this work?

We will maximise these outputs by publishing findings in high impact, open access peer reviewed journals and by presentation at national and international meetings. We will utilise existing networks e.g. BACR, EACR, NC3Rs, LASA and other national and international working groups to further disseminate our findings and we expect both positive and negative results generated will be made available.

The establishment of a Biobank of frozen tissue will provide a valuable resource for future studies and, where possible we will share this resource, and our knowledge and technical skills with other University and external researchers to fully exploit the impact of our research.

We will also publicise our findings via Patient Participation & Involvement groups, as appropriate.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The application of our experimental technologies requires a species with a body structure similar to a human, and it must also be able to generate a sufficient amount of tissue for our experimental needs. Mice are the lowest species in which a genetic mutation has produced an immunodeficiency (a full or partial impairment of the immune system) which allows the growth of human tumours without rejection. There are a number of different strains available with varying degrees of immunodeficiency so the specific strain choice is dependent on the level of immunodeficiency required to allow growth of the particular tumour type being implanted.

Experience has shown us which immunodeficient mouse strain is most appropriate for particular tumour types, but we will always try to improve take-rates by trying new strains as they become available. Therefore, pilot studies may be carried out to identify the most suitable immunodeficient species for a particular tumour type.

Adult mice are the most appropriate age as our samples come from adult humans.

Typically, what will be done to an animal used in your project?

All mice will undergo at least one procedure i.e. it will have a small amount of tumour (fragments or cells) taken from a patient biopsy sample implanted under the loose skin on its flank or, in the case of breast tumours, into the fat pad under the mammary gland, using an appropriately sized needle. Local anaesthetic may be rubbed on the skin first if a large sized needle is necessary. The tumour fragments may be mixed with other cell types and/or a biological support gel to stimulate or encourage growth.

The tumour, which stays as a discrete lump under the skin, will be measured at least weekly, depending on growth rate, until the maximum allowable size (1.2cm diameter) is reached, at which point the animal will be humanely killed and the tumour removed for processing.

Hormone supplements may be required to stimulate certain tumours to grow i.e. oestrogen for breast and ovarian tumours, and testosterone for prostate tumours. These supplements will be delivered via the feed or the drinking water for the duration of the experiment.

In 20-25% of mice which have undergone the tumour implantation procedure, other cell types making up part of the tumour's natural environment (TME) may be injected into or around the developing tumour no more than 3 times during the experiment. These mice will, therefore, undergo between 2 and 4 procedures.

Growth rate of the tumour depends on which type it is, but most experiments end after 3 months, with around 20% lasting up to 6 months.

What are the expected impacts and/or adverse effects for the animals during your project?

In a typical case (95%), the mouse will experience minimal discomfort from the implantation of tumour fragments via an implant trochar (large gauge needle) under local anaesthetic and physical restraint. The resulting tumour growth will be monitored by measuring with callipers, again while physically restrained by an experienced technician. The growth of the tumour should have no impact on the animal’s health and welfare and the animal will be killed when the tumour reaches the maximum allowable size (1.2cm mean diameter). Injected tumours grown subcutaneously or in the mammary fat pad, may ulcerate or develop shiny patches which could lead to ulceration, independent of tumour size, in around 5% of the animals. The animals will, therefore, be observed regularly as soon as growth is established, and any mouse will be humanely killed and the tumour excised as soon as the skin covering the tumour appears to be stretched or broken.

Due to their position, mammary fat pad tumours may interfere with normal movement of the hind limb (5%). At the first indication of this, the animal will be killed, regardless of tumour size.

Injections of cells into or around the tumour should not cause any side effects. However, if any damage to the skin, such as ulceration, is seen as a result of these injections, the animal will be humanely killed.

There may be specific adverse effects to any hormone substances being delivered. Therefore, animals receiving such substances will be carefully monitored and any exhibiting mild symptoms, such as minor weight loss or signs of dehydration or urine scald, will revert back to normal diet or water until recovery is observed. Furthermore, testosterone, may cause increased aggression and fighting amongst males; animals will be separated and singly housed where appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice will experience no more than mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While our experimental programme is focused strongly on in vitro (laboratory-based) non-animal modelling, it is currently not possible to generate a sufficient amount of cells required to develop these models directly in petri dishes from patient samples. Therefore, mice are still required as a vector for this initial tissue establishment and maintenance, until sufficient stock tissue has been generated for in vitro experimentation and investigation, and for banking down by freezing, when the line will be closed in the mice.

Which non-animal alternatives did you consider for use in this project?

A variety of cell culture techniques, including single layer (2D) and 3-Dimensional growth methodologies were considered.

Why were they not suitable?

These other methods currently do not generate a sufficient volume of tissue for the subsequent in vitro

studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used per sample is dependent on the amount and quality of tissue supplied from the operating theatre. Typically, after preparation, the tissue will be

implanted into 1 or 2 mice, but never more than 3. Once the initial samples have grown they will be transplanted into the minimum number required for tissue generation and examination by e.g. histology, immunohistochemistry.

Typically, this will be a further 2 animals but exceptionally, may be up to 4 depending on the amount of tissue required, and how much good quality tissue is available for transplant. This will happen for as few sequential transplants (passages) as possible to generate sufficient tissue to fulfil the above objectives, typically 5 times, although some tumours may stop growing after e.g. 2 passages, or not grow at all. When sufficient stocks have been generated and banked down, or when growth stalls, the line will be closed and will no longer be passaged on.

By using disaggregated (separated out) cells rather than tumour fragments, where the sample is suitable, due to the number of cells generated using this protocol, we are able to implant more mice per tumour thus reducing the number of donor mice required.

Therefore, group size is sample size driven to safeguard the quality and quantity of the developing tumour xenograft, rather than to provide statistical significance, so we will use the minimum number of animals needed for the amount of tissue required, based on experience and data gathered from previous licences.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

From previous experience we calculated our total number required based on the minimum number of animals necessary for the tumour sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will introduce refinement methodologies developed during our previous PPL to optimise quality and quantity of tissue generated from each sample, thereby requiring fewer animals to produce the required amount of usable tissue. For example, we have shown that the take-rate is higher when human stromal cells are co-implanted or, for particular tumour types, in specific immunodeficient mouse strains. Thus, we have fewer numbers of mice in which no PDX is regenerated as a result of refinements we have introduced.

We will also carry out pilot studies on new mouse strains to see if they can produce better growth and, therefore, require fewer mice to generate sufficient tissue, and incorporate these strains into the project if they prove to be successful.

This study also involves the generation of a frozen tissue biobank which researchers will be able to use in further studies reducing the need for more animals to be used and maximising the tissue use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The application of our experimental technologies requires a species with an appropriate mammalian body system, and it must also be able to generate a sufficient amount of tissue. Mice are the lowest species in which a genetic mutation has produced an immunodeficient status which allows growth of human tumours without rejection in a clinically relevant setting. The strain choice is dependent on the level of immunodeficiency required to allow tumour growth as the genetic background may be a factor in determining tumour establishment.

Experience has shown us which immunodeficient mouse strain is most appropriate for particular tumour types, but we will always try to improve establishment and growth rates. Therefore, pilot studies may be carried out to identify the most suitable immunodeficient strains for a particular tumour type, and to try new strains which may become available.

All mice will be housed in containment systems (isolators or IVCs), with appropriate barrier husbandry procedures, in order to protect the mice from possible infections due to their weakened immune status.

Our procedures have been refined to minimise suffering by using local anaesthesia e.g. EMLA cream, and a trochar (large gauge needle) implant method rather than a surgical intervention as the impact of induction and maintenance of general anaesthesia would be greater than that of this method. The anaesthetic cream provides sufficient anaesthesia during recovery from the trochar introduction and further anaesthesia or analgesia is not required during the tumour growth phase as the scientific end point is reached prior to the tumour causing any pain or discomfort to the animal.

Implantation of disaggregated cells is even less invasive than the trochar method, being performed as a subcutaneous (under the skin) injection with a needle rather than a larger implant trochar, however, not all samples are suitable for this methodology. This methodology also creates greater consistency of growth between animals.

In the case of hormone dependent tumours e.g. breast and prostate, we deliver the necessary hormones by incorporating them into the diet or water, rather than by pellets implanted under the skin, having worked closely with the diet company to establish an

appropriate dose equivalent to that of the subcutaneous pellets. This refinement is less invasive, as it is not a surgical procedure, and will reduce the commonly seen effects of oestrogen pellets such as urine scald or bladder stones.

The favoured site for tumour implantation will be subcutaneous, under the loose skin of the flank, with the exception of breast tumours which will be implanted into the fat pad containing the mammary glands (also via the subcutaneous route) as these sites will not compromise the animal's movement or normal behaviour and are easily accessible for measuring.

Primary tissue, particularly oesophageal, gastric and colorectal tumours, may contain residual bacterial contamination. To prevent infection, the primary tissue is washed and incubated with antibiotic media overnight prior to implantation.

Other biological supporting components, such as stem cells, are administered by the injection routes which deliver them directly to the tumour, and these routes should cause no more than transient discomfort.

The mouse's weight will naturally fluctuate during the course of the tumour growth but, given the minimal impact of the entire procedure, it should not fall by below 10%. Therefore, this would be the point where we would take appropriate action, rather than the more generally accepted 20%.

Why can't you use animals that are less sentient?

Adult mammals are required to replicate the body systems and life stage of the human patients donating samples, thereby ensuring appropriate comparison and relevance to human body systems. Mice are the lowest sentient species in which tumours will grow in this comparative manner.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be monitored by trained technical staff (the same ones who have carried out the procedure and, therefore, understand the model) daily and they be weighed and tumours will be measured at least weekly. The maximum allowable tumour size will be as detailed in the NCRI Guidelines i.e. a mean diameter of 1.2 cm. However, any loss of condition or mobility or reddening/thinning of skin which will lead to ulceration will lead to the animal being humanely killed, regardless of tumour size.

All procedures will be regularly reviewed to see if any further refinements can be introduced.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The project will be carried out under the following guidelines-

NCRI Guidelines for the Welfare and Use of Animals in Cancer Research LASA Best Practice Guidelines

Norecopa PREPARE Guidelines

Findings will be reported according to the NC3Rs ARRIVE Guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will have regular liaison with the Named Persons and the AWERB.

I will keep up to date with publications and bulletins from bodies such as NC3Rs, RSPCA, Laboratory Animals.

My membership of Animal Science and Welfare bodies and attendance at their meetings and workshops and my network of colleagues working in similar fields will also keep me abreast of latest development, and I will take every opportunity to introduce any suitable refinements into the protocol, which I will then disseminate further via the above avenues.

70. Enhancing Neuroprotection through Activation of ERK5 MAPK Signalling

Project duration

2 years 0 months

Project purpose

(a) Basic research

(b) Translational or applied research with one of the following aims:

(i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neurodegeneration, Neuroprotection, Alzheimer’s disease, ERK5, MAPK

Animal types	Life stages
Mice	neonate, adult, pregnant, embryo, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The ERK5 MAPK pathway communicates signals from the surface of the cell to the DNA in the cell nucleus and is known to support the survival of some cell types. The aim of this project is to investigate the role of the ERK5 MAPK pathway in neuroprotection by determining if activating the ERK5 pathway can protect neurons from damage typically observed in the early stages of Alzheimer’s disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The primary outcome of this project is to establish that activation of the ERK5 MAPK pathway is neuroprotective. As well as furthering our understanding of the ERK5 pathway in providing neuroprotection in Alzheimer's and other neurodegenerative diseases, this work could also identify new treatment targets.

What outputs do you think you will see at the end of this project?

The key output of this project will be the confirmation or rejection of the hypothesis that the ERK5 MAPK pathway protects neurons from damage typical in early Alzheimer's disease. The results from this proof-of-principle project will then inform further studies that will validate the ERK5 MAPK signalling pathway as a drug target in an Alzheimer's disease model such as APP/PS1 (GA) mice.

Who or what will benefit from these outputs, and how?

Answering the key research question whether activating the ERK5 pathway is neuroprotective will be beneficial for basic science as well as for the advancement of therapeutic treatments. In the shorter term, this project will lay the foundation for future work aimed at testing the mechanisms involved as well as validating ERK5 as a novel treatment target in an Alzheimer's disease model. The long-term aim of this work is to identify and characterize novel therapeutic targets and to developed them for the treatment of neurodegenerative disorders.

How will you look to maximise the outputs of this work?

All findings from this and any follow-on projects will be published under consideration of the ARRIVE guidelines. New knowledge, such as confirmation of the neuroprotective properties of the ERK5 MAPK pathway, will be further disseminated at scientific conferences (e.g. at Alzheimer's Research UK meetings) and through scientific seminars. For projects following on from this pilot study, we will build on existing collaborations with experts in electrophysiological measurements of synaptic plasticity and behavioural paradigms to maximise the impact of the work. This will allow the team to address the aims from different angles, thus maximising the information that can be gained from the animal models.

Species and numbers of animals expected to be used

- Mice: 190

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Alzheimer's Disease is a very complex condition that affects neuronal morphology and function. To date, no established cell line provides the level of synaptic complexity and neuronal functionality required for this project. It is therefore necessary to collect and grow neuron cell cultures from young mice. Mice are the established and well-documented source for the preparation of primary neurons, specifically from the hippocampus region of the brain. The project utilizes well-established protocols, which will ensure the greatest chances of successful cell growth, thus reducing the number of required animals.

For future studies, the genetically modified mouse model from this project offers the additional opportunity to further study the ERK5 signalling pathway in an Alzheimer's Disease model by studying their behaviour and taking electrophysiological recordings of synaptic plasticity.

Typically, what will be done to an animal used in your project?

Animals with a genetic alteration than is not expected to cause adverse effects will be bred by natural mating. The animals will have a sample taken (usually an ear biopsy) for genetic analysis. They will be killed, either by a schedule one method, or by decapitation (young mice only) if fresh brain tissue is required.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected for live animals, the transgene will only be induced in the cell cultures.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild – All animals

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed experiments have to be carried out in neurons, as the mechanisms involved in the modulation of synaptic processes cannot be investigated in any other cell type. Mice are the established and well-documented source for the preparation of primary neurons, specifically from the hippocampus. Lower vertebrates or invertebrates do not have the complexity of the neuronal networks required for this study of neurodegeneration.

Which non-animal alternatives did you consider for use in this project?

Established cell lines.

Ex-vivo wildtype (non-GA) primary cells. UK Brain bank.

Computer modelling.

Why were they not suitable?

To date, no established cell line can substitute for the level of synaptic complexity and functionality required for this project. In vitro assays cannot adequately model the complete array of molecular and cellular interactions necessary to fully understand the processes in the brain.

Ex-vivo experiments using primary cells from wildtype animals are useful for certain studies. However, all currently available in vitro methods to genetically modulate the pathway (such as transfection or transduction with viruses) will only reach a small sub-population of the primary cells. Genetic models such as the one proposed here offer the significant advantage that all of the cells will be equally modified, which is essential for obtaining reliable data for this project.

The UK Brain bank offers a range of human brain tissue samples, which will be considered for follow- on projects. However, the current project requires live cells.

Alternative methods such as computer modelling are not yet advanced and accurate enough to predict the effect of genetic knock-in and would not allow us to achieve the objectives of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The key consideration for estimating the numbers of animals was the number of offspring required to produce the primary neurons necessary to achieve the objectives of the

project. The calculations have been based on similar experiments previously performed in my laboratory.

5 breeder pairs (10 animals) are needed to produce the required pups within the time frame of the project. Finally, the caMEK5DD mice will be received as heterozygous animals that need to be bred to obtain the homozygous mice required for the experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The breeding strategy has been designed following advice from the JAX website and discussions with the BSU staff. The breeding scheme to produce animals for the preparation of primary cells has been devised such that equal numbers of GA and control animals will be produced, so that there will be no surplus animals at this step. Statistical power calculations have been used to estimate the number of animals required to obtain statistically meaningful (significantly different) results. Finally, the use of GA animals will enable the activation of the ERK5 MAPK pathway in all primary cells obtained, increasing the statistical power of the experiments and thus reducing the number of animals from which cells will need to be prepared.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding has been designed to produce the required genotypes in a 50% ratio. Experiments will be conducted on both male and female animals, as the gender is not relevant for the ex-vivo experiments in primary neurons. All animals that will be killed (including the breeder animals at the end of the project) will be offered for use to other researchers within the university to make use of tissue from the culled animals. Throughout the project, all experiments will be analysed by appropriate statistical methods (ANOVA followed by a post-hoc test for pairwise comparisons). The experiments for the relevant experimental group will be stopped when statistical significance at $p<0.05$ has been reached, even if less than predicted numbers of experimental repeats have been used. The experiments will also be stopped if it becomes evident that it is likely that a specific treatment will not result in a statistically significant difference. Advice will be sought from biostatisticians if required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are universally used for work involving genetic alterations and they are the established animals for the preparation of primary neurons. This project is designed such that the transgene will only be expressed ex-vivo, i.e. in the established primary cell cultures. This ensures that there will be no adverse phenotypes present in the mice resulting from the transgene, thus minimizing any detrimental effects.

Why can’t you use animals that are less sentient?

The breeding of the GA mice has to be performed with adult mice. However, as the transgene will not be expressed in these mice, no adverse phenotypes are expected to result from the procedure. The primary cells will be prepared from neonatal mice, which is the optimal time for obtaining viable neurons. Neurons from less sentient animals will not have the required complexity for this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

There are no expected harmful phenotypes resulting from the breeding of the GA mice as the transgene will only be activated after killing. To monitor for any unexpected harm, the animals will be regularly monitored. Animals are checked daily (twice on weekdays) by competent animal care staff who will notify the PIL holder and/or NACWO of any indication of pain, suffering or distress including but not limited to abnormalities in behaviour and/or appearance, such as poor coat condition, piloerection, unusual posture (hunching), discharge or lack of grooming to eyes, ears, nose, ano- genital region, facial grimace, obvious signs of injury, abnormal movement, reduced activity, reluctance to socialise, reduced alertness, vocalisation, indications of reduced eating or drinking. We do not expect to see any harmful phenotypes in relation to the genotype, but litter sizes and health will be monitored for any indication of a decline in health status. Breeder animals will not be kept longer than necessary – up to 1 year - to prevent age-related adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The key procedure for this project is the breeding of GA mice, which will be using standard protocols as provided by ASRU. The “Breeding and colony management - Best practice guidance” on the NC3R website will also be used to ensure the most refined way to breed the animals. In addition, the ARRIVE Guidelines 2.0 will be followed as best practice for reporting the outcome of all experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The investigator and researcher working on the project will maintain regular discussions with the NACWO and animal technicians to review current approaches and stay up-to-date with any new 3R developments. The BSU User Group also shares relevant information including NC3Rs and Norecopa newsletters.

71. Trypanosomiasis: Pathogenesis, Diagnosis and Treatment

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Trypanosome, pathogenesis, virulence, blood-brain barrier, neuropathology

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Trypanosomiasis is a parasitic infection affecting both humans and animals. It affects some of the poorest regions in sub-Saharan Africa. The disease can be fatal to both humans and domestic animals causing significant social and economic hardship. Although trypanosomiasis has been recognised for centuries, many aspects regarding how the parasite interacts with its host remain unknown. The primary goals of this research are: 1) to investigate how and why these parasites cause disease; 2) to determine what effect having other infections has on the severity of the disease; and 3) to discover new drug targets to combat the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Human African trypanosomiasis is not only a devastating neglected tropical disease but can also be used as a tool to understand basic aspects of how our bodies combats infection. In our previous animal license, we generated significant knowledge regarding the mechanisms of skin colonisation, which is critical for parasite transmission. Additionally, we have generated a wealth of knowledge regarding the mechanisms underlying the damage to the brain caused by the parasites, including potential drug interventions. Moving forward, our work will shed light on how the parasite causes weight loss and sleep disturbances. This knowledge is critical to understanding this complex disease and has the potential to open up new possibilities for the diagnosis and treatment of infectious diseases. More broadly it can also provide insights into how our bodies fight infections, and the unintended consequences these processes might have on normal health.

What outputs do you think you will see at the end of this project?

Reaching the goals of this project will not only increase the current knowledge available regarding trypanosome infections, in the longer term our findings could lead to improved chemotherapy or disease interventions. This would greatly benefit, both socially and economically, the developing countries where this disease is endemic. Beyond trypanosomiasis the results of this project could shed light on other infection or conditions that affect the host during systemic chronic infections, including systemic metabolism and brain function.

Who or what will benefit from these outputs, and how?

In the short term, our results will have an immediate impact in the scientific community, including those investigating parasitic infections, as well as those investigating weight loss, brain function, and behaviour in response to infection. In the longer term, we also anticipate that our work will have an impact on disease modelling and potentially improved intervention strategies, including developing novel therapies.

How will you look to maximise the outputs of this work?

Our work is collaborative and interdisciplinary, and so we anticipate that the outputs of this work will be maximised further through ongoing and future collaborations. We will engage with the scientific community in parasitology, immunology, and neurology to disseminate the knowledge generated from our work. Additionally, we will publish the work obtained from all the animal work conducted under this license (including negative data) to reduce the use of animals in duplicated work elsewhere.

Species and numbers of animals expected to be used

- Mice: During the 5-year licence period requested it is estimated that a maximum of 10,000 mice will used.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice as they respond to infection in similar ways to humans and domestic animals such as cattle. Mice also have a well described immune system, genome and there is an array of mutant strains available, which will accelerate our research. The majority of trypanosome research studies have been based on this model and our results will be directly comparable to previous studies, maximising its impact.

We will use adult mice (>8 weeks old) as their immune system will be fully formed and functional.

Typically, what will be done to an animal used in your project

Typically, this project involves injecting mice with trypanosome parasites and monitoring how the infection progresses in the animal by routinely taking blood samples from the tail vein. Typically, wild- type mice will be infected for 1-3 weeks and may receive immunomodulatory substances via injection that may ameliorate the disease or shed light on the disease process. Typically, mice will be closely monitored daily throughout the procedures and supportive treatments such as soft food will be provided, if necessary. Typically, colonies of genetically altered mice will be bred and maintained and then adult mice infected for 1-3 weeks via injection. In a minority of cases, surgery may be performed to implant a wireless subcutaneous or intradermal telemetry device. In some instances, we will irradiate mice or treat with chemical compounds to modify the bone marrow, altering the immune system.

What are the expected impacts and/or adverse effects for the animals during your project?

In the majority of cases infection by trypanosomes may induce mild adverse effects such as the transient pain associate with injection or periodic mild clinical effects of the infection, such as the development of a rough / stary coat or lethargy. In some cases, the mice could develop more moderate clinical signs including staggering when walking. If no signs of clinical improvement are noted during this period, the animals will be humanely killed. It is also possible that a few animals may decline considerably becoming lifeless, if this does occur the animals will be humanely killed. In rare instances, immunosuppresion may occur as a result from irradiation. This could result in unintended side effects such as

opportunistic infections. In such rear events, animals will be humanely killed to avoid unnecessary suffering.

Extensive experience of this infection model and a familiarity with the techniques used, allows us to recognise quickly any unexpected adverse signs. All mice will be closely monitored (at least every three days) throughout the procedures and recorded on the animal sheets and endpoints implemented as required. All animals will be humanely killed on completion of the experimental procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

mice: mild 20%

mice: moderate 80%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Trypanosomes can be maintained in culture flasks and this technique will be used to create genetically modified parasite lines to study genes that may influence parasite survival and in initial drug investigations. However, trypanosome infection cause changes in multiple interconnected systems and organs within the host and neither the development of the disease nor the ultimate success or failure of potentially useful treatment strategies can be investigated fully in the isolation of a culture flask. For example, when the effects of trypanosomes were examined using a culture model of the blood-brain barrier no lasting harm to the integrity of the barrier was detected. When this was investigated using a mouse model of trypanosome infection, a progressive increase in barrier impairment was associated with disease development. This clearly illustrates a disparity between the mechanisms at play in tissue culture models and animal models of this disease.

Which non-animal alternatives did you consider for use in this project?

Human tissue obtained from stem cells generated on a dish (known as organoids), skin explants, and endothelium monolayers.

Why were they not suitable?

Although these models are promising, as they stand, they do not fully recapitulate the responses obtained in animals. For example, brain organoids are devoid of innate immune cells, which limits its utility in the context of modelling infections in living animals. We are and will continue to invest efforts to keep developing organoids into more suitable culture models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Analyses of the data gained from the experiment will usually involve a factorial design to ensure that the greatest amount of information is achieved from a small number of animals. In general, the number of mice required to achieve the goals set out in this project licence has been calculated using an experimental group size of 6. Additional statistical support will be available when required to ensure that we gain the most accurate data using the minimal number of animals. Breeding colonies will be maintained at a minimum size.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

If appropriate, factorial designs will be followed to ensure that the greatest amount of information using the lowest number of animals is achieved. In addition, where possible, experimental groups of animals will be used to fulfil two objectives, e.g. pathology or gene expression studies can be performed using material harvested from animals assigned to imaging studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When appropriate, we will conduct pilot experiments to determine appropriate sample size and power calculations. We are also building a tissue bank repository in the lab, obtained from previous experiments, that can be used as an alternative to conducting repeated experiments. Our breeding system ensures that littermates are used either in experiments or as breeders. As a general rule, we will maintain our colonies in low numbers and will

only expand it when needed, and only for a finite period of time. At all times, we will follow the NC3Rs PREPARE guidelines and Norecopa guidelines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the most suitable laboratory animal to use in this system as trypanosome infections can be manipulated to reproduce each of the disease phases that are essentially similar to those found in both human and animal trypanosomiasis. In addition, the mouse provides a standardised animal with a wide range of analysis reagents and genetically altered research lines available. Where possible, we will use chemical compounds such as Busulfan as alternative, less aggresive, methods to irradiation in order to manipulate the immune system.

Extensive experience in the use of this mouse model provides familiarity of handling and maintaining infections and in the consistent induction of the various stages of the disease. This also results in a reduction in the severity of the procedures performed and in the number of animals required to achieve the goals of the experiment. To minimise the impact to welfare all animals will be closely monitored throughout the procedures and, if necessary, for those animals that require it, supportive treatments, such as soft food will be placed within easy reach.

Why can’t you use animals that are less sentient?

Trypanosomes are able to infect many vertebrate hosts, including mammals and fish. Whilst it is possible to infect zebrafish with trypanosomes, this requires the development of intricate infrastructure and husbandry of large fish such as carp to maintain the life cycle of the parasite. Further to this, it remains unclear whether zebrafish can be used to model the disease pathologies experienced by infected humans. Due to the extended nature of rodent models of infection, it is not possible to limit infection to an immature life stage. Moreover, most humans are infected during late adolescence or adulthood, when they have a mature immune system, meaning that juvenile rodents would not accurately reflect human disease pathology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have and will continue to adopt NC3Rs and local guidelines to handling methods, housing conditions, and environmental enrichment, to ensure the welfare of the animals in our license. Our procedural approaches have been refined over the years to ensure that volume size, frequency of inoculation, and routes of administration (including needle size) do not cause distress to our animals.

We typically monitor the animals after procedures to ensure there are not unwanted procedural side effects. We do not require analgesia but will maintain an open dialogue with the local veterinary team to make sure this is incorporate in a timely manner if needed.

Animal monitoring and pain management are an important part of all the procedures within the project. The need to minimise suffering is always considered when planning experiments and we routinely revise our experiments to reduce animal suffering. When using irradiation which can cause side effects in the gut, we will develop a more targeted approach thus improving the welfare of the animals, for example, by using alternative chemical reagents with less unwanted side effects (e.g., Busulfan). Of note, none of our experiments exceed a moderate severity level.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will ensure our experiments are designed in accordance with the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will engage with local authorities to ensure the work conducted under this license aligns to ethical standards, maintaining the 3Rs principles at the core of our activities. To this end, we will participate national meetings organised by the establishment and National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs) in addtion to in-house 3Rs meetings and events, to incorporate changes to our procedures in an effective and timely manner.

72. Models of Mitochondrial Diseases: Pathogenesis and Therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Mitochondrial disease, Model generation, Gene therapy, Experimental therapy

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To generate and maintain mouse models to understand mitochondrial diseases and and develop effective treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Mitochondrial diseases arise from harmful changes (i.e. mutations) in mitochondrial and/or nuclear DNA, which produce molecules important to normal cell function. These mutations cause changes in the structure and function of mitochondria, which disrupt the normal mitochondrial processes such as energy production (via oxidative phosphorylation), mitochondrial replication and removal (via fission and fusion), and ion transport across the mitochondrial membrane (important for normal cellular functioning). Impairments in one or more of these mitochondrial processes present in patients as diverse metabolic disorders which are difficult to treat, due to the wide range of possible signs and symptoms of these diseases. The work proposed within this licence aims to understand the mechanisms underlying mitochondrial diseases and develop more targeted treatments (such as pharmacological and non-pharmacological therapies).

What outputs do you think you will see at the end of this project?

From the work undertaken in this project, we expect three main outputs:

1. New mouse models of mitochondrial disease which carry mutations similar to those found in humans. At present, there are only a handful of mouse models which replicate the signs and symptoms experienced in patients with mitochondrial disease. More models are required to support outputs of points 2 and 3.

2. The molecular, cellular, and behavioural characterisation of the resulting models, that will grow our understanding of mitochondrial function and inheritance both in health and disease.

3. Potential treatments for correcting the dysfunctional mitochondrial in mice and provide initial data for future clinical translation. At present, there are no cures for mitochondrial diseases.

Outputs from this work will support future applications for funding and potential patents. Outputs will be shared with other researchers in the field via publications in scientific journals and presentations at scientific meetings.

Who or what will benefit from these outputs, and how?

In the short and medium term, the models generated will be used to expand our knowledge on the basic mechanisms of mitochondrial biochemical pathways and the impact of altered gene states in the execution of these pathways. The models developed will be characterised and samples will be collected and made available to internal research groups and external collaborators. The knowledge gained will be used to develop and test of novel therapeutic interventions. This is done with the long- term view of opening new avenues of therapy for patients with mitochondrial diseases.

How will you look to maximise the outputs of this work?

This output of this work will be shared with both national and international collaborators, as well as published in relevant scientific publications.

Species and numbers of animals expected to be used

- Mice: 22675

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have the closest genetic relationship of a model organism to humans. They have a short lifespan which allows researchers to study animals throughout development and adulthood within a relatively short time. In addition, mice are prolific breeders. Over recent decades, the genetic material of mice have proven to be manipulatable using gene-editing technologies.

Mitochondrial diseases can occur at any age. Therefore, we propose using animals across the life stages, from embryo to adult, to study dysfunctional mitochondria, depending on the hypothesis being tested (e.g. inheritance of mutated mitochondrial DNA or accumulation of mutations during adulthood).

Typically, what will be done to an animal used in your project?

Substance administration: Animals used in this project may undergo injection of chemical and/or biological substances, with or without anaesthesia, surgical procedures, sampling of blood/cells/tissues on multiple occasions, and/or administering drugs via food or drinking water. Substances may be given by injection to the eye, vein, muscle, or directly into the brain.

Behavioural testing: Animals used in this project may undergo behavioural testing [e.g. testing muscle function using a treadmill test and/or testing the function of the eye using electro-oculography (EOG), etc.] to characterise the functional differences resulting from the mutation in the mouse mitochondria.

Animals may undergo a combination of both substance administration combined with behavioural testing.

The majority of animals will undergo five or less regulated procedures during the course of an experiment.

It is estimated that the majority (approx. 80%) of animals undergoing regulated procedures will be juvinelle (up to 8 weeks old) and adults (more than 8 weeks old). The remaining 20% will be neonates (new born pups up to weaning - approx. 3 weeks old).

Experiments will vary in duration from days to months. At the end of breeding or experiments, animals will be humanely killed and tissues collected for further study.

What are the expected impacts and/or adverse effects for the animals during your project?

Due to the disruptions in metabolism caused by the gene mutations and/or the therapies applied, some animals may experience symptoms such as weight loss, abnormal movement (e.g. uncoordinated gait), altered behaviour, and possible pain and discomfort. In most cases, pain, stress and discomfort will be kept to the minimum and, if present, it will be mild and transient. Where stated in the licence, pain will be alleviated by giving analgesia. Animals exhibiting behavioural and motor differences may suffer Moderate severity due to the impact of these symptoms on their normal behaviours in the cage, including feeding. Animals experiencing Moderate severity will be closely monitored for weight loss (to gauge the impact of the abnormal movement on their ability to feed) and will be killed immediately if >20% of their baseline body weight is lost. In most cases, weight loss to this degree is observed over weeks. Animals that display ataxia (i.e. observed as a wobbly, lurching gait) for more than 24hrs will be killed immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: Sub-threshold 33.3%

Mild 57.27%

Moderate 9.43%

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal experiments remain a necessary part of our research as mitochondrial diseases affect multiple tissues in the body (e.g. brain, muscle, liver). In order to develop mouse models that mimic human patients with mitochondrial disease, the whole animal is

required to monitor for signs of disease. This multi-system affect cannot be replicated in vitro (i.e. in isolated cells in the lab).

In addition, the gene therapies we develop need to be tested for target specificity when delivered systemically (i.e. administered into the blood via injection of a vein). This currently cannot be simulated in vitro and is a vital step towards translation of our novel therapies to treat patients.

Which non-animal alternatives did you consider for use in this project?

Mouse adult fibroblasts (MAFs) and mouse embryonic fibroblasts (MEFs) may be harvested and used to generate cells which can be studied in vitro, reducing the number of animals used in some cases. Prior to testing in animals, gene editing therapies are tested in vitro, using established mouse cell lines, for their efficacy prior to testing in vivo (i.e. in a living animal, in this licence the animals used are mice).

Why were they not suitable?

The study of cells in vitro does not simulate the environment of the entire body. Hence, in vitro cell culture can help to refine treatments prior to in vivo testing but cannot replace the interaction of all the tissues at once, as in the whole animal. Cells cannot be used to study animal behaviours which may be perturbed in mitochondrial diseases, for example walking, feeding, or vision.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For mitochondrial disease models, the estimated animal numbers are based on our past experience, and reflect the challenges of maintaining a colony of female mice transmitting mitochondrial DNA (mtDNA) within the desired ranges. The effect of unknown mtDNA selection during gestation contributes to the instability of mutation levels in a mouse litter. Maintaining mutation levels within the desired experimental range requires a larger number of breeding pairs due to changes in mutation level during transmission.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The PREPARE guidelines are considered prior to experiments, as well the NC3R's Experimental Design Assistant. These guidelines include calculation of required sample

size for the chosen analysis method and careful planning of colony expansion to ensure any surplus of animals generated is kept to a minimum. Where possible (e.g. animals of appropriate age and sex are available) we will source wild type animals from the 3Rs enquires list for this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Colonies will be reviewed routinely and their size adjusted according to experimental need. Wild type mice will be bought in when needed, removing the requirement for keeping a wild type colony.

Pilot studies will be conducted for planning complex dosing, that require initial in vivo validation and optimization.

In the majority of experiments, it is not optimal to randomise the animals selected for treatment vs control groups. In most cases, we want to study the animals with the highest levels of mutant DNA. Blinding is possible at the point of administration (e.g. substance administration), however blinding may not be effective due to the resulting changes in the animals health or behaviour during the course of the experiment.

We will use a superovulation protocol to increase embryo yields. This results in a reduction in the number of females used, as we can collect more embryos for study. In addition, this will allow the colony to be kept smaller as we will not require as many females with the desired genetic profile.

Whenever possible (e.g. animals of appropriate age and sex are available), we will endeavour to source wild type animals from the 3Rs enquires list.

Whenever possible, we will co-ordinate internally to make spare animals/tissues available to researchers within our department. In addition, we are listed on a 3R's enquiry list, where we shall list surplus tissue/animals for other researchers to use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used to model human mitochondrial diseases. The majority of these mice display mild symptoms of diseases. Mice are the least sentient animals available that share very similar anatomy and mitochondrial functions as humans.

Why can’t you use animals that are less sentient?

The life stages used under each protocol have been carefully considered and meet the experimental life stage need (e.g. early interventions for mitochondrial diseases need to be given to neonatal pups, as therapies may be more effective early in life).

Mice are good breeders, producing offspring with the desired genetic profiles in a feasible time span to allow for experiments to be conducted within the time frame of the licence. Live animals are required to test in vivo therapies. Wherever possible, animals will be killed prior to tissue harvest.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals undergoing substance administration will be monitored daily, in some cases twice daily (AM and PM). Following a regulated procedure, a post-procedure welfare check will be scored using a procedure-specific check sheet, to assess the body condition, feeding behaviour, and (e.g.) site of administration. The procedure-specific score sheets will be developed with the advice of the NACWO and/or NVS. Adherence to the welfare check sheet will ensure that the humane endpoints are adhered to and the assigned severity levels are not exceeded.

Where required, peri-surgical analgesia (i.e. pain relief) will be administered to animals, with the use of voluntary treatments such as medicated flavoured jelly, paste, or milk shake liquid.

All users are trained and encouraged to use methods of handling of the animals to reduce stress (e.g. hand cupping or use of tunnel).

Wherever possible (i.e. in the majority of cases), animals will be group housed. In the minority of cases, it may be unavoidable that males are singly-housed. For example, stud males cannot be group housed due to fighting, which may cause greater suffering than single-housing. In addition to the group housing of animals, enrichment of the home cage will include suitable size cages for the animals age/size, including contents such as tunnels and nesting material, as well as a mezzanine level and freely available food and water.

Where the genetic mutation affects the ability of the animal to feed, for example due to altered behaviour/motor impairments, feeding may be assisted by providing water gel, food, and/or mash diet on the cage floor.

All wild type animals brought into the animal facility will be held for 15 days acclimatization and health monitoring before undergoing a regulated procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following guidelines are referred to and considered prior to starting new projects:

- The PREPARE guidelines, which consists of planning guidelines for in vivo experiments, will be considered prior to starting experiments.
- LASA (Laboratory Animal Science Association) guiding principles, which provide up-to-date guidance on training and education for PIL holders, aseptic surgical practices, good record keeping.
- RSPCA guidance on Research Standards and the role of the 3R's in improving the planning and reproducibility of animal experiments.
- National Centre for the 3Rs (NC3Rs) resources on experimental design, genetic modification, handling, husbandry, welfare assessment, and in vivo techniques.
- Breeding resources from sources such as Jackson Laboratory, The International Mouse Phenotyping Consortium (IMPC), International Society of Transgenic Technologies, and the International Mouse Strain Resource (IMSR).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PPL holder and PIL holders associated with the licence are subscribed to the 3R's enquiry email list. The Named Information Officer sends regular emails with updates on regulatory guidelines and available resources. In addition, the PPL holder routinely attends events organised by the NC3R to keep up to date with the latest developments in animal welfare, experimental design, and new guidelines. The PPL holder attends national and international conferences on animal welfare and the use of animals in scientific research (e.g. Federation of European Laboratory Animal Science Associations 2022 conference in Marseille, France).

73. Pk and Pkpd Studies to Support Respiratory and Immunology Research

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pharmacokinetics, PKPD, Respiratory disease, Immunological disease

Animal types	Life stages
Mice	adult, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This licence has two aims:

To enable us to decide what doses of new treatments we need to use in our respiratory and immunology disease models. We will do this by dosing animals and taking blood samples to measure how much of a new treatment is present at certain times after dosing (pharmacokinetics (PK))

To enable us to understand how much of a treatment is needed to have an effect on the biological target. We will do this by dosing animals which have had a simple pretreatment or challenge, so that we can measure both the amount of treatment in the blood (PK) and

the effect of the treatment (pharmacodynamics (PD)) and use both pieces of information to build a mathematical model (PKPD model). This can be used to inform both future animal disease studies and human dose selection for clinical studies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is an ongoing need to discover and develop new treatments for respiratory and immunological diseases such as asthma, chronic obstructive pulmonary disease (COPD), arthritis and lupus. To bring these life changing medicines to patients takes many years of research and requires demonstration that these treatments are effective and safe. To understand how effective a new medicine could be in human disease we bring together a package of information that shows how it affects human and animal cells, how it interacts with tissues from patients, how it modifies relevant animal models of disease and how much we will need to give to patients to be effective. Before testing a new treatment in an animal model we need to know how much to give and how often to have an effect. This licence will enable us to test new treatments in mice and rats and predict how much to use in these models.

This information also allows us evaluate the doses that we need to deliver to be effective in patients.

What outputs do you think you will see at the end of this project?

This Licence will provide key information about the properties of our novel treatments, such as how long they remain active in the blood of an animal after dosing, which is needed by our research teams to plan and deliver further studies. For example we will obtain an understanding of the peak concentration in the blood, which parts of the body it reaches and how long it takes to be eliminated. These findings along with information from human and animal cell studies will enable us to move suitable novel treatments forward through our pipeline and into human clinical trials, and ultimately result in new medicines to treat patients. Pharmacokinetic data are often reported when we publish results in disease models.

Who or what will benefit from these outputs, and how?

As an organisation our focus is on delivering life changing medicines to patients, and this licence will contribute to that overall goal by generating specific information that is used to determine how much medicine needs to be dosed to have an effect. Without an understanding of how much to give or how often, we cannot conduct effective research in animal models of disease or predict how much we may need to give patients. Our studies

are used to support specific research into new treatments for diseases that affect many patients and have life limiting impacts, including chronic lung disease and immune disorders.

Drug discovery and development can take years if not decades, so novel treatments tested under this licence are likely to enter human clinical trials after the 5-year lifetime of the licence. However, treatments tested under previous licences with the same goal are now in clinical phase testing and we are confident that this will continue.

How will you look to maximise the outputs of this work?

We have an open culture and interactions between our scientists and those from other research organisations are encouraged. Whenever possible we regularly share our findings at academic conferences and symposia, but due to the commercially sensitive nature of the work we are unable to be open about our very early and novel findings until appropriate patent protection is obtained. We do share openly information regarding our animal study techniques and practices with our peers to maximise animal welfare, and are committed to supporting the 3Rs.

Species and numbers of animals expected to be used

- Mice: 4600
- Rats: 2600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The overwhelming majority of these studies will be performed in adult mice, as this is the species most commonly used in the disease model studies we will carry out. Mice are used in those models as they are a mammalian species with a similar (but not identical) organ anatomy and immune system as compared to humans. Although immunological and respiratory disease can affect patients at any age, the majority of rodent studies are performed in adult individuals (ie post-pubertal) as rodent development is very rapid and animals become sexually mature in a matter of weeks. Rats will be used rarely, when the disease model is performed in the rat, or there is some other technical need (such as the target system in the rat being closer to the human in its properties).

Although it will be very rare, we may occasionally need to understand the pharmacokinetics of our new treatments in older animals, which for mice and rats equates to 1 year or older. This will only be done where there is a disease model that requires it.

Typically, what will be done to an animal used in your project?

In a typical pharmacokinetic experiment, adult mice would be implanted with identification microchips under anaesthetic and a few days later weighed and dosed (the dose given being related to the weight of the animals). The dose may be an oral liquid, delivered using a round ended dosing tube attached to a syringe which is placed into the throat of the animal to ensure all the material reaches the stomach. Alternatively, the dose may be given as an injection using a hypodermic needle under the skin, or into a vein or into the abdominal cavity. Animals are returned to their cages and then at set times (which could be over a single day or a number of weeks) taken out and restrained in a small tube for a few minutes while a blood sample is taken from the tail using a small hypodermic needle. Usually no more than 3 samples are taken from the tail vein in the lifetime of the animal, and only if the samples needed are very small. The final blood sample is usually taken under deep anaesthesia, when a hypodermic needle is placed directly into the heart to take a large volume of blood, followed immediately by killing the animal. Apart from these typical experiments we may occasionally dose using other techniques such as directly into the lungs, or injection into a leg muscle, or surgical implantation of a drug delivery pump under the skin.

Some studies may also include giving the animal stimulus (such as an injection of a substance that can trigger release of inflammation markers into the blood) so we can understand activity of the treatment as well as exposure (PKPD studies). These may look similar to a pharmacokinetic study but with the additional injection of the stimulus or other pretreatment.

What are the expected impacts and/or adverse effects for the animals during your project?

Animal dosing may cause some brief pain, such as when a hypodermic needle is used to dose under the skin or into a vein or the abdominal cavity. This is brief in nature and animals are not expected to show any signs of ongoing discomfort afterwards. Similarly, the needle used to take a blood sample is likely to result in fleeting pain or discomfort but should not have a lasting effect. Direct administration of material into the lungs may be done under anaesthetic by introducing a narrow tube to the airway, and this has a small risk of touching the sides of the airway and causing irritation or injury.

The treatments we will dose are not expected to result in any adverse events, and for novel materials that have not been in animals before we will run a small pilot study (tolerability test) to check that this is the case. In studies where we will use a challenge or stimulus some animals may exhibit clinical signs associated with inflammation and illness such as reduced grooming, reduced social interaction and lowered body temperature.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (>90%) of animals are expected to experience a severity of Mild. In our experience, simple PK and PKPD studies with dosing of a novel therapeutic, followed by tail vein sampling, do not result changes to animal condition or behaviour that are greater than Mild.

The remaining animals (<10%) may experience Moderate due to recovery surgery for implantation of drug delivery pumps under the skin, or in the event that animals on the tolerability testing protocol experience greater than Mild severity. Animals on the PKPD protocol may also experience Moderate changes such as reduced grooming or activity over a few days.

These proportions are estimates and may change in either direction if for example the projects we progress in the next 5 years require more or less drug delivery pump work.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not yet technically possible to accurately predict the pharmacokinetic properties of novel molecules, so animal studies are required. Much effort is put into screening out unsuitable molecules during the early stages of research, for example using human and rodent liver cells to see if they are rapidly broken down, and other cell based assays to estimate how easily they might be absorbed from the stomach into the bloodstream. This greatly increases the likelihood of success, in terms of seeing good blood levels after dosing, in our animal studies. The complete characterisation of new molecules that is needed to calculate appropriate doses for use in animal models of disease, or to guide first time in human dosing schedules, still requires us to use animals.

Which non-animal alternatives did you consider for use in this project?

There are multiple stages of non-animal screening of new molecules that are in place before testing in rodent. Depending on the type of new therapeutic agents will have performed tests (both using computer modelling and lab testing) to understand the physical properties which can affect drug absorption and how rapidly it could be broken down in the body. Cell based systems are used to assess how for example liver cells might process and break down a molecule.

Why were they not suitable?

The information gained from these non-animal tests cannot account for the complex interactions that take place inside a whole animal with multiple organs, cells and enzymes which could affect the way a drug molecule moves around the body, is processed or broken down and is eliminated from the body. As these molecules are going to be tested in animal models of disease, it is a scientific and ethical imperative that we select doses (how much treatment, how often to dose, which route to dose) which are likely to give us the necessary information. These studies can also be used to guide selection of doses for human clinical trials when combined with other information such as the way human cells or enzymes interact with the molecule.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimates arrived at based on current and historical usage (how many animals per study, how many studies of each type per year) and allowing for anticipated changes in demand.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Pharmacokinetic studies are usually not hypothesis testing in a statistical sense, so we do not test for a significant difference in blood levels per se. Instead we are interested in obtaining parameters such as the peak concentration in the blood, and how much time it takes for the blood levels to drop (so we can understand how much drug to use and how often to dose). The number of animals per study is therefore a function of how many samples are required, and for how long, and the number of replicate samples required at each time-point, which is normally n=3.

We normally take more than one sample per animal (the limiting factor is blood volume, we do not want to impact animal welfare by sampling too much), so our analysis benefits from replicate samples taken from the same animals. Standard protocols normally require only 3 samples per time point, although this may be increased in certain situations for example when PKPD studies are performed and in these situations statistical methods are used. For some types of new therapeutics we may be able to dose a mixture of different molecules and measure them all simultaneously, which further reduces the number of

animals. This cannot be done as a standard method as there is a risk of interactions or technical limitations on the measurement technique.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The animals we use for these studies are usually standard strains obtained from commercial suppliers which maximises the efficiency of production and animal usage. Occasionally we will use genetically altered animals bred for scientific use and the numbers are carefully monitored to ensure overproduction and wastage is minimised. New types of therapeutic agent which have not been tested in animals before are tested under a tolerability protocol on this licence, which uses very low number of animals (usually n=2) to confirm that these molecules are suitable for use in animals and do not induce any unexpected effects. This reduces the likelihood of us proceeding to a full study only to find a molecule causes an adverse effect that would stop the experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Pharmacokinetic studies normally consist of dosing animals (using a hypodermic needle and syringe, or special tube for dosing into the stomach), followed by taking blood samples, normally from a vein near the surface of the skin on the tail. Different dose routes may be required for different types of new molecule, or to determine if the molecule can be absorbed from the stomach, which may be important for some projects. Sometimes we may need to deliver a constant amount over a period of time, and in these cases we may use specialised miniature drug delivery pumps which we will position under the skin surgically. The use of these pumps may be needed to maintain a steady blood level or to avoid having to give multiple injections.

Why can’t you use animals that are less sentient?

As these studies are used to help design experiments in animal models of disease we need to have high confidence that the doses we pick are relevant. Using species that are less sentient introduces a significant risk that the information we obtain is not relevant and could lead to wasted animals in the disease models. Terminal only studies would be of limited duration and risk giving information that is compromised as for example blood flow

to the liver and other organs may be different under anaesthesia and could affect the measurements, and the presence of anaesthetic could alter the way material is processed by the body.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are kept in modern well equipped facilities staffed by experienced and motivated scientific and welfare personnel. Animals are checked at least once daily when not on a study and at least twice daily once dosing and sampling have started. When surgery (under general anaesthetic) is used for implantation of drug delivery devices, peri-operative pain relief (analgesia) will be given as standard.

Hypodermic needles are always discarded after a single injection so that blunted needles (which can cause unnecessary tissue injury and pain) are not used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA Good practice guidelines; AAALAC programme

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a Project Licence holder I am engaged with local and national 3Rs groups and events and am kept informed by my NIO of relevant new information.

74. Control of Brain Circulation and Metabolism in Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

brain, metabolism, cerebral blood flow, dementia, neurodegenerative disease

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant
Rats	adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The high metabolic rate of the brain, associated with the activities of billions of nerve cells processing information, requires constant and optimal nutrient and oxygen supply, as well as effective elimination of metabolic waste products. There is growing evidence that reduction in the blood flow to the brain, resulting in impaired delivery of metabolic substrates, damages nerve cells and the connections between them, leading to cognitive decline, and the development of neurodegenerative disease, such as Alzheimer’s disease. We will examine fundamental biological processes that ensure nutritional support of nerve cell activity, effective elimination of CO2 as a major brain waste product, and the mechanisms activated in conditions of metabolic emergency, such as when oxygen supply to the brain is reduced.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This research is expected to contribute to our understanding of how computational machinery of the brain is fuelled and protected from deleterious accumulation of carbon dioxide and/or reductions in oxygen supply. This new knowledge may prove to be important for future development of novel preventive and therapeutic strategies designed to maintain cognitive health and promote brain longevity.

What outputs do you think you will see at the end of this project?

This research is expected to make a significant contribution to our understanding of the brain. The experiments are designed to investigate the fundamental mechanisms responsible for metabolic support of neuronal computation and the primary output of this research will be new scientific knowledge. All results will be published in scientific journals and immediately available to the scientific community and general public.

Who or what will benefit from these outputs, and how?

There is growing evidence that a reduction in brain blood flow, impaired cerebrovascular reactivity, progressive acidification, and metabolic insufficiency precipitate neuronal damage, contribute to cognitive impairment, and the development of dementia and neurodegenerative disease.

Understanding the mechanisms of neuronal activity-dependent control of brain blood flow, metabolic substrate delivery, and the innate adaptive mechanisms, recruited in response to acute metabolic compromise, may prove to be important for the development of preventive and therapeutic strategies to maintain cognitive health and promote brain longevity. The earliest beneficiary will be the scientific community, as our studies will inform future research. In a longer term, this research is expected to have an impact on drug development projects by the pharmaceutical industry and on the way how clinicians think about the diseases and treatment strategies.

How will you look to maximise the outputs of this work?

We always aim to maximise both the quality and impact of our research. We use the most appropriate and refined experimental strategies that provide clear, unequivocal results. This is achieved by keeping informed about the latest developments in our field of research and collaborating with the leading research laboratories around the world. We maximise the impact of our research by communicating the data to the scientific community via conference presentations, invited seminars and publications in the leading general science and specialised peer-review scientific journals. Large datasets will be uploaded to public data repositories and/or available to other researchers upon request.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The fundamental questions addressed by this project are common to all mammalian species, including humans, therefore a mammalian species is required for the study. Rodents are usually chosen for the research of this type as the lowest species which accurately mimic human physiology and pathology, in order for the research data to be relevant to human disease. Therefore, laboratory rat and mouse have been used extensively to study the brain function, brain energy metabolism, and the mechanisms of cerebral blood flow control in health and disease. Most of the experimental data addressing these mechanisms were obtained in studies using rats and mice. In addition, the use of mice allows the use of transgenic technology for cell-specific targeting and blockade of the physiological signalling mechanism(s), which is not usually possible to reliably achieve by other experimental approaches currently available. Thus, the laboratory rat and mouse are the most appropriate models for the proposed programme of research, designed to investigate the mechanisms that maintain the brain's metabolic homeostasis.

Typically, what will be done to an animal used in your project?

The majority of our experiments are performed under deep terminal anaesthesia. This experimental model is the least severe and is proven by our track record to produce high quality, physiologically meaningful and significant results. Some protocols of this project involve surgical procedures involving genetic targeting of brain cells to express proteins designed to modulate or monitor the cellular function and/or implantation of the recording devices for non-invasive physiological monitoring. These surgical procedures typically last ~30 min and are not unduly traumatic for the animals; after a rapid recovery from anaesthesia/surgery they eat, drink and gain weight in a similar manner to non-operated littermates. Pre- and post-operative analgesia and antibiotics are given. Not more than two surgical procedures with recovery will be applied. These will be followed by either non-recovery procedures or procedures which do not result in pain, suffering, discomfort or lasting harm. At the end of the experimental studies the animals are humanely euthanised.

What are the expected impacts and/or adverse effects for the animals during your project?

The transgenic mouse strains/lines that we use do not show any adverse/harmful phenotype. A small number of the experiments will involve treatment of mice with

tamoxifen to modulate gene expression. There is some evidence that intraperitoneal administration of tamoxifen can potentially cause weight loss, particularly in younger mice. To avoid these potential adverse effects, older animals (3-4 months old) will be used. Wet diet and/or high energy, palatable food will be provided during the course of treatment to mitigate any potential weight loss.

The adverse consequences of the viral manipulation of the neural circuitry under investigation are expected to be benign. Work under the previous licences has shown that the main adverse effects are short-lived, and result from the surgery itself. The animal may suffer from post-operative pain (alleviated by painkillers) for up to 24h after guided microinjections into the cerebral cortex, and for up to 72h after the microinjections into the brainstem (because this involves dissection to the neck muscles). Similar recovery times are seen after the implantation of the cranial windows, or implantation of telemetry devices to monitor blood pressure and heart rate and electrophysiological recording devices. After this time no differences in behaviour are observed when post-surgical animals are compared to surgery-naive littermates.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (>90%) of animals used under this project are experiencing 'mild' severity or undergo "non-recovery" experimental procedures. Breeding of transgenic strains is per definition 'mild'. The only invasive procedure is ear notching for genotyping, and otherwise just handling of the mice for husbandry. The severity for those animals that are simply tissue donors or undergo procedures under terminal anaesthesia is "non-recovery", as they only experience induction of anaesthesia, and for those animals undergoing recovery surgery it is 'moderate', because of surgical trauma and the healing process. None of the other tests and experimental procedures the animals are undergoing prior and or after surgery produce any pain, discomfort, suffering or lasting harm that would require classification as 'moderate'.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Brain metabolic homeostasis is ensured by complex, multi-layered mechanisms controlling cerebral blood flow, metabolic substrate processing and delivery, maintenance of acid/base balance, and systemic mechanisms that regulate the circulation and breathing. The use of animals is essential in a programme of research of this type as the physiological mechanisms controlling brain circulation and metabolism are extremely complex and cannot be adequately described or studied in reduced systems such as tissue/cell culture or brain slices. In the experiments designed to study these fundametal mechanisms of the body we need to monitor brain activity as well as the key physiological variables (e.g. heart rate, arterial blood pressure, brain blood flow). In our studies we extensively use the reduced preparations such as tissue/cell culture or brain slices. These experimental models are very useful to study the biological interactions at the cellular and molecular level, but the physiological/functional significance of the identified mechanisms can only be determined by using the in vivo animal models.

Which non-animal alternatives did you consider for use in this project?

In this project all the hypothesised signalling mechanisms will first be explored by pharmacological surveys using reduced preparations (cell culture, acute brain slices). These experimental models completely replace the use of live animals. Initial selection of targets is guided by the analysis of gene sequencing data, already obtained by our laboratory, and also available from open sources (e.g. http://mousebrain.org/).

Why were they not suitable?

Full understanding of brain energy metabolism can only be achieved in experimental studies using live animal models, where the blood is delivered by systemic circulation, the blood-brain barrier is intact, the integrity of the neurovascular unit is preserved and all brain cells are interacting and functioning in their normal physiological environment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The indicated number of animals to be used in this project is based on the numbers of animals used previously in the research projects of a similar type. The number of animals to be used over the duration of five years can only be an estimate and is designed to give a maximal number that will not be exceeded. The majority of experiments built upon each other, and thus it is rather difficult to accurately calculate the exact number of animals needed. This is often different for each individual study, which is always powered based on

the magnitude of the effects observed previously with similar genetic models and experimental designs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental animals are used in our laboratory in well-defined and carefully executed studies. Our main preparation is the terminally anaesthetised mouse or rat in which we carefully monitor and maintain a range of key physiological variables such as blood pressure, arterial blood gases and pH and body temperature. We monitor central respiratory drive and cardiovascular homeostasis and often provide positive pressure ventilation with supplemental oxygen. These measures are essential to reduce variability within a sample and, therefore, to minimize the number of animals required to test a specific hypothesis. In a typical experiment the sample sizes in all experimental groups will initially be six animals, but these numbers may be increased if the data suggest that this would increase the likelihood of obtaining significant differences. From many years of experience, we can detect a physiologically significant difference with 6 animals/biologically distinct samples per group, if the treatments cause differences between group means that are as large as 2.25 standard deviations (SD). If the expected difference is as small as 1.75 SD, we increase the sample size to 9. Although, increasing the sample size per group to 15 would enable to detect a difference between means of 1.25 SD, it is doubtful whether these differences have a biological significance. Therefore, it is estimated that between 6 and 9 animals will be required in an average experimental group (α=0.01; power=90%). Carefully designed and executed in vivo studies that provide robust experimental data and published in a timely fashion, ultimately reduce the number of animals used in research by preventing other investigators from exploring unproductive territories in experiments using both the reduced preparations and in vivo models.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Hypothesised physiological mechanisms are first explored by pharmacological surveys using reduced preparations (cell culture, acute brain slices), with initial selection of the most likely targets guided by the analysis of gene sequencing data, already obtained by our laboratory, and available from open sources. Both male and female animals are used, therefore, almost all mice produced through breeding are used in the experimental procedures. Individual animals are subjected to more than one test each and after the in vivo studies their tissue is used for further in vitro analysis, thus reducing the overall number of animals used in this research project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority (>80%) of animals used in this project are experiencing 'mild' severity or undergo "non- recovery" experimental procedures. Breeding of transgenic strains is per definition 'mild'. The phenotype(s) of the animals used in this project is expected to be sub-threshold and genotyping will generally be undertaken using surplus material from ear notching for identification. The severity for those animals that are simply tissue donors or undergo procedures under terminal anaesthesia is "non- recovery", as they only experience induction of anaesthesia, and for those animals undergoing recovery surgery it is 'moderate', because of anaesthesia used, surgical trauma and the healing process. None of the other tests and experimental procedures the animals are undergoing prior and or after the surgery produce pain, suffering, discomfort, or lasting harm. All animals are handled with care (e.g. tunnel handling) and kept in social groups in cages with environmental enrichment (e.g. running wheels, tunnels, small wooden objects).

Why can’t you use animals that are less sentient?

The fundamental questions addressed by this project are common to all mammalian species, including humans, therefore a mammalian species is required for the study. Rodents are usually chosen for the research of this type as the lowest species which accurately mimic human physiology and pathology, in order for the research data to be relevant to human disease. Therefore, laboratory rat and mouse have been used extensively to study the brain function, brain energy metabolism, and the mechanisms of cerebral blood flow control in health and disease. Moreover, all critical molecular biology tools including targeted genetic modifications have been developed and established in mice and rats. In our laboratory all key experimental electrophysiological and imaging techniques that are relevant to the current proposal have been established, tested and verified in rats and mice, thus eliminating the need for the methodology-setting additional experimental animal studies. Animal suffering is minimised or avoided by implementing the experimental routines with analgesia +/- anaesthesia as appropriate for the procedure. A significant proportion of the planned experimental procedures (~70%) will be conducted in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal suffering is minimised or avoided by implementing the appropriate experimental protocols with analgesia +/- anaesthesia. Wherever possible, surgical invasive procedures are replaced with non- recovery protocols or procedures which do not produce pain, suffering, discomfort or lasting harm (e.g. novel object recognition test for the assessment

of memory function). The majority of the experiments are performed under deep terminal anaesthesia and therefore the severity limit for these protocols is “non-recovery”. These experimental models are the least severe and were proven by our track record to produce high quality, physiologically meaningful and significant results. When conscious animals are used, the animal wellbeing is monitored on a continuous basis for the duration of the experiment and frequently during post-experiment or post-surgery recovery periods. We continually refine and optimise our protocols for surgical anaesthesia/analgesia and post-operative care of particular importance, and regularly review these in conjunction with the Named Animal Care and Welfare Officer (NACWO) and/or Named Veterinary Surgeon (NVS) to ensure any updates to the best practice are promptly implemented. We have recently improved our post-operative care protocol to provide a warmed home- cage recovery environment for mice for the first night after surgery, and post-operative analgesia in an edible formulation without the need to perform repeated injections.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experimental design and procedural practice will be informed by best practice guidance published from a variety of sources. In particular, we will utilise the comprehensive list of recommended resources curated by the BSU Named Information Officers, including information from the Home Office, NC3Rs, Laboratory Animal Science Association (LASA), and Federation of European Laboratory Animal Science Associations (FELASA).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institutional Biological Services Units (BSU) are very proactive in disseminating the latest advances and best practice guidance regarding the 3Rs to all users of their facilities. In addition to this excellent source of information, we keep ourselves regularly appraised of general and field-specific advances via social media (e.g. by following The National Centre for the 3 Rs twitter account and blog). Opportunities to implement new 3Rs advances are taken as soon as feasible, via formal and/or ad hoc online and in-person BSU training courses, and refinement of our specific experimental approaches

75. Breeding and Maintenance of Genetically Altered Mice

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Transgenic, Mouse, Breeding, Neuroscience, Behaviour

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this work is to, breed and maintain mice with genetic alterations and supply researchers with strains to examine how sensory information is processed by specialised neural circuits in the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically modified animals, particularly mice, have a widespread use in neuroscience research and have been shown to be of great value in explaining the function of genes and pathways in a wide variety of biological, physiological and pathological processes.

What outputs do you think you will see at the end of this project?

Mice bred under this licence will be used to understand the function and connectivity of neuronal circuits in the normal and genetically altered mouse brain. This work will enhance and advance knowledge on how the brain processes information from the outside world and converts it into behaviour. This information could lead to the design of new highly selective drugs for treating neurological diseases such as epilepsy, Parkinson's Disease, Alzheimer's Disease, depression, schizophrenia and autism.

Who or what will benefit from these outputs, and how?

The establishment currently has around 10 research groups using mouse models and many of these need newly generated mice to fulfil their scientific questions.

How will you look to maximise the outputs of this work?

- Reduction in animal numbers by effective liaison with end-user projects, to ensure the appropriate strains of the desired specification are bred (best model for the research areas), with minimal wastage and sharing of animal lines and/or tissues by several research programmes.
- Reduced transport time for the animals, as fewer animals have to be brought in.
- Strict barrier controls ensure animals remain pathogen free for introduction into barrier accommodation and maintenance at a high health status in optimum environmental conditions.
- High health status, with direct benefit on welfare and science. The standard of facilities available for the work is high, and reflects a high level of investment
- Under the previous Project Licence, there has been a proven record of efficient generation and breeding of GAA strains and this licence will continue and improve the provision of high quality animals to the researchers

Species and numbers of animals expected to be used

- Mice: 101,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have been shown to be of great value in elucidating how sensory information is processed by specialised neural circuits in the brain, and are sufficiently close to humans to reveal principles of information processing.

All life stages will be required for breeding and maintenance. Adult animals will be additionally be required for the following;

- Superovulation to generate ova or blastocysts Transfer embryos into recipients
- To produce sterile male mice for mating to obtain pseudo-pregnant female mice to be used for embryo transfer, if required.
- Embryos will be required for the creation or re-derivation of genetically altered embryos to generate founder stock.

Typically, what will be done to an animal used in your project?

Genetically altered animals will be bred and maintained under this licence in order to understand processes involved in neural circuits and behaviour.

The various procedural steps involved may include:

1. Injection of hormones to increase egg production in female mice.

2. Female mice may have embryos implanted.

3. Vasectomy or import of genetically sterile male mice to allow these to be used to induce phantom pregnancies in females so they will receive embryos generated in other females.

What are the expected impacts and/or adverse effects for the animals during your project?

Each new strain generated will have a well described and expected profile; however, animals will be monitored for unpredicted adverse effects and profiles will be monitored.

Surgical procedures will be performed under anaesthesia, using pain relief and following aseptic methods to minimize risk of post-surgical complications. Anaesthesia will be carefully and regularly monitored to ensure that an adequate depth is maintained throughout any surgical procedure, and animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Mice will be monitored throughout all procedures.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Mild: 95% of animals will have an expected mild severity, this includes all animals only undergoing breeding and maintenance

- Moderate: 5% of animals will have an expected moderate severity, only applicable to those undergoing surgical procedures

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

The different animal models maintained and bred under this licence will integrate the complete range of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes, focusing on neuroscience.

Which non-animal alternatives did you consider for use in this project?

Not applicable.

Why were they not suitable?

Animal models are required for breeding and maintenance.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on the annual Return of Procedures from previous breeding project licence, current and projected use has been considered.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Use of Home Office "Efficient Breeding of Genetically Altered Animals Assessment Framework"

Encouragement of all researchers to use the NC3Rs "Experimental Design Assistant" for animals bred under and requested from the breeding licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Breeding programmes will be agreed in advance and regularly reviewed to optimally meet anticipated demand.
- Breeding programmes will be optimised wherever possible to produce only the required genotype.
- Freezing of eggs/embryos and sperm of lines created in-house will be carried out. Archiving of lines will avoid wastage from the need to maintain colonies by continuous breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use mice to breed and maintain genetically altered mice.

Why can’t you use animals that are less sentient?

Adult mice are required for breeding and maintenance, however immature life stages will be used for the generation of founder lines when creating or re-deriving genetically altered embryos. Less sentient species are not suitable for this project, as they are required to be sufficiently close to humans to reveal principles of information processing in the brain.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The mice will be cared for by dedicated, experienced animal technologists who have the expertise and skills required to breed mice. Welfare problems that may occur at an early stage will be monitored carefully to determine appropriate end points in consultation with experienced animal husbandry technicians and veterinary surgeons.

Surgical procedures will be carried out aseptically and according to best practice, and peri and post- operative analgesia will provided.

When mating to produce pseudo-pregnant female mice for embryo transfer, the import and use of genetically sterile males may be considered as a substitute for in-house, surgically produced sterile males.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- Home Office "Efficient Breeding of Genetically Altered Animals Assessment Framework"
- Jackson Laboratory "Breeding Strategies for Maintaining Colonies of Laboratory Mice"
- Preece, C., Alghadban, S., Bouchareb, A., Moralli, D., Biggs, D. and Davies, B., 2021. Replacement of surgical vasectomy through the use of wild-type sterile hybrids. Lab animal, 50(2), pp.49-52.
- Garrels, W., Wedekind, D., Wittur, I., Freischmidt, U., Korthaus, D., Rülicke, T. and Dorsch, M., 2018. Direct comparison of vasectomized males and genetically sterile Gapdhs knockout males for the induction of pseudopregnancy in mice. Laboratory animals, 52(4), pp.365-372.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project licence holder is a member of several professional bodies within the industry, and as a result attends regular meetings and well as receiving communications regarding animal science and the 3Rs.

The establishment maintains an internal 3Rs group in addition to a working Animal Welfare and Ethics Review Body, both of which regularly review animal work and disseminate key information.

The establishment has nominated Colony Managers within the animal care facility and laboratory groups, that coordinate and review breeding practices at regular interviews.

The Named Information Officer (NIO) at the establishment publishes a quarterly newsletter, informed by other named persons, recent publications, and key information sources (i.e. the NC3Rs, LASA), which directly addresses the 3Rs and disseminates this information to stakeholders.

76. Zebrafish as an Animal Model for Nystagmus and Vision Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

nystagmus, therapy, optokinetic response, vision development, zebrafish

Animal types	Life stages
Zebra fish (Danio rerio)	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the mechanisms of normal and abnormal eye movements in zebrafish by investigating genes involved in the development of systems that control eye movements and vision development. We will also identify drugs that

influence the development of these systems, including a disease called infantile nystagmus (wobbly eyes).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Nystagmus is the involuntary to and fro movement of the eyes, and it affects approximately between 2- 3 individuals per 1000 people. In humans, this is broadly classified into infantile forms (onset within 6 months on life) and acquired forms. Infantile nystagmus is a debilitating lifelong condition associated with poor visual and social function. Mutations in genes that control development of the light sensing organ (retina) are responsible for a large number of cases of infantile nystagmus. In humans there is limited knowledge about how infantile nystagmus develops and currently there are no curative treatments. Thus, there is a clinical need to understand how infantile nystagmus develops and what treatments can be used for this disorder. Patients and charities representing patient groups for nystagmus have highlighted that understanding the mechanisms of disease and identifying treatments are important to them.

The genes identified in humans known to cause infantile nystagmus and/or abnormal retinal development are also present in mice and zebrafish. Previous work in mice and zebrafish have shown that when these genes are made non-functional (knocked out or switched off), they can exhibit abnormalities of eye movements and abnormal retinal development. This suggests that zebrafish is an excellent model to further study how these genes control eye movements and visual system development. Once an animal model is established for infantile nystagmus, it will not only shed light into how nystagmus develops but also it will allow us to test drugs that might be beneficial for use in humans with nystagmus. Therefore, this work has the potential to directly address the research priorities set out by the patients.

What outputs do you think you will see at the end of this project?

1. Resources in the form of zebrafish lines for nystagmus

2. Dose-response data for novel candidate drugs

3. Publications on: (a) techniques for eye movement characterization in zebrafish (b) mechanisms of infantile nystagmus and (c) candidate drugs for this disorder

Who or what will benefit from these outputs, and how?

1. Scientist interested in the mechanistic basis of nystagmus. We will share the mutant zebrafish lines with any interested party (by providing researchers with embryonic offspring

of the relevant adult fish). We anticipate this will be a valuable resource to facilitate further research into the pathogenesis and search for treatments for nystagmus.

2. We will publish and share the dose-response data from our drug studies. This will have significant value to other nystagmus research groups, scientists using zebrafish eye tracking and drug studies.

3. Patients and families who suffer from nystagmus. We will use our model to search for novel treatments for this disease, focusing on small molecules that already approved for use in human patients, to speed up the use in human patients.

4. The general public are fascinated to learn how the brain controls behaviour, including visual processing. We will present our findings at regular outreach events and via social media platforms.

How will you look to maximise the outputs of this work?

We will aim to publish our data in top tier scientific journals. In addition to scientific publications, we will disseminate our findings through social media (twitter) and conferences. Similarly, we have close links with patient advocacy groups and regularly hold patient/public involvement events. These additional platforms to share our findings will ensure maximal output for this work.

We will also deposit all our findings (including negative findings) in pre-print servers such as bioRxiv.org thus providing useful early open access data on both successful and unsuccessful experiments and approaches.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 8400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish are the best choice of model organism for this study. They are easy to keep, freely available and breed prolifically. Zebrafish can also be used to model eye movement disorders. They have similar eye movement characteristics as humans and the neural systems that control eye movements develop rapidly. These systems are testable by 80-96 hours post fertilisation. Therefore, a significant proportion of our experimentation can be performed using early stages of development prior to them becoming protected under ASPA 1986. Additional factors that make it a desirable animal model include ease of

genetic manipulation and transparency of embryos which permits visualization of deep structure within the animal.

Typically, what will be done to an animal used in your project?

We will use genetic techniques (such as CRISPR-Cas9 mutagenesis and morpholino injection) to decrease the expression of genes and identify whether it resembles the human disease, infantile nystagmus. To make genetic changes in zebrafish we will inject molecules and proteins into the zebrafish embryo which will target the exact gene of interest we have identified to be linked with human infantile nystagmus. Microinjections are performed at the 1-cell stage (within a few minutes of fertilisation) and take less than a few seconds per embryo. After the visual system has developed, we will record the eye movements of zebrafish in different conditions and using rotating black and white stripes of varying widths to determine visual acuity. Similarly, we will test the swimming behaviour using the same black and white stripes to see if the fish can follow the movement of the stripes. These behavioural assays are considered mild severity as they are natural reflex response that are part of the developing visual system. The overall duration of these tests are brief typically lasting less than 1 hour. We will record how the retina functions using a technique called electrophysiology in response to various light intensities. We will characterise the structural retinal changes using non-invasive imaging techniques which are used in humans. We will introduce drugs to improve eye movements with the aim of correcting the developmental errors arising due to the genetic changes. This would be manifested as an improvement in vision after drug treatment.

What are the expected impacts and/or adverse effects for the animals during your project?

The microinjections will be performed in the 1-cell stage. At this stage there is possibility of damage to the embryo and non-viability which will be identified immediately or within the first 24-48 hours. The expected impacts from manifestations of the genetic changes include abnormal eye movements or reduced vision. This has previously been documented in the belladonna and albino mutant zebrafish. This would be similar to patients with nystagmus, abnormal eye movements such as nystagmus can be a sign of poor vision and can be present from larval stages. For the drug assays, we will utilise data from previous dose response studies and unpublished data from collaborators to minimise adverse effects. Moreover, we will first test the drugs at lowest concentrations in zebrafish larval stages with incremental increases in drug concentration to achieve the therapeutic response. This will ensure that we maintain mild severity for majority of animals for the main experiments. Most drugs that have been previously tested and thought to act on the nervous system. We will assess zebrafish larva for endpoints that include a loss of balance, or changes in locomotion or breathing. If we observe any change in behaviour we will humanely cull the animal the experiment and contact the NVS or NACWO for advice before proceeding further.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity for protocols 1, 2, 3 for 100% of animals

Non-recovery for protocols 4, 5

For protocol 6 mild severity for 90% and moderate severity for 10%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently there are no curative treatments available for infantile nystagmus. This is partly due to a lack of a suitable validated pre-clinical model to test drugs. Zebrafish are ideal for our experimental design since their visual system develops rapidly; the systems that control eye movement and vision are functional and experimentally testable by 5 days post fertilization (5 dpf). The eye movement and vision responses continue to develop beyond 5 dpf. The systems that control eye movements are similar to those observed in humans. Previous literature have used mice as an animal model for infantile nystagmus with limited success. We will use zebrafish as an animal model for infantile nystagmus and this represents a replacement of previous approaches by using a species at an early development stage. Unlike other animal models, such as mice, zebrafish are more suited for the scientific hypotheses we plan to test. This is due to the similarity between the visual systems of humans and zebrafish. Cones and rods are the light sensing receptors at the back of the eye in the retina responsible for fine and gross vision respectively. Zebrafish are cone dominant making them ideal to study the visual system unlike mice and rats which are rod dominant.

Which non-animal alternatives did you consider for use in this project?

It is unlikely that we can reproduce all the neural circuits needed to control eye movement in a cell or tissue culture, making it necessary to use animals in these experiments. We have checked the FRAME website, NC3Rs website and other sources for other ways to address this question and have not identified a suitable alternative.

Why were they not suitable?

Computational and cell culture studies are not sufficiently advanced to replicate the complexities of oculomotor development, additionally it would not provide sufficient phenotype data to translate into human clinical trials. Moreover, safety and toxicity data for drugs are more translational to human trials from an animal model rather than a cell culture assay.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the sample size based on previous published experiments and the number of anticipated genotypes. We utilized a dedicated sample size calculation software (StatMate for Windows, GraphPad Software, La Jolla California USA, www.graphpad.com) to perform the power and sample size calculations. We may also consider using NC3R EDA during further experimentation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have discussed our experimental plans in collaboration with research groups with extensive experience in eye movement analysis in zebrafish. Their datasets and previous publications were utilized for our sample size calculation. We utilized a dedicated sample size calculation software to perform the power and sample size calculations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where genotypes of interest are already available, we will source them from the Zebrafish International Resource Center (ZIRC) or other centres with authority to provide them for use. Having an established line in another laboratory and utilizsing this in collaboration is more advantageous and reduces duplication. To this end, we have approached collaborators and agreed to share resources (mutant lines) to ensure number of fish used are kept at a minimum. We will adjust breeding and maintenance numbers and tailor mating to ensure we have just enough offspring per experiment.

Similarly, our sample size calculations are robust and based on strong pilot and previous experimental data. We will also make our raw data available so that it can be re-analysed by other research groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish as an animal model. We will use fish prior to independent feeding for most experiments thereby limiting the number of animals used under regulated procedures. In some cases, we may measure the behaviour of older fish, such as 7 dpf because they display a more robust nystagmus response and optomotor response.

Why can’t you use animals that are less sentient?

To generate the nystagmus phenotype entire neural circuits in the brain and retina are required. Similarly, to test the impact of drugs and toxicity profile the whole fish is required. The zebrafish that we will use will be of lower sentience than mice and since our experiments use a very early stage in development. Therefore, these experiments are much less likely to cause any suffering. Healthy adult fish and knockout lines will be maintained at a minimal number to produce sufficient eggs for experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will utilize skin swabbing technique for DNA collection as suggested in the NC3R website (https://www.nc3rs.org.uk/skin-swabbing-dna-sampling-zebrafish).This is considered potentially less invasive compared to the traditional fin clipping technique. Thus, this represents a refinement for DNA sampling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will utilize well established protocols and where possible collaborate with labs where these protocols have been developed. This will ensure there is minimal harm and distress for the fish. Moreover, our facility has extensive experience in breeding and maintaining transgenic zebrafish. This work will also be performed in collaboration with labs where the swab-based DNA sampling technique was developed. This is a significant refinement to traditional DNA sampling techniques.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular NC3R newsletters and other resources regarding advances in 3R’s are circulated by the deputy director of our preclinical research facility and named information officer (NIO). Moreover, regular attendance of meetings organized by the division of biomedical sciences will help keep us informed and subsequently implement changes to reflect advances in 3Rs.

On completion of each experiment, we will review raw data and protocols to determine any refinements that can be applied to future experiments. Additionally, we will be collaborating with other centres interested in this work and therefore by sharing the results and experiences with methodologies will allow refinement of techniques.

77. Convection Enhanced Delivery for the Treatment of Disease of the Brain

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

convection, brain, cancer, CED, dementia

Animal types	Life stages
Sheep	adult
Pigs	juvenile, adult
Minipigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To facilitate the testing of developments in Convection Enhanced Delivery (CED) systems and to evaluation the safety and efficacy of drugs administered using this technology for the treatment of neurological diseases, including brain tumours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diseases of the brain are a major cause of suffering and death, and the lack of effective treatments constitute a largely unmet medical need. In the UK, an estimated 16,000 people per year will be diagnosed with a brain tumour, the number one cause of cancer deaths in children and young people. Over 850,000 suffer from dementia, more than 600,000 have epilepsy, around 6,700 have Huntington's disease, and about 5,000 have motor-neurone disease. Currently there are no curative treatments for any of these conditions.

A major obstacle to the treatment of diseases of the brain is the difficulty in achieving therapeutic levels of drugs at the tissue level due to the low permeability of blood vessels within the brain which effectively prevent the passage of all but the smallest of molecules, the so-called blood brain barrier. As a consequence, the use of drug for the treatment of brain cancers and neurodegenerative conditions has been severely restricted. To circumvent the limitation to drug delivery, posed by the blood brain barrier, my group has pioneered the development and use of Convection Enhanced Delivery (CED).

This system utilises catheters, inserted into the target region of the brain, to infuse the drug at a low flow rate under pressure. As a consequence, the normal distribution of the drug is enhance by the resulting pressure gradient created within the tissue enabling therapeutic levels to be obtained at the target site. In order to ensure that the insertion path of each catheter avoids blood vessels and vital structures an analysis of a 3D image of the brain, obtained by high resolution MRI scanning, is undertaken. At the time of scanning an external MRI compatible head frame is fitted to the animal to provide external reference points to enable the precise insertion point and trajectory for each catheter to be determined, using either a manual or robotic device.

As a result of the work conducted thus far CED has enter clinical use within the NHS however, further development work is needed to improve the technology that underpins this delivery system in order to optimise its effectiveness and exploit its full clinical potential. In addition, there remains a need to demonstrate the safety and efficacy of therapeutic agents delivered using this system and to obtain the data needed to progress such treatments into human clinical trials. The purpose of the outlined studies is to facilitate these developments in order to realise the full potential of CED for the treatment of diseases of the brain.

What outputs do you think you will see at the end of this project?

The primary outputs from this project will be the efficacy and safety data needed to progress treatments given by Convection Enhanced Delivery towards human clinical trials. These outputs will include data on drug distribution, neuro- and systemic toxicity, imaging characteristics and infusion methodology.

Who or what will benefit from these outputs, and how?

The primary benefit of these outputs will be the advancement of novel treatments for diseases of the brain towards human clinical trials. In the short term, the information gained will be of benefit to scientist and engineers working to optimise Convection Enhanced Delivery systems. In the medium term, the work is expected to facilitate the translation of novel treatments into human clinical trials. In the long term, it is to be expected that the work undertaken will lead to the introduction of more effective treatments for disease of the brain into clinical practice.

How will you look to maximise the outputs of this work?

The findings of the study will be disseminated through presentations at scientific conferences and publications in peer reviewed journals, whenever this is not precluded by intellectual property rights. I engage extensively in collaborative projects, which provide the opportunity to both gain expertise and disseminate knowledge. I have a proven track record in the publication of research findings from work undertaken in previous projects and will continue to do so wherever this is possible.

Species and numbers of animals expected to be used

- Sheep: 120
- Pigs: 120
- Minipigs: 70

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to generate the safety and efficacy data needed to progress the translation of novel treatments towards human clinical trials, it is necessary to use an animal model that closely replicates the conditions applicable to humans. For the outlined studies, the key criteria for the animal models is a brain that is similar both anatomical and in size to that of human. Consequently, sheep and pigs have been selected for these studies as their brain closely resembles that of human's anatomically and, although smaller, is of sufficient size to enable comparable volumes of drugs to be delivered to target regions. Juvenile pigs will be used for studies involving only a single treatment. Mature adult sheep will be used for long term or repeat delivery studies as these require animals that are no longer growing.

Typically, what will be done to an animal used in your project?

Animals will undergo a surgical procedure that closely mimics that used in human clinical practice. A surgical plane of general anaesthesia will be induced, and the animal fitted temporarily with the head frame used to align the Convection Enhanced Delivery (CED)

catheter. Brain imaging will be undertaken to determine the coordinates for catheter insertion. A small skin incision will be made at the catheter insertion point and the underlying skull exposed. A small burr hole will be drilled through the skull and the CED catheter inserted to the required coordinates. The drug will be infused, and further imaging may be undertaken to assess its distribution. For pigs, the catheter will be withdrawn whilst for sheep it will be fixed to the skull. The head frame will be removed, and the skin incision closed, in the case of sheep leaving the catheter end exposed (capped). The animal will be recovered from anaesthesia and post-operative analgesics given until it is free of pain.

Sheep may undergo one or more additional infusions, under general anaesthesia, or may have the catheter attached permanently to a delivery device implanted at the time of surgery.

At predetermined time points, animals will be re-anaesthetised and killed by anaesthetic overdose so that tissues can be collected for subsequent analysis to determine drug distribution, drug tissue concentration and to assess safety by histopathological examination.

What are the expected impacts and/or adverse effects for the animals during your project?

Before any procedure are undertaken, the animals will be habituated to human contact for at least a week to minimise any stress whilst inducing anaesthesia or when undertaking post-operative checks. During anaesthetic induction, animals may experience mild transient pain caused by the insertion of a hypodermic needle. Thereafter, animals will be maintained at an anaesthetic plane that ensures they do not incur any suffering. All animals are expected to make an uneventful recovery from surgery and the analgesic regime used will ensure that any pain is minimised. All animals are expected to resume normal behaviour within a few hours of recovery. The drugs used are not expected to result in any harm to the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Sheep- Moderate (100%)
- Pigs- Moderate (100%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To progress novel technological developments and treatments into clinical practice, it is essential to demonstrate their safety and efficacy using representative animal models that meet the requirements of the regulators responsible for authorising first in human clinical trials.

Which non-animal alternatives did you consider for use in this project?

At all stages of the work, we seek to use non-animal alternatives and only progress to assessments involving the use of animals where there is no alternative to obtaining the data required. To this end we have developed and optimised gel/phantom models for preliminary assessment of CED catheters and the distribution of drugs, which will be used and further developed during the course of the outlined work

Why were they not suitable?

We have developed non-animal alternatives for preliminary assessment of new technologies and novel agent that ensure that only those that are likely to succeed are progressed into animal studies.

However, as yet, the data generated using these does not meet the requirements of the regulators responsible for authorising progression to human clinical trials. Consequently, there is no alternative to the use of animals for the outlined studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animals required for the outlined studies has been determined using data generated during similar work conducted under my previous licence to determine experimental groups size; the pipeline of work already secured and the use of the NC3Rs Experimental Design Assist application to ensure the appropriateness of the study design. Statistical input is sought, where necessary, to strengthen the overall scientific quality and relevance of the studies to be performed, with sample size calculations performed for specific studies to determine the group size.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power calculations were undertaken to determine experimental group sizes, using data generated during similar work conducted under my previous licence. Where appropriate, control group data obtained in previous studies will be used to minimise or eliminate the need for specific controls. I utilise the experimental design software, such as that NC3Rs Experimental Design Assistant when planning experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where appropriate, control group data obtained in previous studies will be used to minimise or eliminate the need for specific controls.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The outlined work aims to generate safety and efficacy data to support the translation of new treatments for diseases of the brain administered using Convection Enhanced Delivery. The procedures used closely mimic established techniques use clinically within the NHS. All procedures will be conducted under general anaesthesia and upon recovery an analgesics regime will be implemented that ensures pain is minimised. All animals are expected to recover uneventfully from the procedure and to resume normal behaviour within a few hours. No adverse effects are expected as a result of the drugs administered.

Why can’t you use animals that are less sentient?

To undertake the outlined study, an animal with a brain of similar anatomical structure and size to that of humans is required. Only highly evolved species of a moderate size, such as the pig and sheep, are able to meet these criteria.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The outlined procedures have been refined during work conducted under my previous licences. Upon arrival in the unit, the animals will be habituated to human contact before

any procedures are undertaken. Surgery will be conducted in a manner that mimics that used clinically within the NHS. Following surgery, the animals will be provided with post-operative pain control until they show no discernible signs of pain. All animals are expected to resume normal behaviour within a few hours of recovery from anaesthesia and to continue to live normally throughout the study. I am committed to ensuring that all of the procedures undertaken by my group are refined to minimise suffering and that the experiments are designed to use the least number of animals needed to obtain the required data.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The procedures used will closely match those used clinically within the NHS and will be conducted using full aseptic precautions in line with LASA guidelines for aseptic surgery. Studies will be conducted in compliance with GLP standards.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My institute places a strong emphasis on the promotion of the 3Rs and organises regular event to raise awareness and encourage the dissemination and uptake of 3Rs developments. We are supported by a regional NC3Rs representative, who actively publicises and promotes engagement with the 3Rs. The institution's AWERB committee promote the 3Rs by challenging licensees to demonstrate their full commitment during licence reviews and the NVS and NACWO review all pre-study briefings and raise any 3Rs concerns with the applicant when these arise.

78. Testing Novel Strategies for Bone Repair in Sheep

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Skeletal, Tissue engineering, Biomaterials, Stem cells, Bone repair

Animal types	Life stages
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of the project are to develop and test biomaterials that can repair broken or diseased bone. Our rationale is centred on the urgent need to develop materials capable of activating and growing both bone and blood vessels to help patients repair their damaged and diseased skeletal tissue.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With an increasing ageing population, skeletal tissue loss due to injury or disease is rapidly growing. This significantly impacts the quality of life for the patient over time and has socio-economic costs for healthcare providers. For example, each year in the UK there are over 50,000 primary hip replacement operations at a cost in excess of £350million. Hence,

for reconstructive bone surgery and fracture repair, the need to develop better techniques and alternative bone therapies is vitally important.

From a patient's perspective, the ultimate goal is to repair and replace their damaged skeleton with bone material, harvested with minimal complications from their own skeleton. However, the current clinical approach for the treatment of bone defects and non-unions is bone grafting or metal implants, which both have significant drawbacks. The combination of a bone stimulating material combined with bone tissue generating cells to produce a therapy would be an invaluable surgical option, reducing both complication rates occurring in patients undergoing bone replacement surgery. Therefore, generating materials that can help bones repair themselves will be invaluable for patients and animals suffering from diseases and fractures affecting the skeleton. These include non-healing bone fractures and weakened bones due to diseases like osteoporosis and bone cancers.

What outputs do you think you will see at the end of this project?

The proposed models being used in these studies will help us to gain new insights in the development of tissue regenerating biomaterials to rebuild broken bones

Specifically.

We want to understand how biomaterials stimulate bone cells and tissue to grow and repair large bone fractures.

We hope to develop innovative biomaterial structures that can stimulate bone regeneration in large bone defects in order to provide new and improved treatments for patients who have fractured bones or who have lost bone owing to other diseases like cancer.

We will present our findings at scientific and medical conferences and we will publish these outcomes in peer-reviewed scientific journals.

Finally, any new procedures/methodologies for improved welfare settings developed during the project licence will be published and shared with the scientific community in order to benefit both human and animal patients.

Who or what will benefit from these outputs, and how?

As with all our research goals the aim is to develop improved therapeutic strategies and products for patients who suffer from skeletal diseases and bone trauma injuries. We envisage that new biomaterials have the potential to provide improved treatments to help rebuild bones and skeletal tissues. In addition, the findings from musculoskeletal research can be applied to the veterinary field due to similarities in orthopaedic conditions between people and animals, leading to novel applications in a ‘one health’ approach.

Beneficiaries will include:

Patients and animals suffering from broken bones and skeletal diseases. Healthcare providers.

UK, EU and worldwide tissue engineering/biotechnology companies involved in tissue regeneration, stem cell biology or developing innovative tissue scaffold technologies,

The academic community in the generation of new protocols and avenues for skeletal tissue regenerative research.

Many materials we use in our studies are biocompatible and currently used in clinical practice for other applications. Modifying them to enhance their properties can result in new therapies in a relatively short time frame, benefitting patients due to the known track record of efficacy and safety. However, with the complex materials proposed the final outcomes for patients may require months to years of investigation due to thorough testing to ensure safety and efficacy prior to use in the clinic.

When these new treatments become available, we envisage growing the tissue constructs in the laboratory and transferring the regenerated samples to the patient in theatre. Ultimately, we believe this work will be translated to the clinic and benefit patients within the National Health Service and the wider medical community in the area of musculoskeletal repair. Alternatively, the development of materials that exploit the regenerative potential of the patient's own repairing cells would minimise costs and hasten the material's therapeutic implementation.

In addition, the information from this project, including the study protocols and techniques will be made freely available via publication in peer-reviewed journals, in order to benefit patients, other researchers, doctors, vets, and pharmaceutical companies who are involved in the development and assessment of novel therapeutics which target the repair and regeneration of skeletal tissues due to disease and injury.

How will you look to maximise the outputs of this work?

Training & Collaborations

The team undertaking the research will acquire skills and expertise in bone repair, blood vessel and skeletal stem cell biology, biomaterial development, imaging techniques in real-time such as 3D x-ray scanning and 3D optical imaging. Training will be achieved through an extensive local network of multidisciplinary collaborations within the University Hospital and established national and international collaborations in regenerative medicine.

In addition, the protocols and research work will be communicated to our student & postdoctoral researchers to provide information regarding the models available for research projects at the University and to foster collaborations. We are part of the Regenerative Medicine Platform collaborative group network where we share our methods and results from acellular materials that will be available to be tested in skeletal and other tissue/organ regenerative models.

Education & Public engagement

The information and findings generated from this project will be presented through the scientific community by presentations at national and international meetings. We will also communicate findings to the public through outreach activities such as the University Science Day, and laboratory open days for GCSE and A-level students in tissue regenerative medicine.

Progress of the study and results will be regularly presented at ongoing teaching events and public lectures. The press office of the University will also publicise the results.

Species and numbers of animals expected to be used

- Sheep: 48

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Whilst all attempts are made to reduce the use of animals by using cell-based laboratory methods, it is inevitable in work of this nature that animal investigations have to be undertaken. We can determine a number of key factors to ensure the biomaterials we make is suitable for bone repair. However, there are also a number of biological factors (angiogenesis, inflammation, multiple stem cell recruitment, proliferation, differentiation in a coordinated manner. Multiple coordinated secretion of cytokines and growth factors to stimulate bone) that we are still unable to recapitulate in the lab that only a living organism can provide.

Biomaterials will be examined for the bone repair in smaller animals such as mice or rats. Only the best bone repairing biomaterials will be considered for scale up and use in repair of large critical sized bone defects.

Bone disease and fractures may occur across the lifespan, ranging from young to old, however, it is predominantly in the adult and aged populations that the repair mechanisms in bone start to fail.

Therefore, it is expected that the vast majority of experiments will be performed in adult animals.

One of the biggest hurdles to overcome in clinical orthopaedic repair is the regeneration of large segments of bone that have been lost due to disease or trauma. We will therefore use skeletally mature female sheep (as they have a similar body size and rate of bone remodelling as humans) in these studies as this provides a larger bone defect model to

test the potential of our repair materials to regenerate significant amounts of bone tissue before it can be translated into use in a humans.

Typically, what will be done to an animal used in your project?

Sheep through a surgical procedure will have a section of bone (maximum width of 11 mm x 15 mm height) removed from the femoral condyle of lateral hind limbs. As each leg serves as a separate sample, the number of animals used in the study is reduced. Biomaterials will be implanted into the bone defect site, with an empty defect acting as negative control and implanted bone grafts acting as a positive control (gold standard of bone current bone repair). Bone trephines have been designed to allow sufficient bone cores to be collected from two femoral condyles in a single sheep to fill one defect with bone graft, therefore removing the need for bone harvesting from the iliac crest. An empty defect is used as the negative control. Pain relief will be administered during and after the operation. Sheep will be slightly lame for up to three days but are able to stand and move directly after surgery with no hinderance in feeding and drinking.

The animals will be housed indoors in pens for the duration of the study which further activity (e.g. Fitbark) and clinical monitoring may be undertaken. The duration of the study will be for up to 52 weeks

In addition to the above scenarios

1. the animals may receive on several occasions an injection of bone inducing factors to localise to the bone defects to enhance the repair.

2. The animals may receive on several occasions an injection of bone labelling drugs e.g. tetracycline to label new bone formation

3. The animals may be subjected to a scanning device, such as ultrasound, in order to improve the implanted biomaterials' ability to promote bone healing.

4. The animals may be subjected to imaging of the defect site by radiography, CT, ultrasound as deemed appropriate to visualise the defect and assess healing at different time points e.g. on the day of surgery, week 4, week 8, at the study end etc.

At the end of the study, animals will be killed and when dead the femoral condyles will be removed and fixed for further analysis. Defects will then be scanned using micro-computed tomography (micro-CT) before carrying out histology and immunohistochemistry to assess bone quality and cell types.

What are the expected impacts and/or adverse effects for the animals during your project?

In this model the overall severity the animal will experience is moderate short term pain due to the procedure. With the limb defects we will expect the animals to be slightly lame

for a couple of days with no adverse effects from the surgical procedure. Normal movement and locomotion resumes thereafter. In our experience the sheep are standing within 10-15 mins post recovery after surgery. Analgesia will be continued for 72 hours (and continued if required after veterinary consultations) after recovery and closely monitored during this period.

Although the animals will be regularly monitored, weight loss has not been an issue with these procedures.

X-ray scanning. There is the risk that radiation doses during an x-ray examination may produce adverse effects such as delayed growth or repair. However, doses of x-rays and duration of scans are way below any threshold that will cause problems to the animal. These scans are usually in the duration of 2- 5 minutes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the bone defect models in these protocols, we estimate the severity to be moderate and that 100% of the animals will experience this due to the surgical procedure.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Initial bone tissue engineering research work and biocompatibility will utilise all relevant laboratory cell based methods at our disposal. However, the clinical relevance of the approaches proposed, and the quality and quantity of bone tissue formed can only be assessed in relevant animal models. Cell growth, toxicity measurements and bone forming biomaterial assessments performed in the laboratory cannot, to date, mimic the complex physiological in vivo microenvironment involved in bone tissue repair. Thus, this proposal necessitates the use of animals to test the ability to generate new bone using the bone tissue engineering principles outlined. It is important to stress that initial laboratory cell based studies are undertaken to evaluate and optimise the growth of human bone cells and skeletal stem cell populations on the scaffolds under examination. Where possible we will utilise our organotypic/organ culture ex vivo models as a replacement to the animal models to examine the ability of our regenerative strategies to repair skeletal defects.

Finally, to address the efficacy of biomaterials in the repair of large bone defects there requires an understanding of its effects on integration, inflammation and blood vessel formation, that can only be adequately examined in the environment of the whole animal.

Which non-animal alternatives did you consider for use in this project?

Using laboratory cell culture experiments we are gaining as much information as possible to understand the biocompatibility, functions and toxicities of new biomaterials being developed. In addition, we are using 3-dimensional bone tissue known as organoids to study the interaction of the many cell types that create fully functional bone tissue. We are using this data to create biomaterials with functioning coatings which can mimic the bone growth processes.

In other studies conducted in our group Artificial Intelligence (AI) modelling is being developed to test biomaterials implanted into the developing chick membrane, so that this technique can be used to predict and determine how a new material will act in producing blood vessels and new bone tissue.

However, there are limitations at the moment as this AI modelling is based on data provided from real studies. Once enough data has been accumulated for AI, this can, in principle, be applied to the animal models used in these protocols when researching new biomaterials. As AI modelling obtains a better understanding of the outcomes and mechanisms of these materials in the aforementioned bone models, the number of animals required will eventually decrease. With continual learning of the models and how new therapies interact in repairing and rebuilding bone AI in the future will be one avenue to replace the use of animal models.

Previous human studies have been reviewed for evidence-based information and outcomes. There is a wealth of clinical literature providing data on the efficacy of biomaterials on implants in hip replacements that will provide us with guidelines of what works in the patient. In addition, there are number of clinical trials with data on the dosing of growth factors and of skeletal stem cells which give insights into the positive outcomes and the negative outcomes. We will use this information to improve our biomaterials and avoid the negative consequences that have already been discovered in these clinical trials.

Why were they not suitable?

The above strategies are suitable for screening, in part, the many biomaterials that are developed. We only resort to animal studies due to the complex factors that are involved in regeneration and repairing of bones. The generation of new bone requires multiple steps and the interplay of many different bone factors (inflammation, skeletal stem cells, blood vessel cells, collagen structures, calcium and phosphate (for hardening the new tissue), mechanical stimulation and cells that re-shape the new bone in a 3D environment to fit the defect bone exactly (without scarring) in a co-ordinated manner.

This interaction cannot be consistently or correctly reproduced under tissue culture conditions to meet the criteria expected to inform a clinical translation. Furthermore, in vitro model systems make it difficult to detect unexpected toxicities or inflammatory responses, as well as observe material integration and degradation over time.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used our current and past experimental data to inform us of an estimation of the number of animals required per group and the number of control and test groups to give statistically valid experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the design phase we have used organ culture and chick eggs to reduce intra-group variability of biomaterials and by using this model and the results obtained has allowed us to reduce progressive experiments in mice models. This screening has reduced approximately 60% the regenerative biomaterials being taken forward for testing in animal studies.

In addition, we have run experiments in mice models to determine the suitability of scaling up to be used in a large sized bone defect model in the sheep. Only the biomaterials with significant bone repair and biocompatibility shown in the smaller animal models are considered for translation to the large sheep model.

We have designed experiments using the fewest animals consistent with obtaining statistically valid results as determined from our power calculations. Using the NC3R's Experimental Design Assistant we have calculated the minimum number of animals required for a determined amount of new bone tissue formation in the test implant material comparison to control (no implants) or control (implanted biomaterials without stimulatory factors). From previous studies we will be using a minimum of 6 defects per experimental group (i.e. 3 sheep) to attain significance between the test groups. Where possible we will use historical data obtained from previous studies to compare negative and positive controls so long as the time points, dimensions and sheep age and breed remain the same.

In certain cases, mathematical modelling may be used to predict the release of growth factors from biomaterials under certain biological conditions, allowing us to determine how many animals we can exclude while still achieving a meaningful outcome in the experiments. In addition, multiple scanning and imaging of the animal bone implant or bone defect site at different time points reduces the number of animals required in these types of studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Rigorous laboratory testing will be performed on the newly constructed biomaterials before any candidates are assessed in the rodent models. Only after assessment in these models with a (stop/go scenario) will the optimal biomaterial candidates be considered for scale up and testing in the sheep bone defect model. Based on previous studies from our group and collaborations both nationally and internationally we have collected historical data of control autograft and empty defect bone repair results where we can use less animals for the control groups.

Multiple analysis will be undertaken on biomaterial samples implanted into the animals, this will include X-ray and microscope imaging, blood vessel scoring, biochemical and molecular analysis, and histology. The multiple data that can be derived from one sample will optimise and minimise the number of animals to be used in a single study. Finally, at the end of the study we collect marrow from the iliac crest for isolation and storing of sheep stem cells and in addition, any unwanted tissue may be harvested by other groups for us in other and further research projects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The disadvantage of using small animal bone defect models, such as mice, is the intrinsic disparities in bone composition, density, and quality between humans and small animals. These models are not suitable to evaluate at scale materials for bone repair for the translation to the clinic. For this reason, we are employing a larger species, sheep, which closely resemble the bone structure, mechanics, and repair characteristics associated with humans. Sheep have been used in numerous bone conditions to assess the benefits of biomaterials to regenerate bone. The femoral condyle defect model causes the least pain,

suffering and complications as complex support structures to hold the bone defect in place are not required reducing the chances of implant failure, additional bone fractures and infection that can occur with other bone defect models.

Why can’t you use animals that are less sentient?

The development of new bone is incredibly complex involving factors and cells from the blood, the bone marrow, inflammatory cells, minerals and mechanical forces. In addition, bone fractures take a considerable time to successfully repair.

Unfortunately, we are still not at a stage to incorporate all these components in the laboratory therefore these animal models are required to help us understand and improve the development of materials to aid in bone growth and repair. We can mimic some of the components in the laboratory, and this has led us to refine the materials and cells that we will use in these studies.

There is a chick egg embryo model that we use to determine the efficacy of these biomaterials in generating bone. This model is a less-invasive in vivo model allowing for the assessment and function of these biomaterials in a living organism. However, these are short term models (max. 10 days) whereas bone repair can take months to repair in vivo.

One of the clinical problems with bone defect repair is producing large amounts of material to implant in the defect. This cannot be assessed fully in less sentient animals. Therefore, the sheep bone defect model provides the size and the similar human bone physiology to test the potential of these biomaterials to repair large bone defects in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We shall continue working to minimize welfare costs for the animals in the following ways:

Reviewing the need for these experiments to be undertaken. Weighing up the balance of potential successful outcome of undertaking the experiment and the level of harm/distress the animal will endure.

We will ask for feedback from technicians and welfare officers in the BRF and their valuable day- to-day knowledge to revise protocols to improve the animals' experience.

Prior to the surgical procedures, researchers will familiarise and handle the animals on a regular basis to reduce stress for both the animal and the user.

The femoral defect created in both hind limbs is well tolerated by the animal. This allows for 2 implants to be tested in the animal. This refinement has reduced the numbers of sheep required to carry out a study.

General best practise guidance for injection, blood sampling and aseptic techniques will be followed. This has been developed and refined as best practise over a number of studies carried out by the group.

Animals are closely monitored for several days after the bone defect surgery, with continued pain relief given for at least 72 hrs in the first instance and further pain relief administered if signs of pain persists in the animal. Wounds will be carefully monitored to ensure that sutures have not loosened or come off or there are any signs of infection.

The sheep will receive pain relief (a patch e.g. Fentanyl), as advised by the Named Veterinary Surgeon (NVS), pre- and post-operation to allow for a continuous supply of pain relief for an appropriate period. If for unforeseen circumstances the surgery must be cancelled the patches will be removed and the sheep returned to the pens. Sheep will not then be re-patched and starved for a minimum of 72 hours.

The sheep will receive local pain relief in the injection/incision site.

To reduce the risk of infection the sheep will receive antibiotics pre- and post-surgery.

There are three clinical score sheets to guide us when monitoring the animals. One covers the mobility, food intake and water consumption, body temperature, demeanour and respiratory rate and is routinely used for all animals for a minimum of 3 days post-operation. There is a posture and locomotion scale that is used to assess the levels of lameness and we use the grimace scale to assess levels of pain in the sheep.

Delivery of any material to a defect site will be closely monitored to ensure that there is not significant inflammation. If inflammation occurs the sheep will be carefully monitored and graded using a locomotion scoring system after consultation with the NVS. Any severe soft tissue inflammation will be treated with antibiotics and local pain relief provided to the animal. If this has not improved the animal's condition over 24 hours then the NVS will be consulted regarding the short term use of an anti-inflammatory drugs. If the sheep is significantly lame on both hind legs and is not responding to additional analgesia it will be killed immediately.

During a study, animals may be injected with fluorochromes, at 2 known time points post-operatively, to allow assessment of the rate of bone growth within the defect. The stain binds to calcium ions on the mineralisation front and stabilises after 24 – 36 hours after injection. This has been used in many animal studies with no adverse effects.

Animal weight is frequently monitored for the duration of the studies. In addition, an activity monitor may be worn by animals for either part or all of the duration of a study. The ‘Fitbits’ allow us to continuously record the ‘play’, ‘rest’ and ‘activity’ of the sheep before and during the experiment. This allows us to identify early indicators of reduced welfare in the animals and to intervene accordingly. If reduced activity or play and increased rest is

noted, the NVS will be asked to examine the animals to identify the cause of the reduced mobility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE guidelines which provide a 20-part checklist of the minimum information required to be reported by groups using animals in research. ARRIVE guidelines are essential to help overcome issues in science such as reproducibility, reducing bias and the correct use of statistical methods of analysis.

In addition, we will follow and consult the Norecopa (Norway's National Consensus Platform for the advancement of "the 3 Rs" (Replacement, Reduction, Refinement)) in connection with animal experiments database platform and PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for better science experiments using animals to ensure that we are using the best defined models for our work in the investigations of biomaterials for skeletal biology.

All surgery will be carried out aseptically in dedicated facilities, according to the LASA guiding principles for preparing for and undertaking aseptic surgery.

Our group will meet on a regular basis to discuss best practises (new publications, surgical methodology) for upcoming studies, as well as post-study analysis to improve experimental design and animal welfare for future studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs website to identify any changes that will be relevant to the workings of this model. In addition, we will follow the latest findings from the Laboratory Animal Science Association

(LASA) and the PREPARE guidelines from Norecopa in better planning for research involving animals to prepare for better science and advance the 3Rs. Any changes will be implemented directly through the experimental design, and if necessary, through a project licence amendment.

In addition, we follow the latest publications on using these models and identify any new methods that reduce, replace or refine the biomaterial implant and bone defect models. If applicable to this model in improving the 3R's we will request amendments from the Home Office to adjust the techniques/methods required and training or notification of relevant staff in updated techniques.

Continual training will be undertaken to ensure that users will be proficient in running these studies particularly on the aftercare post- surgery.

Attendance at BRF meetings and/or discussion of BRF meeting slides at group lab meetings.

We will liaise with other experienced research groups, clinicians and veterinarians who have experience of running these models to obtain advice on updates on best practise for anaesthesia/analgesia, husbandry and surgical procedures similar to the ones we will be undertaking in this project.

79. New Tools for Improving Ovarian Cancer Care

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:

(i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Ovarian cancer, STIC lesions, Sperm, Spermbots, Cellular microrobots

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To engineer sperm as novel diagnostic and therapeutic tools to sense and eradicate early ovarian cancer lesions arising inside the fallopian tube.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ovarian cancer ranks fifth amongst cancer deaths in women and top amidst all gynaecological cancers. Due to a lack of early detection and treatment methods, the field has long been hampered by low survival rates (<30% at ten years) and has seen few advances in ovarian cancer management for decades. Indeed, apart from surgery, conventional cancer chemotherapies remain the backbone of current therapies. These generic treatments elicit severe side effects, highlighting the sore need for new and more specific approaches, such as the ones proposed in this project. Ovarian cancer has long been thought to arise inside the ovaries. Instead, it is now well established that the most common and aggressive ovarian cancers predominantly develop inside the fallopian tube as so-called serous tubal intraepithelial carcinoma lesions (STICs) before spreading to the ovaries and beyond. This paradigm shift opens up an unprecedented opportunity for detecting and treating ovarian cancer earlier inside the fallopian tubes, such as via the engineered 'spermbots' to be developed in this project.

What outputs do you think you will see at the end of this project?

By the end of the project we will have shed light on currently under-studied early ovarian cancer characteristics, as well as tested the potential of engineered sperm as novel diagnostic and therapeutic tools in relevant in vitro and in vivo settings.

Who or what will benefit from these outputs, and how?

Combined with the patient and public involvement and engagement we will perform (e.g. taking advantage of regularly meeting ovarian cancer patient groups at the Establishment), this work will form the groundwork towards future clinical translation. In the longer term, our studies could serve as a paradigm for a new platform of cell-based diagnostic and therapeutic treatment agents, highlighting the ground-breaking nature of the work. Thus, if successful, our findings have potential to, in the longer term, lead to a radical change in practice, in which engineered human sperm would be used routinely for diagnostic and prophylactic purposes. In particular the approach might be used in women who are most at risk of developing ovarian cancer: postmenopausal women and women with certain genetic predispositions such as mutations in the breast cancer (BRCA) genes. As such, this proposal has potential to overcome major hurdles in the field that have prevented significant improvements in these areas for decades.

How will you look to maximise the outputs of this work?

Our findings will be made available to other scientists through collaborations, publication in peer- reviewed journals and presentations at scientific conferences and meetings.

Species and numbers of animals expected to be used

- Mice: 420

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is a model organism most closely resembling humans. The human and mouse genomes are approximately the same size, and display an equivalent number of genes, which are functionally conserved. Mice can be genetically altered, there is extensive literature concerning the topics of our investigation, and our own studies can be enhanced by exploiting appropriate ovarian cancer models developed by others in the field. These mouse models will be important for placing the findings of our in vitro (test tube) studies into an appropriate and meaningful in vivo (living organism) context. It is the combination of in vitro and in vivo studies that will provide the insights required to understand the early ovarian cancer events occurring inside the fallopian tubes and subsequently exploit these findings to the development of new theranostic (diagnostic and therapeutic) approaches, such as the engineered spermbots to be developed in this project.

Typically, what will be done to an animal used in your project?

Events mimicking early ovarian cancer developments occurring in humans will be induced by different means: (1) Female mice will have genes, known to be key in the generation of ovarian cancer, modified, so that they can be switched on by a chemical inducing agent when added for example to the drinking water or food of mice; (2) We will also undertake studies, initially pilot (using very small numbers of mice), to determine if ovarian cancer cells can be directly injected into the oviduct or neighbouring lower reproductive system sites, e.g. under ultrasound imaging conditions and recovery anaesthesia. At various time points after this the mice will then be inseminated, with sperm engineered to sense and/or detect early ovarian cancer lesions or appropriate control treatments (e.g. unmodified sperm and individual components added to the sperm during their engineering process), so that the various modalities can reach the oviduct. Towards this, we will perform pilot studies to optimise the least invasive method of applying sperm to the mouse reproductive system, so that they can reach the oviduct, such as artificial insemination via the vagina requiring no anaesthesia or injection into the uterus or oviduct, imaging-guided or via surgical means under recovery anaesthesia. The ovarian cancer development and efficiency of the engineered spermbots in targeting and eradicating early ovarian cancer lesions will be monitored by a combination of palpation and non-invasive imaging (the latter under recovery anaesthesia). Targeting of the sperm towards early ovarian cancer lesions will be tested by coupling the sperm to ovarian cancer cell-targeted antibodies and/or other targeting moieties, such as magnetic caps to facilitate guidance via external magnetic fields, which we will trial in pilot experiments. The success of these approaches will be compared to current standard-of-care treatments for ovarian cancer (such as doxorubicin-/platinum-/paclitaxel-/olaparib-based chemotherapies) using the least invasive method. Occasionally, the mice may be perfused, once only, with preserving agent whilst

under non-recovery anaesthesia. At the end of the study the mice will be killed humanely and tissue taken for microscopic examination.

What are the expected impacts and/or adverse effects for the animals during your project?

See section below.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The most severe of procedures will be the the induction of cancer lesions/tumours in genetically engineered and normal mice and insemination combined with regular induction of anaesthesia. All of the mice used will experience this since it is required for the insemination/injection of the mice and the guidance/imaging procedures. For Protocols 2 and 3 the most severe procedures will be the above combined with the induction of cancer lesions/tumours in genetically engineered and normal mice. The majority of mice (up to 95%) are not expected to show signs of adverse effects that impact on their general well-being. In line with this, the STIC lesions induced in the mice will not cause adverse effects per se, and the majority of mice will not progress to tumour development as a consequence of the spreading of STIC lesions to the ovaries and beyond. The vast majority of the procedures will therefore result in no more than transient discomfort associated with any of the individual steps and no lasting harm. The health of all mice will be observed daily. Notwithstanding this, all the mice will be humanely culled at the end point of the experiments.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to have a species with an intact reproductive system, including oviducts. Insects and fish are therefore unsuitable as they develop eggs ex vivo. Moreover, cancer development and spread involves a plethora of interactions between the cancerous cells and their surrounding environments, governed by multiple signals originating from both their immediate neighbours and distant tissues. Combined with the contributions that different components of the reproductive system have in facilitating sperm transport to the

oviduct, the proposed research cannot be carried out in tissue culture alone, but can only be addressed with the use of animals.

Which non-animal alternatives did you consider for use in this project?

We will fully take advantage of non-animal alternatives to test the engineered sperm in different 2- dimensional and 3-dimensional models of in vitro grown ovarian cancer cells. However, the aims of this study cannot fully be achieved without using living organisms, as there are too many factors contributing to sperm transport inside the female reproductive system and ovarian cancer development inside the fallopian tube to be appropriately modelled (see also above). However, extensively optimising the efficiency of different types of engineered spermbots in vitro, will allow us to take forward the minimal number of engineered spermbots for animal testing.

Why were they not suitable?

We need to have a species with an intact reproductive system including oviducts. As such, mice are the lowest sentinent species that can be used. The study of engineered sperm and cancer cells in culture (in vitro) provides us with clues on the mechanisms of the efficiency of sperm targeting and eradication of cancer cells in a simple and valuable context, which allows the establishment of hypotheses as to which spermbots will be the most suitable for the proposed purposes in a living animal. However, these systems do not recapitulate the complex cellular and organ interactions described above to allow us to investigate the impacts of sperm transport through the reproductive system on the targeting and eradication of early ovarian cancer lesions via the engineered spermbots that we will develop.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on published studies in this area, group sizes of between 5 and 8 animals (dependent on the readout, typically fewer for transplanted tumours compared to spontaneous tumours in genetically engineered mice) per experimental group suffice. We would typically examine more than one model cell subpopulation/line of ovarian cancer. Likewise, we may use several doses of a sperm(bot) load, several types of engineered spermbots, or several different drugs or treatment combinations together with the appropriate controls (unmodified sperm and components used to engineer the sperm individually) to test a hypothesis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken advice from the local statistician within the Establishment and have adopted the principles described in the National Centre for the 3Rs' Experimental Design Assistant. As such, the use of mice will be minimised in several ways: (1) By considering on-going statistical estimation of power requirements in each of the studies, using prior results in order to use the minimum number of animals while retaining sufficient numbers for statistical significance. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence; (2) By incorporating as many test groups as possible within a single controlled experiment, reducing the number of controls required compared to a series of smaller experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be undertaken in order to determine the best approach and numbers of mice to be included in each treatment and control group in order to be both scientifically and statistically valid. The use of mice will be minimised in several ways: (1) By optimising our breeding programme to maximise use of mice in experimental protocols minimising the number of mice we do not require. Breeding is performed on a different Project Licence, by a dedicated group in our Establishment; (2) By doing as much preliminary work as possible in culture models in vitro and in situ prior to engaging in in vivo studies; (3) By minimising variability in results through utilising inbred strains and by housing them under identical conditions to limit variability; (4) By performing pilot studies using few mice when no information is available in the literature so that the number of mice utilised in experiments is reduced to minimal levels; (5) In all new protocols, we will establish the base line by procuring help and advice from husbandry staff and researchers at the Establishment but also from our experienced collaborators across the UK and internationally; (6) Furthermore, we will design small pilot experiments, carried out referring to https://www.nc3rs.org.uk/conducting-pilot-study, that will allow us to select the ideal conditions, so fewer animals are used, to calculate the minimum cohort size given the rate of expected events and also to determine gravity of these, allowing more accuracy for statistical powering calculation of group sizes in potential repeats.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The use of inbred and fully back-crossed mice not only reduces intragroup experimental variability but also eliminates incompatibility when cell transfers are carried out between various knockout, transgenic and wild-type strains. Our humane endpoints and check-points will help us keep pain, suffering distress and lasting harm to the mice to a minimum.

Why can't you use animals that are less sentient?

The cancer mouse models that we will use very closely recapitulate the human disease and thus will allow us to understand the molecular and cellular events and steps involved in the targeting and eradication of early ovarian cancer lesions developing inside the mouse oviduct by engineered spermbots. Since we are investigating ovarian cancer progression, we will need to use fully mature mice. As tumour growth is a long term process we cannot undertake the studies in terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where appropriate and possible, any short-term procedures will be undertaken under anaesthesia with the administration of analgaesia to minimise the experience of pain. We will constantly work to improve husbandry and procedures to minimise actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare. Mice will be maintained in individually ventilated cages under barrier environment, to avoid infections. When considering which route of administration of substances to employ, we will use the least invasive route whilst maintaining direct control of dose.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgical procedures will be carried according to the Laboratory Animal Science Association Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Unless otherwise specified, this project will follow the "Guidelines for the welfare and use of animals in cancer research" and the administration of substances and withdrawal of blood will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm (Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555- 77 (2010)).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our Named Animal Care & Welfare Officer, Named

Veterinary Surgeon and Animals in Science Regulation Unit. I will be a regular attendee and contributor to our Retrospective Review and Licensees meetings and the 3Rs Poster session, all of which take place annually at our Establishment.

80. Implantation of Biologically Derived Tissue Scaffolds

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Tissue engineering, implant, stem cells, biomaterials, decellularization

Animal types	Life stages
Minipigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Scientists and clinicians have intended to replace a section of diseased organ/tissue with one which had been tissue engineered in the laboratory. This tissue engineered organ/tissue can restore normal function for the patient thereby improving their quality of life.

The aim of this study is to tissue engineer an oesophageal tract to replace and restore function of a section of oesophagus in minipigs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A diseased or dysfunction organ/tissue sometimes require a tissue repair or replacement to restore function. However, due to limited source of autologous or allogeneic tissue available, this treatment become difficult. The ability to use xenogenic sources, which will not be rejected by the host will play an important role in clinical application. The radical approach of decellularisation of donor tissues and repopulation of those tissues with host cells makes this type of transplantation or implantation possible.

What outputs do you think you will see at the end of this project?

The ability to supply organs or tissues for transplantation, possibly from xenogenic sources, which will not be rejected by the host, will transform the prospects of patients who currently suffer considerable morbidity due to failure of tissue function. The radical approach of decellularisation of donor tissues and repopulation of those tissues with host cells makes this type of transplantation or implantation possible. This will not only transform the lives and aspirations of the recipients but will also considerably reduce the financial burden to the NHS.

As we have developed 3D cell culture technology, we have had to develop more complex perfusion systems allowing for the assessment of cells and scaffolds simultaneously. The data generated is vital for scientific arena both in terms of the bioengineering concept but also in providing fundamental information on how cells interact with their environment and how their growth and development might be beneficially modified using growth factors.

Who or what will benefit from these outputs, and how?

The benefits from this tissue engineering technology is not restricted just to patients and health care providers, there are substantial benefits to the wider medical and pharmaceutical community. We have optimised a three-dimensional (3D) method to culture oesophageal, intestinal and hepatic cells as organoid units (OUs). The success of this project can also contribute to the tissue engineering and tissue regeneration scientific community.

How will you look to maximise the outputs of this work?

- The work will support researches to advance and improve scientific knowledge and to achieve scientific breakthrough in human health.

- Whenever possible, TGI adopt data management & sharing policy to maximise the outputs of researches through publication or other routes, thus to maximises benefits to health & society

- Whilst publication of results would not be discouraged, it is expected that in most cases publication or dissemination will not be possible as the research will be conducted as a commercial service to companies.

Species and numbers of animals expected to be used

- Minipigs: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Minipigs are selected for this study because of their size of oesophagus similar to human's. Minipigs grow slowly and steadily in size which will help the host oesophageal tissue to incorporate with the implanted tissue for the period of the study (6 months) in order to assess the function of the replaced tissue.

Typically, what will be done to an animal used in your project?

The animals will undergo some interventional procedures including surgery and general anaesthesia, some of the procedures are optional

- to remove or retrieve part of the tissues (up to four tissues) or organs (up to two organs)

- to implant biological derived tissue or tissue engineered scaffold onto the body, such as oesophageal section.

- to perform surgical intervention as part of the procedures for investigating some adverse affects

- to perform blood sampling to inject contrast media

- to perform non-invasive imaging such as CT scan or ultrasound

If repeat blood sampling is required for the experiment, up to two (usually one) indwelling catheters may be inserted and tunnelled through the skin. This would be done under general anaesthesia. Alternatively, if blood samples are only required occasionally, they may be taken directly from a blood vessel while the animal is restrained.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible general adverse effects include reduce apatite, infection, tissue rejection, pain (moderate), bleeding, leakage and stricture in anastomosis and non function of implanted tissue. All these will be monitored and kept to a minimum.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

the overall expected severity level for all the animals included will be moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tissue regeneration is a complex living body process. If we can show that the tissues/organs that we have prepared are appropriately functional in a complete physiological system (the whole animal) their use can be progressed very quickly into human clinical cases.

Which non-animal alternatives did you consider for use in this project?

Over the past we have been able to design many of our experiments so that more work was done in the lab before moving to the animals. By developing these 3D cell models we can take very tiny amounts of cells from any animal and grow the cells over longer periods and look to see how they react to different stimuli e.g. growth factors. We also hope to be able to offer these models to other scientists as well.

Why were they not suitable?

Even with every efforts to replace of using animal with other methods, some of the researches on biological response cannot be simulated or tested in the laboratory. Therefore, the animal is carefully selected to form an experimental model to achieve its research objectives. If we can show that the tissues/organs that we have prepared are appropriately functional in a complete physiological system (the whole animal), their use can be progressed very quickly into human clinical cases.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals that will be used under this licence before it expires are estimated through our past experiences and current demand from the study sponsors.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to reduce the number of animals being used in this project, a robust study design is essential to minimise the animal usage and to maximize the scientific achievement. Where possible, all tissues/organs for decellularisation will be retrieved from animals undergoing termination at the end of other projects thus reducing the need for specific donors. However, it may be necessary to use animals as specific donors if appropriate tissues/organs are not available. We will ensure that the number of specific donors is kept to absolute minimum.

- All initial research to establish proof of potential will be carried out using sophisticated bioreactors and 3D culture models thus eliminating the need for live implantation at these stages of the projects.

- As our in-vivo studies will aim to establish function of the recellularised tissues/organs, they are observational rather than statistically driven which means we will be able to use very few animals to prove function (typically 3-4 per tissue/organ) and progress to human clinical implantation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All the studies will be carefully designed to use minimal number of animals without compromising the scientific output. This can be achieved from past study experience, published data, and pilot study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In order for some of the regenerated tissue/organ to be clinically relevant, the donor species need to be of similar size to humans. Therefore, the minipig is selected as the most suitable model for the duration of the study.

All the possible measurements will be carried out to minimise the pain, distress and harm to the animals, including staff training from external expert and closely work together with NVS and NACWA.

Why can’t you use animals that are less sentient?

Our choice of animal is in part dictated by human anatomical correlation. For this study, the minipig is a better anatomical model for oesophagus implantation. We, for both scientific and moral reasons, do not use dogs, cats or non-human primates.

As the most likely for future clinical application, xenogenic donor for human tissues/organs scaffold is from the pig, this will be the animal of choice for our tissue/organ retrieval and the technology

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All adverse effects will be closely monitored during post-op care period, which including pain management, which will be kept to absolute minimum.

Staff will be specially trained to handle minipig, and to observe any of these adverse effects. An video camera will be used to 24/7 monitor the minipigs

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

A number of published best practice guidance will be followed such as:

Guiding principles on good practice for Animal Welfare and Ethical Review Bodies,

ARRIVE: Animal Research Reporting In Vivo Experiments

Government Guidance on the Operation of the Animals (Scientific Procedures) Act 1986
LASA guidelines on surgery, anaesthesia and asepsis.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will closely work together with ASRU inspectors, our named information officer, NVS and AWERB; use of resources provided by the UK NC3Rs and Norway NORECOPA to update any advance policies, regulations and other information and impartment these accordingly and effectively during the project.

We will work closely under LASA guidelines on surgery, anaesthesia and asepsis, and seeking advice from specialist expert.

81. The Regulation of G-Protein-Coupled Receptor (Gpcr) Function in Health and Disease: Pharmacological and Genetic Manipulation

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

GPCRs, Inflammation, Cardiovascular Disease, Type 2 diabetes

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to elucidate how the function of certain membrane receptors called GPCRs impacts on whole animal physiology and how manipulation of these processes, either pharmacologically or genetically, influences disease progression and to identify new targets for drug discovery.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

GPCRs comprise the largest family of membrane receptors in the human genome, controlling almost all physiological processes, and are tightly regulated by a series of molecular events which serve to titrate signalling and prevent overstimulation. Disruption of these processes leads to disease. As such, GPCRs are highly sought-after drug targets by the pharmaceutical industry due to their 'druggable' nature i.e. being located on the plasma membrane and displaying tissue specificity. Indeed, therapeutics targeting GPCRs are available for almost all diseases including cardiovascular disease, mental health disorders, metabolic disease, cancer and inflammation. Despite their pre-eminence in the field, 80% of approved therapeutics target <20 specific GPCRs (out of ~350 tractable GPCRs).

However, it is currently unknown which receptors are involved in which physiological and disease processes and, in addition, many more have yet to be de-orphanised. These represent critical avenues for therapeutic intervention.

What outputs do you think you will see at the end of this project?

The projects and experiments performed will provide essential new information of GPCR contribution to health and disease and uncover novel therapeutics for pharmaceutical exploitation. This will be important for advancement of our understanding in the GPCR field as well as providing specific insight to GPCR dysregulation and disease. The data generated will subsequently lead to publications and presentation to the scientific community both national and international. There will also be significant public outreach to disseminate research findings to a lay audience.

Who or what will benefit from these outputs, and how?

The proposed research will identify novel GPCR and GPCR-effector targets that are important in the regulation of disease processes such as metabolic heath (obesity, type 2 diabetes and non-alcoholic liver disease or NAFLD), cardiovascular disease (atherosclerosis) and inflammation (sepsis).

Importantly, specific changes in GPCR molecular processes will be elucidated which, in the short term, will be a significant contribution to the field. In addition, longer-term, elucidation of whether pharmacological manipulation of GPCR function can reverse disease will have a profound impact on the pharmaceutical industry. The identification and development of new therapeutics with increased efficacy, reduced side effects and the

potential to reverse disease (as opposed to merely treat symptoms) will, overall, lead to improved patient health and a reduced cost and burden on the NHS.

How will you look to maximise the outputs of this work?

All work will be presented at national and international conferences and disseminated to the public during outreach and institute open days. In addition, all work will be published in peer reviewed journals. All work will be hypothesis driven and published regardless if confirmed or refuted.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice share ~85% homology of their protein coding regions with humans and are the lowest model that effectively recapitulates the human condition. Specifically, they express GPCRs highly homologous to human counterparts so that ligands are active at both species. This is not true of lower organisms (e.g. Flies and worms). In addition, disease models of metabolic health, cardiovascular disease and inflammation have been well established in mice to be directly relevant to the human condition. Finally, lower organisms do not have the complexity to adequately model higher complex behaviours or signalling networks.

Experiments performed in this license will use C57BL/6 mice or genetically altered (GA) mouse models on a C57BL/6 background. In addition, there are multiple genetically manipulated Cre lines commercially available that can be used in these studies. We will generally use mice from 8-10 weeks of age for our experiments and, for high fat/high cholesterol studies, animals will be kept on this diet for approximately 4-5 months.

Typically, what will be done to an animal used in your project?

We will use a wide range of techniques to address specific disease questions.

Metabolic health and cardiovascular disease. Mice fed a high fat/high cholesterol diet have increased weight gain, develop type 2 diabetes and, in genetically modified animals (ApoE-/-, LDLR-/-), have accelerated atherosclerotic plaque formation. We generally begin our experiments when mice are 8-10 weeks of age and are fed either chow or high fat/high cholesterol diet for a maximum of 20 weeks. During these experiments, mice be assessed for fat and lean mass changes using a Magnetic Resonance Scanner. Mice will be

individually placed in a tube and inserted inside the machine. The procedure will take ~5mins, after which the mouse will be returned to its home cage and will be performed multiple times (i.e. beginning, middle and end) per animal throughout the duration of the experiment. Mice will also be assessed for development of type 2 diabetes using glucose, insulin and pyruvate tolerance tests (GTTs, ITTs and PTTs respectively). Scanning and GTTS will occur 2-3 times per experiment and ITTs/PTTs once at the end. All tolerance tests will be performed a week apart in line with LASA guidelines and consist of a 5hr fast (overnight for PTTs) followed by blood glucose measurement. In addition, we will also assess whether pharmacological intervention (Intraperitoneally, I.P.) using drugs targeting GPCRs or GPCR adapter proteins will change these responses. Finally, we will use genetically altered transgenic lines to delete GPCR adaptor proteins exclusively in specific tissues to assess potential changesin disease progression.

Inflammation. To investigate the inflammatory response due to pathogen exposure, mice will be injected I.P. with the bacterial pathogen lipopolysaccharide (LPS) or peptidoglycan, or the fungal pathogen zymosan, that have been found to cause a mild inflammatory response and results in the recruitment and activation of neutrophils and macrophages. Typically for a C57Bl/6 mouse on chow diet, we would inject 1mg/kg of pathogen and cull 6h or 24 hrs post-injection and blood harvested for further analysis of immune cell composition. In addition, we will also assess whether pharmacological intervention using I.P. injection of compounds targeting GPCRs or GPCR adapter proteins will change these responses. Experiments may also be undertaken in transgenic mice exhibiting deletion of GPCR adaptor proteins exclusively in immune cells, leaving other tissues unchanged, to assess the impact of deletion in these cells on infection.

Terminal Culls. All mice shall be culled via Schedule 1 methods. For metabolic and cardiovascular experiments, mice will be fasted for 5h prior to culling and, in some cases, injected with insulin 10 mins before culling.

What are the expected impacts and/or adverse effects for the animals during your project?

Breeding

We do not expect any adverse effects during breeding of our genetically altered (GA) conditional and Cre lines.

Metabolic Measurements

No adverse reactions are expected during experimentation. For tolerance tests, mice will be injected

I.P. and blood collected from a single needle prick to the tail. This will result in mild discomfort that will be transient. Some drug interventions may result in weight loss during

HFD intake, however this should be beneficial to the animal. For experiments in modelling atherosclerosis, either the ApoE-/- or

LDLR-/- GA mice will be used. These will be obtained from commercial suppliers.

Inflammation

The dose of pathogen (LPS, peptidoglycan, zymosan) should only result in mild transient discomfort. Pharmacological intervention should result in beneficial to the animal and not cause additional stress.

Skin Conditions

In some cases mice have been found to develop ‘itchy ears’ and skin irritations due to scratching in response to HFD-feeding. These are usually treated with salt baths and topical medications. However, mice are culled if these persist.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect all mice to have severity level no higher than mild. The severity level for our GA mice in breeding is subthreshold. ApoE-/- and LDLR-/- mice used to model atherosclerosis have a moderate phenotype, but do not express any clinical symptoms when used under this project licence, therefore we expect mild severity and the same for our GA lines. For pathogen injection, all side effects are dose dependent and, for our scientific purpose we expect to be using doses that exhibit no more than mild severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice are the lowest model that effectively recapitulates the human condition. Lower organisms (e.g. Flies and worms) do not have the complexity to adequately model higher complex behaviours or signalling networks. By using mouse models we can investigate whole animal physiology that cannot be recapitulated in vitro and investigate genetic, protein and structural changes in tissues collected post-mortem as well as immune cell

analysis from blood. In addition, there are multiple genetically manipulated Cre lines commercially available that can be used in these studies.

Which non-animal alternatives did you consider for use in this project?

Prior to animal experimentation, all hypotheses are tested in vitro in cellular models to elucidate pharmacology before using animals as the final stage of investigation. Specifically, using immortalised cell lines expressing our proteins of interest, ligand affinity is determined using competition binding and efficacy via cell signalling assays. This ensures drug concentrations that fall within the ‘therapeutic window’ are selected before use in vivo and are not too low to be ineffective nor too high that would result in toxicity or off target effects.

Why were they not suitable?

In vitro systems do not recapitulate complex whole animal physiology, therefore animal experimentation is necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have extensive experience and published data in the area of metabolic health, cardiovascular disease, inflammation and addiction. These have been used as resources to calculate the numbers needed for experimentation. For in vivo studies a sample size of 8-10 mice is required per group for most physiological studies. This may be increased to 12 per group if some tissues are required for both histological and RNA/protein analysis. For examples, hearts collected at terminal culls are too small to be analysed by more than one method, hence numbers will be increased to allow for analysis by several methods. Both male and female mice will be used as appropriate for the disease/experimental design.

Breeding will be required to develop GA animals from our conditional lines using tissue specific Cre transgenic mice. We will use the expertise from our breeding wing to ensure the appropriate number of breeding pairs are set up to allow lines to be generated with minimum wastage. Any surplus animals will either be culled, and tissues stored for future analysis, or offered to other users. We will also use our ‘non-crossed’ conditional mice as our wild type controls to ensure all mice are utilised.

Appropriate advice will be taken from suitably qualified statisticians within the institution in order that our studies are always undertaken using the minimal number of animals but retaining appropriate statistical rigour throughout.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All animal studies are preceded by extensive in vitro experimentation to elucidate the molecular pharmacology of the pathways being investigated and the NC3R's experimental design assistant consulted. We also have published extensively on the optimal number of animals required to perform each experiment. During terminal culls, most tissues are harvested along with blood, and stored until required, to ensure nothing is wasted and each animal used to its full potential. These tissues are also available to other collaborators within and out with our institute.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At all points we will follow ARRIVE guidelines for all of our experimental set ups; blinding will be used whenever possible. However, for all the physiological testing, animals will be randomised in order to avoid bias. We will also consult the PREPARE guidelines to reduce waste and ensure reproducibility of experiments. Whenever possible, we aim to use both male and female mice to ensure relevance to the disease and explore potential sexual dimorphism in treatments.

Animal numbers bred for use on this Project will be minimised as far as possible by matching breeding to experimental requirements. Pilot studies, appropriate statistical analysis and power calculations will be employed to refine the number of animals used. The methods chosen will generate the greatest amount of data for the fewest animals used. To maximise the information gained from a single animal we aim to perform multiple in vitro analyses on each animal using the tissues obtained from terminal culls. Any pilot studies will be run in such a way that they will be rolled into the main study wherever possible, so that they are not additional to the numbers ultimately required for the main experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use C57BL/6 mice for all our experiments and all GA animals (ApoE-/-, LDLR-/-, tissue specific Cre, conditional knockouts) will be on a C57BL/6 background. This strain is used routinely for all experiments set out. For cardiovascular studies, ApoE-/- or LDLR-/- transgenics will be utilised since C57BL/6 mice do not develop atherosclerotic plaques. Furthermore, for LDLR-/- mice, require cholesterol in their diet to induce plaques, whereas ApoE-/- models spontaneously form these which can be accelerated via high fat/high cholesterol feeding.

For our metabolic measurements and experiments assessing atherosclerotic plaques formation, it will be required for mice to be fed a high fat/high cholesterol diet, to induce obesity and obesogenic pathologies. Type 2 diabetes development will be monitored via GTTs, ITTs and PTTs using the most refined ‘needle prick’ to the tail tip. In most experiments, only GTTs will be required in the middle and end of the study and in some cases, when comparing genotypes, at the beginning. PTTs or ITTS will be performed in the final two weeks of the study, a week apart. In some studies where obesogenic diet is used, pharmacological intervention could result in weight loss. However, this would be a beneficial consequence of the study and provide proof of principle that our intervention could be exploited for future therapeutic development.

We have opted to use I.P. injection for our bacterial inflammatory model, as less invasive than caecal ligation puncture.

Why can’t you use animals that are less sentient?

Less sentient animals do not have the physiology to accurately recapitulate the human condition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In addition to keeping up to date with the most refined methods in the literature, the N3Rs database will be used as a resource for information regarding refinement. We will be kept up to date of any changes to procedures from our Named Information Officer and our Named Veterinary Surgeon. Additional training will be undertaken when required including reverification if needed. We will also consult with our experienced animal staff and Named Animal Welfare Officers to ensure the most refined practices are used at all times.

All procedures are the most refined and up to date methods to ensure minimal distress to the animal. Ear biopsies will be used to perform genotyping analysis as these give the least harm and stress to the mice. For tolerance tests, we will use a single needle prick to the tail rather than snipping the end that was used previously. We have also opted to use the AlphaTRAK 2 glucometers during these tests as found this equipment to be more sensitive and use less blood than other models. Echo MRI scanning used for body mass measurements do not require anaesthesia (unlike DXA analyses) and is undertaken in <5mins per mouse, ensuring minimal discomfort.

For the induction of bacterial infection, mice will be injected I.P. with LPS/peptidoglycan which is less invasive and more reproducible than caecal ligation puncture.

Mice will be handled routinely, prior and during experimentation, using the cupping and tubing method and group housed unless separated for welfare reasons (i.e. fighting).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance for the project will be taken from resources provided online by NC3Rs, ARRIVE, Norecopa, PREPARE (hubs and microsites) and LASA guidelines for administration of substances. This includes links to publications, other online resources, and video and training materials. The vast array of resources guide on the general principles underlying the experiments highlighted in this project, including anaesthesia, breeding strategy and numbers, and experimental design. Changes in current guidelines will be implemented to the project in line with current literature and published reports. We consult with experts to implement improvements in animal welfare. Local refinements will also be implemented.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly receive updates in advancement from the N3Rs newsletter. In addition, our Named Information Officer is involved with several databases and forums to keep informed of any changes to procedure.

82. Studying the Regulation of Immune Responses in Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cancer, Immune response, Immunotherapy, Vaccines

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to understand the processes that support the initiation of immune responses to cancer to enable the identification and design of immunotherapeutic approaches for clinical benefit. The specific aims are:

1. Determine the mechanism of action by which immune responses to cancer are regulated (both positive and negative), and how tumours are able to influence this regulation.

2. To test the hypothesis that manipulation of these mechanisms can enhance immunity to tumours and be exploited in vaccines.

3. To evaluate potential new therapeutic agents targeting these pathways of regulation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

ne in two people in the UK will be diagnosed with cancer in their lifetime with 375,000 new cases of cancer in the UK every year and >165,000 deaths. There have been significant advances in screening, diagnosis, and treatment of cancer, however, fewer than 50% of people will survive the disease for greater than 10 years. Current treatments of cancer, which have been developed over the last 40 years, typically involve surgery together with chemotherapy and/or radiotherapy and are effective in some cancers improving patient survival. Despite this, one of the main issues with these therapies is that for a significant proportion of patients these treatments fail, and the cancer will return. Over the past 20 years, it has become evident that the immune system is important in detecting and combatting cancer. Crucially, recent developments in therapies that harness the immune system (immunotherapy) have shown significant advances in improving patient outcomes in some cancers. However, these immune responses are variable and only observed in a small minority of patients following treatment.

Therefore, having a better understanding of how cancers interact and regulate immune responses will help to enable the development of new more effective cancer therapies to improve patient outcomes.

What outputs do you think you will see at the end of this project?

Immunotherapy allows us to treat patients with therapies specific to the tumour, either utilising or ‘educating’ the patient’s own immune system to destroy cancer cells while leaving normal tissue mostly untouched. It is envisaged that this approach would mean that unlike conventional treatment, antibody treatment and vaccination (including changing how tumours look to the immune system) should not be associated with long lasting harm to the individual. Vaccination would lead to the development of a memory of the cancer cells meaning that the immune system would continue to search for, recognise and kill cancer cells long after the treatment has ceased providing long-term protection. Despite this promise, current immunotherapies work in only a minority of patients with variable responses in different cancers. In this project we therefore aim to understand how immune responses to cancers are regulated and how they are manipulated by cancers. Through this information we hope to gain better understanding of why some treatments fail. This

would allow us and others to develop new therapies to overcome these barriers and improve patient survival.

The overall aim is to gain a greater understanding of the way in which cancers are detected and identified by the immune response. If successful, this will allow the identification and design of therapies that harness the immune system for patients to better target their cancers. In addition, an understanding of the immune processes that support immune responses that target and kill cancer will permit continued monitoring of anti-cancer responses during remission and allow very early signs of relapse to be investigated. The ability to predict response to immunotherapy is also vital as current treatments works in only ~5-25% of patients. During this programme of work we anticipate the development of new drugs and approaches and will collaborate with partners such as charities and biotech/pharmaceutical companies to bring these to clinic. A drug that was developed under the current licence is scheduled for first in human trials.

Our findings will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings. Under the current project licence, we have published 14 papers in well regarded scientific journals and have presented our findings at 12 international scientific meetings and participated in public outreach activities and events. Together, the outputs of this work will advance fundamental scientific knowledge of how cancers are detected and interact with the immune system and the induction of protective immune responses. The work in this project will contribute to the early detection, potential new treatments and management of cancer for both clinical and veterinary applications.

Who or what will benefit from these outputs, and how?

Our studies will have multiple beneficiaries. In the short term we will publish our discoveries in open- access peer-reviewed journals, present at scientific and clinical conferences and participate in public outreach activities. These manuscripts will be available on eprints (online and freely accessible university repository) 3 months after publication. This data will be of particular interest to other scientists, clinicians and biotech/pharmaceutical companies. This new knowledge will provide others with a greater understanding of immune responses to cancer and enable development of more effective therapies in the future. The development of new therapies that benefit cancer patients is a long-term impact. In addition to cancer, the knowledge of how immune responses are regulated by cancer will be of interest to other research fields. There are direct parallels between cancer and infectious disease in the need to induce strong immune responses to clear either the cancer or the infection. Therefore, new knowledge from the programme will be of benefit to both human and veterinary clinical applications in this area. Another application could be in autoimmunity where the patient’s immune response attacks their own body. By understanding how immune responses are regulated, we may also gain a greater understanding of how to turn off overactive immune responses. This could be used to develop new therapies.

How will you look to maximise the outputs of this work?

We will aim to maximise our outputs through publication and presentation of our findings. We will publish our findings in open access journals and ensure all raw data is disclosed. This will enable them to be accessible to all. In addition, we will publish early drafts of our findings on bioRxiv which is a pre- published archive for life sciences and copies of our publications are available on the University ePrints server. This will make our findings immediately available to the scientific community. We have a strong track record in reporting our findings with 14 papers published during the current licence and include approaches that were ultimately unsuccessful to prevent unnecessary replication of this work. Most of the work undertaken is collaborative, involving other research groups and/or pharmaceutical companies. This collaborative approach further ensures that we can maximise our outputs.

Species and numbers of animals expected to be used

- Mice: 2900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We make every attempt to reduce the use of animals by using in vitro methods, for example isolating and performing experiments on various blood cells that are an essential part of the immune system outside of the body and creating new reagents from these cells for future use in vitro. However, as we are examining interactions between various arms of the immune system in different tissue and organs, in vivo investigations must be undertaken. The animal models we use are essential in providing the proof of concept and efficacy in an amenable system that can be manipulated to define the underlying mechanisms of action to translate successfully to humans; something that is not possible in humans.

Adult mice will be used in this study as they have a mature immune system, which is well characterised, with the cellular and molecular interactions broadly similar between mice and humans. This allows investigations of immune mechanisms and immunotherapies in these animals that are likely to translate to humans. The use of inbred mouse strains ensures that there is reduced variability in our experiments enabling valid conclusions to be drawn from the data obtained while minimising numbers of animals used. Our use of a number of tumour models that have been established in mice, whilst not fully replicating human disease, allow specific questions in relation to anti-tumour immune responses to be addressed to enhance the potential for translation into humans.

Typically, what will be done to an animal used in your project?

This work will involve a series of experiments to examine immune responses to cancer. This will be performed by introducing immune-modulatory agents and assessing their effects on the immune system and tumour cells.

In experiments to isolate specific immune cells, which can be maintained in the lab, mice will be injected with material to stimulate an immune response over a period of weeks (typically three weeks) before the mice are killed and their immune cells isolated to use in the lab.

In experiments to assess immune responses to vaccines or immune stimulatory agents, mice will be injected with a vaccine or stimulatory agent typically on three occasions (at least 2 weeks apart). The immune response is measured by taking peripheral blood to assess changes in immune cell populations over a period of weeks. A proportion of mice (85-90%) will be killed typically after 3-4 weeks, and their tissues examined to understand how the immune response is developing in different organs. These experiments are often done in the presence of a growing tumour, injected earlier in the experiment. This allows assessment of anti-tumour responses and to understand if immune cells are homing to the tumour. A proportion of mice are followed to measure tumour growth over time in experiments that may last up to 60 days.

We constantly endeavour to use the most appropriate model to address our objectives and therefore periodically we acquire or develop new tumour models which need to have their humane endpoints established to ensure we can reproducibly use these models to achieve our objectives whilst minimising the impact on welfare. Typically, 3-5 mice will be injected with tumour cells by an appropriate route and tumour growth and animal welfare monitored to determine the humane endpoint and to ensure no unexpected or excessive harms are evident.

What are the expected impacts and/or adverse effects for the animals during your project?

We typically identify mice by ear notching – this is expected to result in only mild and transient pain with no healing problems.

Mice will be injected with various substances that can stimulate immune responses using a combination of different volumes, routes, and frequencies. Injections will cause momentary pain which will be minimised by administering analgesic to the area and using the smallest needle size.

Substances may also be given orally to ensure they are taken up effectively. This can cause mild and transient pain and discomfort, but this resolves quickly. The minimum number of administrations and routes will be used to achieve the scientific objectives. Typically, animals will receive no more than three intraperitoneal injections, or five oral

gavage doses a week for 1-2 weeks. On some occasions mice may receive two injections on a given day through a combination of different routes.

For some experiments, mice will receive tumour cells by subcutaneous (under the skin) injection. The tumours grow at this site and can be readily monitored and measured over time using digital callipers. Mice are euthanised prior to or when the tumour reaches a size that is deemed to impact their normal behaviour, which may vary for different tumours, based on previous research. Throughout, the health status of the animal is the primary consideration. Experiments will be terminated, or individual mice euthanised at the earliest signs of tumour-associated symptoms such as piloerection, restricted movement, abnormal posture, abnormal gait, hunching, and/or weight loss up to, but not reaching, 20% body weight.

In some experiments which measure immune changes, peripheral blood is taken from a superficial vessel. Pain from bleeding is controlled by suitable anaesthesia/analgesic and no long-lasting harm with minimal volumes being taken.

When the immune system is stimulated, for example with immune stimulatory substances e.g. vaccines, this can result in symptoms similar to those experienced during an infection (lethargy, fever etc.). This can result in mice becoming less mobile, exhibiting pilo-erection etc. Typically, these symptoms are transient (first few hours) but can recur as the immune response develops (e.g. after several days) potentially resulting in further effects such as weight loss. These effects are therefore carefully monitored with mice killed if their symptoms become more severe or pass defined humane endpoint

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

During our current project licence, the proportion of mice experiencing sub-threshold, mild, moderate or severe severities was as follows and we expect similar proportions in our new project licence:

Sub-threshold – 2.5%

Mild – 71.2%

Moderate – 26.3%

Severe – <0.1%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Every attempt is made to reduce the use of animals by using in vitro methodology (in vitro experiments on mouse and human T cells and tumours, generation of T cell hybridomas). The generation of T cell hybridomas serves as a direct in vitro replacement for the need to generate T cell reagents from the immunisation of mice. This ensures that we can remove the requirement for multiple mice and reduces the variability of responses observed. However, as we are examining the immune system and the interactions between different tissue and organs, in vivo investigations must be undertaken. The animal models we use are essential in providing the proof of concept and efficacy in an amenable system that can be manipulated; something that is not possible in humans. Studying the complex interactions between various arms of the immune response in different tissues and organs is currently not possible using in vitro systems, therefore systemic in vivo studies are still necessary to study these complex immune processes.

Adult mice will be used in this study as they have a mature immune system, which is well characterised, with the cellular and molecular interactions broadly similar between mice and humans. This allows investigations of immune mechanisms and immunotherapies in these animals that are likely to translate to humans. The use of inbred mouse strains ensures that there is reduced variability in our experiments enabling valid conclusions to be drawn from the data obtained. Our use of a number of tumour models that have been established in mice, whilst not fully replicating human disease, allow specific questions in relation to anti-tumour immune responses to be addressed to enhance the potential for translation into humans.

Which non-animal alternatives did you consider for use in this project?

During the current licence we have been able forge links with clinicians which has enabled us to gain access to primary human material (tumours, blood, lymph nodes) to study human cancer more directly. These tissues allow us to reduce our requirement for animals, however these models are ultimately limited compared to the complexity of studying holistic in vivo responses and whole body systems. We therefore still need to use mice to study the influence of tumours on immune responses and how they are regulated using appropriate mouse models.

In a further attempt to replace the use of mice, we have generated a library of research tools such as T cell lines/clones and hybridomas that can be used in in vitro assays as a replacement for freshly isolated T cells from immunised mice. We have also explored the use of in silico methods to aid the prediction of immune responses. In some instances, this

allows us to predict the expected immune responses following vaccination and tumour challenge replacing the need for in vivo experiments.

It is difficult to quantify the reduction in the number of mice these replacement strategies have resulted in as the experiments are not directly interchangeable and form the basis for answering different scientific questions. However, the greater use of human material and the generation of research tools that can be used in vitro, enables us to replace the need for mice in our studies.

Why were they not suitable?

We are investigating the therapeutic effects of vaccines and examining the interactions of various arms of the murine immune system, with a view to therapeutic applications in humans. These interactions occur between multiple cell types, different tissues and organs, and as such they cannot yet be effectively reproduced in vitro. Whilst we can model particular aspects of the immune response in different in vitro systems, these currently do not fully recapitulate all facets of an intact immune system in a whole organism and therefore in vivo models are fundamental to our studies. In addition, they do not allow the assessment of unknown interactions throughout the body, which are critical to observe in developing new therapeutics e.g. liver, kidney toxicity.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate of the expected number of animals is based on the annual usage of animals in the current project licence whilst accounting for reductions in number for this new project licence compared to the current licence. This new project licence represents a reduction of almost 70% in comparison to our estimate from the current project licence. This reflects our shift to use primary human tissues where possible and strategies employed to replace the need for animal experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design is always based on the consideration of how we can achieve meaningful and reproducible results whilst using the minimum number of mice. We are committed to reducing animal waste, implementing the three Rs, and maximising the

reproducibility of research and so follow the PREPARE guidelines (https://norecopa.no/prepare) when considering our experiments.

As a means to reduce the numbers of mice in our project, inbred strains of mice will be used to reduce variability and allow reduced numbers whilst delivering reproducible data. In addition, we routinely use age- and sex-matched mice that have been bred in the same facility to further minimise variability.

Furthermore, developments in techniques and assay sensitivity (e.g. tetramer staining, ELISpot, intracellular cytokine staining) permit the detection of very specific immune responses in individual animals, rather than pooling animals from a larger group for analysis, allowing a reduction in the total numbers of animals required.

We have been using a range of tumour models for some time and so are aware of the reproducibility of controls and appropriate mouse numbers required in tumour growth and therapy experiments. Where we are studying new models or treatments, we will first confirm expected humane endpoints and then perform pilot experiments to gain more understanding and knowledge for the design of larger studies. This includes aspects such as dosing regimens, as well as to monitor for any signs of adverse events. Typically, these early experiments will consist of small groups (two mice) inoculated with a new tumour at different cell numbers to establish the tumour growth kinetics etc., even where data exists in the literature, as we appreciate the impacts of the local environment, microbiome etc on immune responses and tumour growth kinetics etc.. We also seek to minimise experimental bias through the use of empirical measurements where appropriate in relation to humane endpoints, such as the use of callipers to measure tumour size in tumour challenge experiments.

Where we have useful data (typically from pilot experiments), power analyses will be used to help guide the optimal numbers of mice needed for each experiment, taking into account expected magnitudes of impact. Power analysis is performed using the PS: Power and Sample Size Calculation programme: www.biostat.mc.vanderbilt.edu/twiki/bin/view/Main/PowerSampleSize):

For example, when assessing the immune responses in mice to immunotherapy experiments in either of the two commonly used in-bred strains of mice (C57BL/6 and Balb/c), we estimate that the difference in average time to reach humane endpoint that we need to be able to detect a significant effect due to the immunotherapy is 10 days e.g. tumour inoculated mice treated with immunotherapy survive 10 days longer than the vehicle treated tumour inoculated control mice the typical time to reach humane endpoint for control mice is 25 days. Using this information, a power calculation based on the ability to identify a difference between the groups indicates that we need a total of six mice per group. From our experience, we have found that we can reduce this number to five mice per group to enable us to detect a difference in immune response between treatment and control groups in the tumour models we use (CT26, B16F10, MC38). Similarly, for

assessing immune responses to vaccines or other immunostimulatory agents we typically use five mice per group for each experiment as this allows us to identify relatively small difference between groups (10-20% reduction in expression of Major histocompatibility complex molecules on the surface of immune cells) at the 5% significance level.

Therefore, the proposed mechanistic studies will be performed with experiments using groups of 5 mice in a standard vehicle versus drug manner. Throughout, replicate experiments will be performed to ensure reproducibility and when appropriate such studies may be combined to increase sample size (e.g. therapeutic survival). To assess animal survival Kaplan Meier curves will be analysed by Log rank test.

If substances or tumour models are used for the first time, pilot studies will be performed on individual mice and humane endpoints established as indicated above. Typically, substances will be administered and monitored within the first hour and then after 4 and 24h for adverse effects before proceeding; a dose escalation schedule conforming to accepted practice will be used should adverse effects be predicted from literature or expected mechanism of action. When agents are used for the first time in the laboratory, their dose will be based on previous published data whenever possible.

When new tumour lines are introduced, they must go through quarantine to ensure no animal pathogens are transferred to the facility and ensure their safe introduction into the animal facility. As an additional measure of reduction, we use this period to also monitor growth and humane endpoints reducing the need for additional animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mice used across experiments are inbred thereby minimising intra-group variability and allowing reduced mouse numbers for experiments. Experiments are always designed with the least number of animals that allow us to obtain statistically valid results. We use Power analysis calculations to determine the numbers of mice required to deliver statistically significant results, although with established disease models with which we have experience we can often use smaller numbers of animals whilst retaining our ability to achieve statistical significance.

Developments in technologies, techniques and assay sensitivity have enabled detection of very specific immune responses and hence more information to be obtained from one individual mouse than was previously possible e.g. multi-parameter flow cytometry, thus enabling multiple parameters to be assessed simultaneously from small samples. These higher dimensional analysis tools reduce the need to kill multiple mice at different time points. As an example, we now routinely use multi-parameter flow cytometry that allows us to look at 16 pieces of information in individual cells from mice where previously we were only able to assess 3-8. Soon we will be expanding this technology to allow us to look at up to 40 pieces of information further reducing the amount of material needed.

Other optimisations to reduce animal use include:

We routinely freeze additional animal tissues (whole and as single cell suspensions) when a mouse is killed to provide controls in in vitro experiments reducing the need to kill mice specifically for this comparative purpose.

The in vitro use of immune cells isolated from mouse tissues offers several benefits and aids in optimising the number of animals used for in vivo experiments. Importantly, this strategy is in line with the 3Rs. Due to the relatively low numbers of cells required to perform in vitro assays, this experimental approach allows the screening of immune regulating drugs or combinations, with potential for in vivo activity, whilst minimising the number of animals required. Furthermore, they allow refining doses, and identifying potential mechanisms of action and adverse reactions, prior to in vivo testing. In addition, in vitro assays using mouse immune cells represent a powerful reductionist approach to study their activation. They also allow the isolation and analysis of distinct cell subsets, and the direct assessment of drugs on each individual cell population, otherwise difficult to accomplish.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Adult mice will be used in this study as they have a mature immune system, which is well characterised, with the cellular and molecular interactions broadly similar between mice and humans. This allows investigations of immune mechanisms and immunotherapies in these animals that are likely to translate to humans. The use of inbred mouse strains ensures that there is reduced variability in our experiments enabling valid conclusions to be drawn from the data obtained. Our use of several tumour models that have been established in mice, whilst not fully replicating human disease, allow specific questions in relation to anti-tumour immune responses to be addressed to enhance the potential for translation into humans.

Our investigations of how immune responses are regulated or altered by tumours typically involve the use of in vitro approaches to first establish that we can observe differences that we expect. These experiments may include the ability of immune cells to kill tumour following treatment with a reagent. If successful we would progress to pre-clinical animal tumour models. This is a necessary step as the use of in vitro cell lines are not able to fully

recapitulate the complex interactions between multiple different cells and tissues and hence the need for animal experiments. In experiments where we are assessing new reagents that alter the immune response, we would first examine their effects in the absence of tumour to assess ensure any changes are observed without unnecessarily increasing the welfare impact to the animals by adding the cumulative harm from additional interventions and/or activities of the tumour. In all experiments we ensure humane endpoints are established that minimise harm to the animal without compromising the validity of the data obtained.

Why can't you use animals that are less sentient?

Our work examines the regulation of the immune system which is a complex system involving many different elements throughout the body and organs that work together to target foreign pathogens or cancer. The cellular and molecular interactions of the mouse immune system are broadly similar to that of humans, and therefore allow the investigation of potentially clinically relevant immune altering and/or activating treatments and their mechanisms of action in these animals. The use of less sentient species is not appropriate as they have very different immune systems as key components are either absent or are not as complex e.g. nematodes do not possess adaptive immunity. Younger animals also do not display the mature, antigen experienced, immune systems (the immune system becomes educated with age and development) that we seek to investigate and is most relevant for translation to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continually review our procedures and protocols and if unnecessary harms are identified or can be reduced, we modify protocols through discussion with the NACWOs, PPL holder, academic lead for the animal facility and Named Veterinary Surgeon (NVS) as required.

Over the period of the current project licence, we have instigated a number of changes that are listed below that serve as examples of our commitment to refinement:

1) We have moved to a new purpose-built animal facility. This unit is more conducive to high quality in vivo research utilising a 'barrier' system meaning that all materials coming into the unit are clean and enter via a dedicated positive-pressure pass-through hatch. All personnel entering must now change into scrubs and pass through an air-shower on entering (and leaving). The new facility also houses a separate quarantine facility that is no longer inside the main unit, but attached and accessible separately, with dedicated technicians only permitted.

2) All new strains of mice entering quarantine undergo rederivation before offspring are allowed in the main unit. All new cell lines must be screened in mice in the quarantine room, and serum from these mice and sentinels are assessed for the presence of

pathogens before cells are allowed to enter the main unit. All mice are now housed in individually ventilated cages. These changes minimise the risk of infection with obvious potential implications for the welfare of the animals and the quality of the research. In addition, the IVCs permit less disturbance to the animals as an additional refinement.

3) We have also implemented a number of new policies to improve welfare and reduce adverse experiences. All mice undergoing an injection now undergo a 'second check' by the person performing that procedure, within 30 mins-4 hours. This was instigated to prevent animal welfare impact should an unanticipated adverse event occur. If a procedure is delegated to a technician, this second check also incorporates a 'positive handover' between the technician and the PILh to transfer the responsibility for the mice back to the PILh to ensure it is always clear where responsibility for welfare ultimately lies.

4) In response to changing guidelines several further and specific refinements have been put in place. These include:

(a) Mice are handled by 'cupping' or by gently moving them using a dedicated tunnel, prior to any restraint to ensure mice are calm and habituated to the person performing injections, serving to reduce anxiety when handling mice.

(b) A policy has been instigated that needles are only to be used once. This single use policy is to prevent mice receiving an injection with a blunted needle. (c) We have transitioned towards the use of venesection as the primary method of taking blood samples instead of tail tipping. While this is not always possible (for instance when mice are receiving concurrent intravenous injections) new PILh are now trained in venesection and established PILh who regularly bleed mice have undergone re-training.

(d) We have instigated a policy that new in vivo experiments must be detailed on a 'study-plan' that encompass the experimental aims and how they address the project licence objectives, number and strain of mice, substances/cells administered, treatment dates, confirmation of required competencies and/or delegation of procedures, any known or anticipated adverse effects, welfare measures and monitoring employed and appropriate risk assessments. This study-plan must be submitted to the project licence holder and then responsible NACWO for approvals prior to experiment commencement. This has ensured that there is evidence of an appropriately detailed dialogue between the personal and project licence holder prior to work and as necessary enabled a discussion about the number of mice used and procedures administered.

5) We also have a new system that records training competencies for individual PILh to ensure that training on all procedures is renewed every 3 years. Training is conducted by dedicated trainers using Directly observed practical skills (DOP) forms written specifically for this purpose. As the project licence holder, I have access to these records, and reference is made to them on the 'study plan' ensuring that PILh also review their records regularly.

6) We have also adopted the practice of transferring male mouse nesting material, not substrate, to minimise male mouse aggression (the nest has calming pheromones in it, but the sawdust aggravates aggression as it holds the testosterone).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are a number of detailed publications and guidelines for the welfare and use of animals in cancer research that provide excellent guidance in the methodologies, study design and best practice that we will follow and adapt as appropriate to our research (Guidelines for the welfare and use of animals in cancer research Workman, P., Aboagye, E., Balkwill, F. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010). https://doi.org/10.1038/sj.bjc.6605642).

We will follow the ARRIVE guidelines https://arriveguidelines.org/ which provide a checklist of the minimum information required to be reported by groups using animals in research. ARRIVE guidelines are essential to help overcome issues in science such as reproducibility, reducing bias and the correct use of statistical methods of analysis.

In addition, we will follow and consult NORECOPA https://norecopa.no/3r-guide : Norway's National Consensus Platform for the advancement of the 3Rs (Replacement, Reduction and Refinement associated with animal experiments) database platform and PREPARE https://norecopa.no/prepare (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for better science experiments using animals to ensure that we are using the best models for our research.

Finally, regular communication with other users of tumour models at the University and communication with our peers at seminars and conferences and in published literature ensures any new or updated best practice is identified and adopted. Best practice information is also disseminated by our Named Information Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have a very active users' group that meet regularly (~3 times a year) to discuss issues that arise within the animal facility. These are attended by personal licence holders (PILh), project licence holders (PPLh), NACWO, Home Office Liaison Contact (HOLC) and establishment licence holder. Any issues and incidents that PILh need to be aware of are discussed at this meeting. In addition, the BRF user's meeting are used to disseminate information from Animals in Science Regulation Unit (ASRU), National Centre for the replacement, Refinement and Reduction of Animals in Research (NC3Rs) and other organisations and to provide details of training opportunities to enhance welfare and research practice. We have also begun a strategy of ensuring that PPLh and PILh undergo

regular refresher training (at least every 3 years) to ensure that they remain up to date with changes to best practice and aware of their responsibilities under the Animals (Scientific Procedures) Act 1986 (ASPA). These advances are further communicated through our active team of NACWOs and regular email updates.

We will also stay up to date with specific cancer groups, databases and alternatives (NC3Rs) for cancer models such as https://resources.researchanimaltraining.com/faqs/breast-cancer-research- alternatives-database; https://data.jrc.ec.europa.eu/dataset/352f7dfd-05cf-434b-a96a-7e270dc76573

83. Understanding the Balance of Immunity in the Skin in Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Skin, Immunology, Cancer, Dendritic cells, Immunotherapy

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this work is to use our study of skin disease to better understand how immune responses are controlled in healthy and diseased skin, and how cancer might exploit skin immune responses in order to grow and spread.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The skin is an important barrier site, but it is also the most common site of disease. In particular, the skin is prone to diseases caused by the inappropriate activation of white blood cells called T cells, either due to auto-immune disease or when patients take drugs that activate their immune system. Most people are also unaware that skin cancers are more common in the skin than any other site.

Because most skin diseases are not life-threatening, research into skin disease has lagged behind other diseases, but these diseases seriously impact on quality of life due to discomfort and disfigurement. We need to understand how immune responses are balanced in the skin in order to work out why they go wrong so easily and how we can being to prevent it from happening. In particular, we are focused on specialised groups of innate immune cells called dendritic cells and Langerhans cells. We know that these cells are important for detecting foreign invaders in the skin, but also for making sure that we don't start immune responses to harmless insults. But, we don't understand what the signals are that allow these cells to live in the skin and how these changes when things go wrong in disease.

Cancer is caused by our own cells that become changed so they can grow without control. Our immune system can be taught that cancer cells are a problem and need to be destroyed. This approach is called cancer immunotherapy, and has led to a dramatic change in our treatment of cancer in the last decade. But these treatments still don't work in most patients and we need to know more about how immune cells interact in tumours in order to find new ways of improving outcomes. One of the problems is that T cells activated by treatments to kill tumour cells can attack healthy tissues to cause graft-versus-host disease (GVHD), and the skin is one of the worst affected sites. This can lead to complete breakdown of the surface of the skin and patients die from dehydration and infection. This means that GVHD is a major problem limiting the success of these cancer treatments.

What outputs do you think you will see at the end of this project?

This project will provide new information about the way immune cells talk to each other in the skin. From this, we can begin to learn why this goes wrong in skin diseases like graft-versus-host disease (GVHD) in people who have received bone marrow transplants, and also other so-called autoimmune disease where the immune system attacks the skin. This work will be published in journals that can be read by people around the world, and we will also talk about our findings with other scientists at conferences in the UK and abroad.

Our work investigating dendritic cells in tumours will also provide new information that we will publish and share. We hope that this work could lead to new ideas about how to improve cancer treatments that work by activating our immune systems to destroy cancerous cells.

Who or what will benefit from these outputs, and how?

In the short-term (3-5 years) the main beneficiaries from this work will be members of the academic and biotech research communities. Understanding how immunity is regulated at barrier sites such as the skin is becoming increasingly important as we live in an aging society, where more and more people are suffering from diseases caused by activation of immune cells. We hope that in the long- term (10 years+), our studies will lead to better ways of treating people with skin diseases.Treatments for cancer have also improved significantly in the last decade, but there are still too many people who do not respond to treatment, and some of the new immunotherapies can cause side-effects in the skin. We still don't know what the long-term effects of these treatments will be on individuals.

How will you look to maximise the outputs of this work?

We aim to publish all novel, robust research findings, whether results represent new findings and insights or simply support a null hypothesis. Storing manuscripts with pre-print servers will help to maximise speed of spreading new data and prevent other labs duplicating work un-necessarily.

As part of our work we also generate large datasets, for example of gene expression, which we will share by depositing it on publicly-available databases. The advantage of these datasets is that they become a resource for the lab, to be mined over time as projects mature and we develop new hypotheses.

Species and numbers of animals expected to be used

- Mice: 15500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The aim of our research is to better understand how the immune system is maintained and functions in healthy skin and disease. Because of the complex physical arrangement of the immune system, and migration of immune cells between different sites, we need to use models that have the blood flow and other tissue features that allow cells of interest to meet and interact. We still cannot fully replicate this anatomical detail using in vitro models. The mouse is the best system to study the immune system; we know that the types of immune cells and the way they work are very similar between mice and people, and the immune system of the mouse, next to that of human, is the best characterised immune system of any organism. This means there are lots of tools and reagents available to study our research questions. We can also genetically manipulate mice, which is a key tool to unravelling the importance of important factors that allow immune cells to

communicate and do their job. We are focused on using adult mice for our work because we want to understand how immune cell changes to the skin in adults can be repaired.

Typically, what will be done to an animal used in your project?

All our mice are kept in sealed "individually ventilated cages" in groups of up to 5 mice. This means that they have a clean air supply and they are also given clean bedding and food and other items such as cardboard tubes to make the environment as comfortable as possible for them. We need to keep the mice in these special cages because sometimes the experiments mean that their immune systems are not working properly, so we have to protect them from catching diseases.

Healthy mice will typically receive an intervention to perturb skin immune cells, for example we might paint something onto the skin that we know will activate Langerhans cells. We normally use the back of the ears for these experiments because there is less fur there and it is a fixed area of skin. Mice might also received injections of drugs or antibodies to get rid of different immune cells to see how the response to what we have painted on the skin changes when certain immune cells are missing. When we give drugs this might be by different routes, but usually we try to make sure the drugs reach the skin immune cells so we inject them sub-cutaneously or into the dermis (intra-dermal). Sub-cutaneous injections are very quick, we pick up the mouse and hold it in a secure way so it does not move, then inject the substance under the skin usually at the side of the body or between the shoulders. The experience for the mouse will be very similar to when we have vaccinations in the arm. Intra-dermal injections will be more painful so we use a gas anaesthetic to put the mouse to sleep before injecting the drug into the skin on the side of the body. As soon as the mouse is moved away from the nozzle with the gas they wake up and are running around the cage within less than a minute. Sometimes we need to inject drugs or antibodies directly into the bloodstream of the mouse to make sure that they have an effect all over. We also take blood samples from some mice when we want to track changes in immune cells over time. Here injection is into the tail vein because it is the easiest vein to access with the least discomfort to the mouse. We need to warm the mice up so that we can see the vein so we put them in a special dark box with a carefully controlled heating system than heats to no more than body temperature for a maximum of 10 minutes. The mice are then placed in a tube-shaped restrainer that is the right size to keep them still while their tail is exposed, while also being large enough not to squash the mouse or restrict breathing. The person doing the injections will receive training for tail vein injections and usually (90% of the mice) the injection itself is very quick with only very short-term discomfort to the mouse. However, for some of our experiments we have to use older male mice and here the skin on the tail can be thicker, making it harder to see the veins. To minimise the suffering for the mice we start our injections about a third of the way down the tail from base, and only try 3 times at sites moving towards the tail base. If this does not work then the mouse is returned to the cage without injection. A similar procedure is used to sample the blood except a needle is use to puncture the tail vein with a small hole and special tubes used to collect the drops of blood that form. We only collect

very small volumes of blood (typically 50-100 microlitres) which is less than 10% or the total blood volume. When we have enough blood, pressure is put on the puncture site to stop bleeding and the mouse returned to the cage. In all out experiments with healthy mice, these interventions are quick and

the mice rapidly recover when returned to their cages. The substances we inject have all been used by our lab in the past and by other researchers and are given in amounts that we know do not cause discomfort or suffering to the mice. We then check the mice regularly before they are killed by a humane method (usually between 1 to 4 weeks from the start of the experiment) and tissues taken for analysis after death.

An important part of our work is investigating how Langerhans cells and dendritic cells cause graft- versus-host disease and how it subsequently alters the balance of immune responses in the skin. To do this we have developed a mouse model of graft-versus-host disease that closely mirrors the disease seen in male patients who have received stem cell transplants from female relatives such as sisters. For this adult male mice receive radiation treatment to remove their blood and bone marrow cells, which includes all their immune cells. We then inject female bone marrow cells and T cells into the tail vein to replace the missing immune system. Sometimes we use bone marrow from genetically modified mice for these experiments. This allows us to either trace specific cells because they carry a fluorescent marker and/or find the function of a protein by using bone marrow from mice that lack that protein. For the radiation, the mice are placed together in a special box and put into the irradiator which is a dark warm space that they are comfortable in. The radiation dose we use means that they sit in the irradiator for 10 minutes before being put back into their cages. We have carefully monitored the amount of radiation needed to mimic the conditioning treatment that patients need and have found that it works best when the final dose (11Gy) is split and given as 2 radiation sessions of 5.5Gy 2 days apart. This means that the radiation hit each time is less and helps stop problems that might happen due to e.g. damage that happens in the gut. We also put the mice on antibiotics, which are mixed in the drinking water, before the first irradiation. This stops the mice from getting sick because they can't fight infection without an immune system, and also because the radiation can cause leakage of bacteria from the gut. After the second round of radiation, we injected the bone marrow and T cells in the tail vein as described in the paragraph above. Graft-versus-host disease will develop in all of the mice that receive T cells. In most of the mice (80-90%) the disease lasts for about 4 weeks until it begins to resolve and the mice recover. The most obvious sign of the disease is that the mice lose weight. We check them every few days to make sure that this is not excessive which is judged as 20% of their body weight. The mice are also given special soft food in their cages so it is easy for them to eat if they are feeling poorly. While the mice have graft-versus-host disease we check them every few days using a health check system that we know gives a very reliable indication of how sick the mice are. This includes assessing how active the mice are, and whether their fur is sticking up, which is a sign that they feel unwell. Most of the mice some some signs of disease but remain active and begin to gain weight again about 2 weeks after the transplant. A small number of the mice will develop

more severe graft-versus-host disease however, in which case we will kill them humanely before they get too sick.

The other area of work we do in the lab is to investigate immune responses to tumours in the skin. For this the mice will receive injections of tumour cells in the skin (intra-dermal as described above). This is important to make sure the tumours grow in the same place as melanomas would in patients. These tumours grow as a single mass that we can measure over time up to about 15 days. We inject the tumour cells into the skin on the side of the body of the mouse to make sure that as it grows it will not be in the way when the mice move around and carry out daily activities. At different time points we will kill the mice humanely and analyse the dendritic cells and other immune cells in the lab. These mice might receive injections of e.g. antibodies via the tail vein to increase T cell activity to mimic immunotherapy treatments used in the clinic. In this case the mice will be injected approximately even 3 days for up to 2 weeks and we will compare tumour growth to control animals that did not receive the antibodies. Injections of antibodies or other drugs to block different aspects of the immune response will only cause transient discomfort as explained above.

In a few experiments we will use a microscope to see the movement of cells in the skin. Do to this the mice are given a general anaesthetic using an injection so that they are asleep and still while we do the experiment. Typically we use what we call terminal anaesthesia which means that the mice will not wake up from the experiment and will be killed in a humane way at the end. We look at the cells in the ear skin by putting the mice in a special restrainer so that the ear is in the right place for the microscope imaging piece, and record the image on the microscope for about 2 hours. By using the ear skin we do not need to do anything to the mouse to expose the area we are looking at, and because the mouse is asleep them won't experience any discomfort. We can top the anaesthetic up during the experiment if the mouse is coming out of deep sleep and the mouse is placed on a warmed heating mat to make sure they do not get cold during the experiment.

At the end of by far the majority of experiments (>95%) the mice will be killed using humane methods, usually this involves putting them in a dark box attached to a machine that provides controlled levels of carbon dioxide. Under these conditions they go to sleep before stopping breathing. We then make sure they are dead by breaking the join between the spinal column and the brain, known as cervical dislocation. Occasionally (<5% of the mice) we need to get more blood cells from the mice than we can get from tail vein blood samples. In this case we will use an alternative method to humanely kill the mice by using terminal anaesthesia to put them in a deep sleep before taking the blood by putting a needle into the heart (known as cardiac puncture). The mouse will be killed without waking up and so will not experience discomfort or any distress during this method of euthanasia.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of healthy animals analysing skin immune cells following an intervention of some kind, mouse health and behaviour is not expected to be altered as a consequence. Because we are studying immune responses in the skin, we frequently apply substances topically, by painting them onto the back of the ear or the shaved body skin. This may happen over a period of 1-2 weeks.

Repeated application of something that causes inflammation could lead to dermatitis. In this event we will stop applying the substance, and kill the mouse by a humane method if the irritation has not improved within 1-2 days.

However, because we are investigating how immune cells function during and after graft-versus-host disease and cancer, we need to cause disease in these mice. This means that our programme has a moderate level of severity. For our graft-versus-host disease model, mice will initially show clinical signs of graft-versus-host disease including weight loss and loss of activity, and will feel unwell (as patients do after transplants) but most of them will recover, gaining weight from about 3 weeks post- transplant. In the lab we have developed a very sensitive scoring system which allows us to monitor the mice closely, and if they are not recovering from graft-versus-host disease or are looking very sick, then we will kill them in a humane way.

For our cancer experiments, we need models in which skin tumours are growing in order to find new strategies to activate the immune system to destroy tumour cells. We make sure the tumours grow in places that do not get in the way of day-to-day activity of the mice (e.g. moving, grooming, eating) and

the mice are monitored to make sure the tumours do not get too big. Therefore, we do not expect the tumours to make the mice feel unwell. In the rare cases where tumours suddenly grow very quickly or break down to cause wounds, the mice will be killed in a humane way. Patients presenting in clinics with cancer ofter have metastatic disease, which is much harder to treat that single primary tumours. For a minority of our cancer experiments (<10%) we will inject tumour cells into the blood of mice to replicate metastases and spread of skin cancers. In these experiments mice may show signs of being sick by losing weight and being inactive. We will use our severity scoring system to monitor these mice closely and kill them if they are very unwell.

For all of our protocols we will use standard techniques such as injection of cells or substances to alter immune responses, and sampling the blood to monitor changes during an experiment. We do not expect these interventions to adversely effect the mice beyond the transient discomfort at the time of injection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of protocols in this project (3/5) require disease models and as such severities may reach moderate levels for 70% of mice used. 30% of mice will experience a mild severity due to breeding of genetically-modified mice, and limited interventions carried out on healthy animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our work focuses on understanding complicated interactions between lots of different white blood cells within a 3-D tissue environment (the skin or tumours). Part of these interactions need cells to be recruited from other parts of the body via blood vessels. Because of this, these experiments can only be done in live animals. In order to achieve our goals we propose to use the mouse as the model organism to study interactions between cells of the immune system in the skin and tumours in the development and function of the immune system for several reasons. Genetic modification of mice is well-established and their blood and immune system has been intensively studied and bears extensive similarities to that of humans. There are numerous reagents that help the study of the immune system, which is not the in other organisms. To our knowledge no other species of lesser sentience can fulfil the requirements of this programme to the same extent as the laboratory mouse.

Mice are the lowest vertebrate group in which well-characterised animal disease models have been developed. Furthermore, the mouse immune system is probably the best characterised amongst vertebrates, and a number of immune models now exist in genetically modified mice that help us to investigate the molecular interactions between immune cells.

Which non-animal alternatives did you consider for use in this project?

There has been a lot of work developing human skin equivalents in other labs and skin organoid cultures.

While we do not think we can completely replace the use of mice for our experiments, we have projects in the lab that are investigating the use of computer models to generate interactive maps of cell behaviours, specifically Langerhans cells and melanomas in the skin. We think that these could be used to predict ways in which Langerhans cells might sense and respond to growing melanomas and identify the most important signalling

molecules before we start experiments in mice. This approach could replace the use of mice for early discovery experiments.

Why were they not suitable?

At the moment scientists have not found a way to add white blood cells to these models, which live and function as they would in the body. These models also do not allow us to study the entry of white blood cells from the blood into the skin or tumours. We will continue to follow progress into these models in order to integrate them into our research in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of mice are based on our experience with previous projects that use similar experiments. This includes 5000 mice over 5 years fro breeding based on the use of genetically-modified mice which often requires breeding of heterozygous mice to produce homozygotes and wild-type littermates as controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will adopt the best possible practice on the principles of experimental design wherever possible and all data will be published following the ARRIVE guidelines. We have received training in the use of the NC3Rs experimental design assistant (EDA) tool and this was used to plan experiments for protocols in this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible, we use both male and female mice.

Breeding strategies for genetically-modified mouse lines ensure that, where possible, control groups can be taken from littermates or that control and experimental lines are derived from common parentage to ensure background genetic composition is equivalent.

An advantage of working with the skin is that we can obtain a lot of tissue from one mouse, and also other organs may be shared and used. For example, we frequently use non-involved skin from the same mouse for controls. We can also divide skin and tumours so

that tissue from a single experiment is subject to different analyses (e.g. microscopy and flow cytometry).

Lab analyses such as flow cytometry (FACS) and sequencing of expressed genes allows us to generate large data sets from small numbers of mice. These data allow us to generate hypotheses that we can test in larger groups of mice designed with the EDA.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In order to address our experimental aims, we need to use animal modes that allow us to replicate the aspects of human disease that are important to our work. For this project this is the movement of cells into and out of the skin and tumours in the skin, and interaction between these cells during graft- versus-host disease.

We propose to use mouse models for the following reasons:

1) These experimental models are well-established in mice and as such have been optimised to generate the minimal level of disease that still induces the effects that we are studying. For example, in our graft-versus-host disease model, the T cells from the transplant need to be present in sufficient numbers to enter the skin and kill immune cells, including Langerhans cells, therein. But we have titrated the number of T cells so they cause a self-limiting disease that reduces the duration of suffering. Alternatively, for our tumour experiments it is sufficient in most cases for mice to grow a single primary tumour, and we do not need models where this tumour spreads or gets too big.

2) There are a wealth of well-tested reagents for use in mice that mean that we are not testing new drugs with unknown effects that could cause harm and suffering.

3) We have worked with the animal house staff at our establishment under our project licenses for nearly 10 years and have a established an excellent partnership of support and understanding about our models. This means that the staff know when the mice are most likely to feel unwell after receiving irradiation and bone marrow transplants and are careful to minimise distress and suffering, for example by providing soft food and extra bedding in cages of transplanted mice.

Why can’t you use animals that are less sentient?

To our knowledge no other species of lesser sentience can fulfil the requirements of this programme to the same extent as the laboratory mouse. This is because the cells and functions of the immune system are highly conserved between mice and humans. Other model organisms such as flies or zebrafish share some aspect of the innate immune system, but do not have an adaptive immune response. Also, these organisms do not share the conserved skin immune anatomy that is present across mammals, for example the presence of hair follicles.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have a very carefully worked out scoring system in the laboratory (that has been adopted by many other groups which share our animal unit). This recorded monitoring allows us to identify mice that are looking more unwell then we expect from our experiments. Depending on the score, these mice will either be given soft food to help them eat and drink to aid their recovery, or, if necessary killed by a humane method before they suffer too much.

We have a lot of experience with our graft-versus-host disease model and have refined it to minimise suffering for the mice. This includes giving the irradiation as 2 separate doses over a period of 2 days. This reduces damage to the intestines caused by higher doses of irradiation and therefore the mice are healthier. We have also tested the number of T cells transferred to cause clinical sub-lethal graft- versus-host-disease, where most of the animals recover.

By working with the skin, we can often paint a substance onto the skin rather than injecting it into the mouse. This reduces suffering both because we avoid the use of needles for injections, and also because we can induce a local response that does not make the animal feel unwell.

For some of our work we may be able to use inducible genetically engineered models which are more refined because they allow us to investigate the consequences of changing a gene or cell-type at defined time-points.

In the event that any of our animals are unexpectedly unwell, then the vet will be called to advise on how we can minimise suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Use of NC3Rs resources and links within the website provides us with best practice guidance, for example there are guidelines on the use and design of pilot studies (https://www.nc3rs.org.uk/3rs- resources/conducting-pilot-study), breeding colony management (https://www.nc3rs.org.uk/3rs- resources/breeding-and-colony-management), non aversive methods for handling mice (https://www.nc3rs.org.uk/3rs-

resources/mouse-handling) and the single use of needles for injections (https://www.nc3rs.org.uk/3rs-resources/single-use-needles). We also use the guidance by Workman et al on the welfare and use of animals in cancer research (https://pubmed.ncbi.nlm.nih.gov/20502460/).

We will seek to up-date best practice using the NC3Rs website and on advice from the named information officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All new members of the lab are encouraged to attend NC3Rs training courses, and use NC3Rs resources to keep us informed about advances. We also benefit from posters and information in the foyers of our animal units.

3Rs approaches are embedded in the ethos of the lab and we are constantly looking at technological advances that would allow us to replace the use of mice with alternative systems.

84. Neural Bases of Action

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Neural circuits, Motor control, Sensory System

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Goal-directed behaviours rely critically on internal representations of the surrounding space. While we understand increasingly well how neurons represent space, how brains construct such spatial representations and use them to guide action remains unknown. Here, we plan to investigate the transformation of neural spatial representations into actions, and how such representations emerge from sensorimotor experience acquired during developmental stages.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The voluntary control of actions is an essential mechanism that allows us to live a purposeful life. We operate it effortlessly in normal circumstances and only become aware of its importance in debilitating neurodegenerative conditions. Our work aims to identify the

key neuronal and molecular mechanisms responsible for the normal function of the action control system.

What outputs do you think you will see at the end of this project?

We believe that our research will improve our fundamental knowledge of movements execution by: a) identifying neuronal populations that are crucial for specific features of motor execution. b) characterising novel aspects of the function and assembly of motor circuits. c) in prospective, long term, identifying and targeting neuronal populations whose impairment leads to the severe motor defects.

Who or what will benefit from these outputs, and how?

Our research will principally benefit our basic understanding of how the nervous system control motor planning and execution. While the focus is on basic research, our discoveries might also have clinically relevant repercussions through the identification of novel therapeutic targets for the treatment of movement disorders.

Within the context of our work we have generated and will generate transgenic mice that will be of use not only to our project but the all scientific community. Within the scope of this work we already generated viral vectors that have already been adopted by the scientific community and will continue to do so. These technological developments have been greatly appreciated by the scientific community and have been the main focus of review works. Our latest work also led to a successful patent application indicating that the output of the work might also have a translational impact of interest to the pharmaceutical industry.

How will you look to maximise the outputs of this work?

Findings will be made available to other scientists through publication in open-access journals and presentations at scientific conferences and meetings.

Species and numbers of animals expected to be used

- Mice: 23700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The role of neural networks activity in motor performance can only be studied in the intact, freely moving animals. Implantation of chronic indwelling electrodes in humans is only permissible in a very small number of clinical situations and thus is impractical for research purposes. Mice are the experimental species of choice because it is possible to generate

and acquire genetically modified strains, which allow the visualization and manipulation of selected neuronal populations. Adult mice will be used to study neural circuits involved in action selection, while neonates and juvenile will be used to study how these circuits shape during critical phases of development.

Typically, what will be done to an animal used in your project?

The advantage of using mice for our project is that we can selectively mutate genes of interest. To this aim we generate mutant animals by injections, for example, of genetic material in eggs followed by in vitro fertilization. To make sure that the animals born from these procedures do indeed carry the mutant gene, we take a very tiny piece of tissue from the outer ear and test the expression of the genes of interest. This causes minimal distress or pain to the mice. Some animals, adults ad neonates, most typically adults, undergo surgical procedures and for this reason we expect them to show clinical signs of a moderate severity as a result of electrodes, fibers or cannulae implantation. Surgeries last about

1-3 hours, during which we will make a very small window in the skull to gain access to the brain. After which, we implant tiny screws and a probe no more than 5 mm long. We finally seal everything with dental cement. They are expected to recover very quickly from the surgery, typically they are already walking around the recovery cage 15-30 minutes after the surgery. To study the visual system, we also perform injection in the eye, the capillary we use for the injection is very small, about 2-3 times the size of a hair. Mice recover quickly and normally show no signs of sight loss. Mice are then assessed in a variety of behavioural tasks. At the end of the experiments mice will be euthanised using a large dose of anaesthetic followed by cardiac perfusion, which allows preserving the tissue for the successive analysis. At no point during the procedure the animal is conscious or feels any pain.

What are the expected impacts and/or adverse effects for the animals during your project?

Surgical mice will experience some discomfort after surgery, and this is expected to last no more than 24 hours. Very rarely after surgery the severity of clinical signs may be such that the humane end points may be reached. Unless otherwise specified, the administration of substances and withdrawal of body fluids will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm.

To assess the behaviour of the animal, mice are kept on a diet so to increase their propensity to perform specific tasks in order to obtain food reward. These diets only take down the weight of the animal of about one tenth of their initial weight. This is only a partial deprivation as a food will still be given daily to the animals, they simply won’t be in a free feeding regime. Since food intake is not restricted during the task, well-performing mice might overall receive the same amount of food that they would normally receive in an ad

libitum feeding regime, however confining the majority of this food intake in shorter period of time.

Body weight will be measured daily. On the rare occasion that an animal approaches 20% weight loss within the food restriction period, then it is given immediate access to additional food.

With respect to the administration of noxious substances, this will lead to temporary irritation of the injected site. The irritation should disappear within 6h of the administration

Localised heat will provoke a transient mild pain for the duration of the stimulation. The painful state disappears shortly after the stimulus is removed <1h. Animals will be monitored at regular intervals. While the intensity is set so not to cause burns, there is still the chance of skin burns.

Animals will be monitored after the tests for sign of excessive persistent protracted licking/scratching of the stimulated sites or presence of sustained skin irritation. Animals will be monitored at regular intervals and a score sheet for pain and oedema will be implemented. Mild cortisone creams can be topically applied if such reactions are noticed. Analgesia can also be given immediately following the test to prevent the occurrence of pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for the vast majority of the mice (>80%) will be mild as we don't expect to work with animals carrying debilitating genetic conditions. Mice are expected to reach moderate level of severity exclusively during surgery and during the period immediately following the surgery, which represents <2% of the time spent by the animal in this protocol.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The role of neural networks activity in motor performance can only be studied in the intact, freely moving animal. This is because network activity depends on the communication of

multiple, distant brain areas and incoming sensory stimuli. Hence, we can only uncover the network dynamics in vivo.

Which non-animal alternatives did you consider for use in this project?

We have collaborated (and will continue to do so) with colleagues who devise computational models of motor networks and have on occasion used these to design experiments and predict their outcomes.

We have also considered the possibility of studying these aspect directly in humans.

Why were they not suitable?

With regard to carrying on these studies in humans, the implantation of chronic indwelling electrodes in humans is only permissible in a very small number of clinical situations and thus is impractical for research purposes. There is no non-invasive method of monitoring the firing patterns of groups of individual neurons in humans. Human neuroimaging techniques (fMRI, PET, MEG) lack either fine temporal resolution (PET and fMRI) or fine spatial resolution (MEG), and anyway deal with comparatively large sections of cortex. They cannot provide information about individual neurons.

With respect to computational models, these are still extraordinarily simple in comparison to the complexity of the brain, and cannot substitute for experiments themselves.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Husbandry: In order to pursue the key objectives of this license we will need to make use of transgenic animals. We estimate that over the course of the years we will need to make use of about 50 distinct transgenic lines. These includes mostly but not exclusively: population specific CRE and FLP mouse lines, which will be used to identify genetically defined neuronal populations; various versions of reporter lines, which will be needed to visualize those neuronal populations; activity modulators that will be crossed to FLP and CRE lines in order to alter the activity state of the identified neuronal populations. The establishment of those colonies will require, based on our previous experience, about 2075 animals.

Breeding and maintenance of the established lines is estimated to require, based on our recent experience, around 17000 animals for the duration of the licence. This is taking into

account the need of refreshing any given running line about 5 times per year and an expected usage of about 30 distinct mouse lines per year. We plan to maintain for any running lines an average of 12 females and 6 males.

These numbers ensure a smooth work flow for 4 lab members in order to provide access to the lines also in the case of parallel work with the same lines of multiple members (a situation that will occur frequently for the most commonly used lines, such as reporters' lines).

Experimental testing (e.g. electrophysiology, imaging, tracing, behaviour): Below we provide estimates, with justifications, for the number of mice required to test the family of hypotheses raised in each work package. While not exhaustive of all described experiments this paragraph presents the statistical reasoning behind four specific examples that capture the key features of proposed work.

Outline of the classes of hypotheses: Broadly, these hypotheses revolve around whether or not populations of cells are similarly/differently tuned to certain features of the movement in wild type animals (A) and genetically defined neurons (B); similarly, we wish to determine whether the neural networks upstream of these populations are both spatially non-overlapping (C) and/or functionally distinct in their tuning e.g. to sensory stimuli (D).

In considering tuning to features of the movement in WT (A), our previous experiments suggest that n=8 mice per collicular site for tetrodes recordings, and n=12 mice per site for the optogenetic experiments, are enough to reveal a statistically significant effect if it exists. Given our ambition to map a matrix of 3x3 collicular sites, and our combined historical success, we estimate around ~90 mice will be required for the optrode recordings and a further ~20 mice for the combinatorial stimulations experiments using custom-designed optic fibre arrays.

For tuning to features of the movement in genetically defined populations (B) (our preliminary results indicate a yield of tuned genetically defined units of ~5-10% of all recorded units depending on genotype. We estimate the need of recording ~10 mice per site per genotype. We aim to characterise at least 2 genetic types (inhibitory-pre and inhibitory-post) for the inhibitory population, a general inhibitory population and a general excitatory population. Given the initial exploratory phase for the search of the correct inhibitory populations, we estimate ~150 mice to characterise three distinct SC domains. Numbers will scale as with the number of genetic lines to be tested

For the spatial organization of brain-wide networks (C): our null hypothesis is that the sets of cortical inputs emanating from a given area of interest (AOI) converging onto any two distinct collicular glomeruli are spatially indistinguishable. Our experiments will consist of viral injections in such glomeruli pairs, aimed at revealing the spatial distribution of their cortical inputs. Due to the finite spatial resolution of viral injections, paired injections will need to be performed on a coarse 3x3 grid of 9 collicular sites at most (the same sites in all mice), and replicated three times to validate consistency. Among the 36 distinct pairs of

glomeruli/sites, we will investigate those that are two grid points away from each other, i.e. 8 pairs. For each pair, we shall test the null hypothesis by projecting the topographical locations of all labelled presynaptic soma for each of the two sites, onto the axis that maximally discriminates between them. Based on our experience with viral-based tracing, we estimate that we will exceed the necessary discrimination-threshold of 1000 labelled neurons in only about 1/3 of our attempts.

With respect to functional sensory tuning specificity (D), we shall follow a similar approach, now testing the null hypothesis that the cortical inputs to distinct glomeruli have no distinguishable tuning to sensory stimuli of the relevant modality. Although no research group has ever traced the cortical input to defined collicular neurons, let alone their tuning, we can roughly estimate the typical spread in preferred orientations for visually-tuned neurons in the superficial layers of the superior colliculus.

From this, we can caluclat with the appropriate statistical methods that ~80 tuned neurons per module are required. Based on previous studies in the V1 of awake mice, we may expect 30% of all labelled neurons to be tuned to the stimulus features of interest (e.g. orientation), meaning that we need to label at least 270 neurons. Based on our experience with viral-based tracing, we estimate that we will obtain this number in about 2/5 of our attempts. Thus, we require 8 (pairs) * 3 *(replications) * 5/2 (inverse success rate) = 60 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

With regard to the husbandry requirements, we leveraged on the data accumulated in our previous licenses that consisted of very similar workflow. With regard to the experimental work, thanks to the work in our previous license we have a good idea of our expected data distributions and we could build wherever possible accurate power calculation models.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Generally we run pilot studies to explore the parameters of an effect before the final design is decided upon. Whenever a non-standard experimental design will be required, statistical advice will be sought.

Whenever possible we make use of ex vivo recordings, this will reduce the instances in which we have to perform in vivo acute or chronic recordings, which greatly decreases the number of animals used under these protocols. However, in most of these cases we still rely upon a phase of in vivo work and rarely on behavioural training prior to the ex vivo work. In these cases we will adhere to ARRIVE guidelines.

Cryopreservation will be used to preserve important lines and remove the necessity to hold stock for extended periods. On occasion we may need to ensure that our protocols are

optimised and this may require the re-implantation of un-manipulated oocytes, embryos or blastocysts. Cryopreservation of embryos and sperm will be used for long-term storage of genetically altered mouse lines and pedigree lines with in vivo viability assessed to ensure that lines can be re-established successfully.

Rederivation will be undertaken should the health status of the animals be compromised in a way that would significantly affect the welfare of the animals or where the experimental results might be altered unduly.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the species of choice in most areas of biomedical research, allowing us to use powerful techniques such as transgenic animals and knock in/knock out, which would not be available for other species. For instance, the mouse is the only animal for which transgenic strains are currently available that allow us to genetically identify neuronal populations that would be otherwise undistinguishable.

This is crucial for the success of our project, as it relies on assigning individual function to identifiable neuronal cohorts.

The surgical approaches used are the least severe available, involving the smallest amount of tissue damage. Animals are given extensive post operative care including analgesics. Animals are closely monitored throughout the experiments and any signs of problems with implants or other aspects of surgery are immediately dealt with, or, if this is not possible, the animal will be culled. Similarly, animals are closely observed and monitored during the recording experiments and during interactions with other animals. All surgical procedures are carried out with the best possible level of asepsis and according to best practice (internal guidelines).

Prior to behavioural testing animals might be subjected to a dietary restriction of food. These restrictions are required in order to have the animal engaged in the task, in particular when multiple choices are presented and one has to be reinforced. Based on our previous experience the exclusive presentation of a reward is not effective in mice in absence of a dietary restriction and the animal is incapable or unwilling to perform the task. In a typical behavioural session, the animal is unrestrained moving in an open field

and can be presented with multiple water or food delivery ports or delivery sites and it has to reach one of them in order to obtain the reward. Reaching movements might involve limb or head/body movements to the target. Assessing animal behavior is key to determining whether or not the brain regions and neuronal populations we study are indeed involved in the planning and execution of spatially directed movements and hence an essential part of this programme.

In a separate behavioural testing paradigm, we will investigate the ability of the animal to identify the location of a noxious sensory stimulus (e.g. mild pain). In order to produce a very localised noxious stimulus, we will use either a localised source of heat or the injection of small quantities of formalin and then test the ability of the animal to identify the location of the stimulus under different experimental conditions and different genetic backgorunds.

Why can’t you use animals that are less sentient?

The mouse is one of the simplest mammals in which to study neural control of motor function. The role of neural networks activity in motor performance can only be studied in the intact, freely moving animal. Implantation of chronic indwelling electrodes in humans is only permissible in a very small number of clinical situations and thus is impractical for research purposes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Every step of our work has been carefully assessed so to minimise welfare costs and it's constantly re- assessed as improved methods become available. These steps include:

- post-operative care: e.g. our animals are hosted in a temperature/humidity regulated cabinets and monitored post-operatively by qualified staff.

- pain management: e.g. together with out vet we assess and implement the most effective systems for pain management pre, during and following surgical procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the Home Office Guidance on the Operation of the Animals and NC3Rs guidelines, specifically the ARRIVE guidelines(Kilkenny et al., 2020).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Biological Services Group and NIO keeps us constantly informed with advances in the 3Rs, we follow the NC3Rs newsletter and their seminars and demonstrations. We

constantly try to refine our techniques and standardise them once these bring tangible improvements.

85. Investigating the Regulation of Energy Metabolism

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

AMPK, Cancer, Lipids, Metabolism, Obesity

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

AMP-activated protein kinase (AMPK) is an enzyme that plays a major role in regulating cellular energy metabolism. The overall aim of this project is to gain a better understanding of how AMPK regulates metabolism and how this regulation is altered in certain diseases, such as obesity and cancer. An important aspect of the work is to determine how modulating AMPK activity either genetically or pharmacologically impacts on disease progression in pre-clinical mouse models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

AMPK is widely distributed in our body and acts as a master switch to regulate the energy metabolism in our cells. Changes in cellular metabolism are known to play an important role in a number of human diseases, including two of the most common health problems in the world, namely obesity and cancer. However, the underlying mechanisms that drive these changes remain poorly understood. It is important to carry out our scientific work in order to increase our understanding of the precise causes that lead to dysregulated metabolism. This will help us to design ways to prevent or slow disease progression. These could include both changes in lifestyle e.g. diet, or pharmacological approaches, targeting key proteins involved in metabolism. Additionally, a greater knowledge of the key molecules that drive altered metabolism might themselves provide new biomarkers for predicting disease progression and/or diagnosing disease.

What outputs do you think you will see at the end of this project?

The outputs of the work will include:

1. Increased understanding of the regulation of energy metabolism and how this contributes to diseases such as obesity and cancer.

2. Identification of new targets for drugs aimed at the prevention and/or treatment of these diseases.

3. Characterisation of new markers to diagnose and evaluate disease progression and/or monitor the efficiency of treatment.

4. Written information such as publications available to other researchers and the public to increase their understanding of energy metabolism.

5. Presentations at scientific meetings and public engagement events.

Who or what will benefit from these outputs, and how?

In the short-term, our work will benefit:

1. Biochemists: they will increase their understanding of the fundamental role of AMPK in energy metabolism;

2. Biologists: they will increase their knowledge in how AMPK is involved in metabolic diseases such as cancer and obesity;

3. Our current research: outputs from the work such as publications and public engagement events will help us to get further funding to continue our research and for training early-stage scientists in metabolic research.

In the long-term, our work will benefit:

1. Collaborative opportunities: if AMPK is defined by our work as a pivotal factor in obesity and cancer, then collaboration with pharmaceutical companies will lead to the design and testing of new drugs.

2. Clinicians: clinical trials using new drugs can be undertaken. Our research will also enrich the knowledge of clinicians in treatment of obesity and cancers. In turn, this will help us in recruiting patients for future clinical studies.

3. Patients: if clinical trials are successful and new drugs are approved for clinical treatment, patients suffering these diseases will benefit. Importantly, their families will receive indirect benefit from our work that will help improve their quality of life.

4. The Economy: effective treatment of obesity and cancer will reduce the financial burden of the UK health service and/or worldwide.

How will you look to maximise the outputs of this work?

We will use a number of approaches to maximise our outputs:

1. Collaboration with other groups to bring new expertise, access to new reagents and/or new technologies that we do not currently have ourselves.

2. Collaboration with industry when our work reaches the translation stage. Our institute has excellent resources for helping researchers to establish collaborations with industry.

3. We will use a variety of approaches to disseminate our findings, including the traditional routes of journal publications and conference presentations, but also including social media threads, podcasts and interviews.

4. For approaches that report null results, we will deposit our findings on preprint serves, as well as discussing them at scientific meetings to ensure that the information is accessible as widely as possible.

5. We will also publish methodological papers in addition to papers describing our scientific findings, in order to move the whole field forward and increase the rate of progress.

Species and numbers of animals expected to be used

- Mice: 17000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice for our studies. Mouse models have been widely used to study metabolism and to model human diseases, e.g. obesity and cancer, and are the lowest mammalian species available for such studies. In addition, the mouse is the most tractable mammalian species for genetic manipulation. The techniques required for generating genetically modified mice have been extremely well characterised and provide a robust and reliable approach for developing new mouse lines for studying metabolic regulation. Most of our studies will use adult mice as we want to understand long-term changes in metabolism and related disease situations. For some studies, we may use juvenile mice (under 8 weeks of age) to study the impact of altering diet at an early stage e.g. beginning a high-fat diet study on mice aged 4-6 weeks. This will allow us to understand the effect of altering diet before the mice have reached the adult stage.

Typically, what will be done to an animal used in your project?

Wild type and/or genetically modified mice will experience the specific procedures according to the disease categories (obesity or cancer) being studied.

1. Mice required for the study of metabolism and obesity will typically have the below procedures done on them.

We will feed mice either with standard chow diet or altered diets (e.g. a diet high in fat) and monitor their metabolism. To monitor their metabolism, we would record their food intake (once or twice for several days during the course of the study), record their body weight weekly, and take blood samples to measure blood glucose levels monthly. We would also use a special instrument called an echoMRI machine to measure their body fat composition (two or three times to during the course of study). The data from these monitoring experiments will help us to determine how the mice have responded to the altered diet.

In some cases, we will use wild type mice that are treated with a specific drug to target a known enzyme in order to alter metabolism. In this case, we may administer the drug using a special type of pump, usually inserted just beneath the skin, in a process requiring minor surgery.

In all cases, if we see a response, we would measure the respiratory rate of the mice using specialised home cages (typically for 5 days, once, possibly twice during the study). These specialised home cages record the volume of carbon dioxide the mice produce as well as the, volume of oxygen they consume. This allows us to calculate the calories they burn, indicating their metabolic rate. In some cases, we may implant small, specialised probes which allow us to measure physiological parameters over time, e.g. blood glucose, blood

pressure, core and/or localised body temperature, heart rate. We need to use surgery to implant these probes and this would be carried out under anaesthesia. For studies requiring implantation of these probes or the specialised pumps, we would usually restrict surgery to a single procedure and would remove the devices on termination. The total duration of all of the combined studies mentioned above would normally be 3-9 months. At the end of the study, mice will be humanely killed and tissues removed for subsequent analyses.

2. Genetically altered mice bearing cancer models (e.g. prostate cancer or liver cancer) will undergo the following procedures:

Typically, we would not routinely monitor their whole-body metabolic phenotypes, so would not normally carry out any specific procedures (other than monitoring the mice for signs of adverse health). At the end of the study, mice will be humanely killed and tissues removed for subsequent analyses.

In some cases, we may change the diet of the mice, e.g. from a standard chow diet to a high fat diet (for up to approximately 3-4 months). In other cases, mice might be treated with or without a drug, administered either by oral gavage or in the food or water (for up to approximately 3-4 months). The total duration for these studies would typically be between 4-12 months. At the end of the study, the mice will be humanely killed and tissues collected for subsequent analyses.

3. Implantation of cancer cells into mice

In some cases, we will study tumour growth by injection of cancer cells either under the skin into the flank of the mouse or into the site where the cancer would normally grow e.g. the prostate. In this case, mice would require a surgical procedure to inject the cells into the tissue. Following injection (either under the skin or into the tissue) the mice would be treated with or without a drug, administered either by oral gavage or in the food or water or through surgically implanted pumps. Tumour growth would be monitored during the study either by physically measuring the size of the tumour with calipers (for tumours under the skin), palpation (for prostate tumours), or using special imaging approaches that allow the tumour cells to be visualised with a modified camera. Typically, the duration of the study would be 4-12 weeks. At the end of the study, mice will be humanely killed and tissues removed for subsequent analysese.g. to determine whether metastasis has occurred.

4. Implantation of adipose cells into mice

In some cases, we will study the effect of transplanting adipose cells (adipocytes) under the skin into the flank of the mouse. The transplanted adipocytes will be isolated either from other mice, or in a limited number of studies, from human subjects. Once transplanted, we will monitor the mice in order to determine whether the adipocytes alter the metabolism of the mouse. In some cases, this will mean feeding the mice altered diets

(e.g. a diet high in fat). Typically, we would record their food intake (once or twice for several days during the course of the study), record their body weight weekly, and take

blood samples to measure blood glucose levels monthly. We would also use a special instrument called an echoMRI machine to measure their body fat composition (two or three times to during the course of study). The data from these monitoring experiments will help us to determine how the mice have responded to the altered diet. If we see a response, we might extend our study to measure the respiratory rate of the mice using specialised home cages (as mentioned in point 1 above). Similarly, as mentioned in point 1, we may implant small, specialised probes which allow us to measure physiological parameters over time, e.g. blood glucose, blood pressure, core and/or localised body temperature, heart rate. We need to use surgery to implant these probes and this would be carried out under anaesthesia. For studies requiring implantation of these probes or the specialised pumps, we would usually restrict surgery to a single procedure and would remove the devices on termination. The total duration of all of the combined studies mentioned above would normally be less than 6 months. At the end of the study, mice will be culled and tissues removed for subsequent analyses.

What are the expected impacts and/or adverse effects for the animals during your project?

In general, for the majority of animals we use, we do not anticipate any significant adverse effects. Animals undergoing invasive procedures such as surgery are expected to make a quick and full recovery.

In some mice, the expected impacts and/or adverse effects might be:

1. Hight fat diet may cause a greasy coat to mice, but this won’t irritate them. In rare cases, this may lead to slight skin damage which is treatable.

2. Diet alteration such as fasting and restricted food intake may cause temporary weight loss and we will control the loss to no more than 20% of their starting weight at the point of the procedure.

3. In some studies, we will be using a genetically modified mouse strain that shows progressive obesity from 3-4 weeks of age. These mice may show clinical signs such as laboured breathing. They also have impaired wound healing and hypothermia. Wounds can be treated and hypothermia can be controlled by supplying extra bedding. Laboured breathing will be an indication to stop the study.

4. In some studies, we will use a genetically modified mouse that can sometimes lead to a degree of cardiac hypertrophy which may cause laboured breathing, and can on rare occasions result in sudden cardiac arrest, particularly when under stress, in mice older than 6 months.

5. In some studies, we will use a genetically modified mouse strain that pre-dispose the mice to certain cancers, such as prostate and liver. However, for our studies, these cancers are subclinical and therefore are unlikely to show any adverse health signs such as pain or excessive weight loss (more than 15% of their initial body weight).

6. In some studies, we will use mice that have a compromised immune system (immune deficient mice). Although these mice will be housed in sterilised cages and maintained on sterilised bedding/food/water, they may develop infection and we carefully monitor the mice for any adverse health signs.

7. In some of our studies, we may administer drugs, e.g. tamoxifen that may result in local inflammation around the injection site and/or cause reduced food or water consumption leading to weight loss or dehydration. We will monitor mice for these adverse effects and if they cannot be treated and persist for more than 72 hours we would terminate the study.

8. Some studies require the mice to be singly-housed e.g. monitoring food intake, measurement of respiratory rate, and in these cases environmental enrichment will be provided to encourage normal behaviour. For all studies requiring single housing, experimental plans will place such studies towards the end of the protocol, so that subsequent single housing will be kept to the minimum period possible to complete the experiment.

It is important to note that in all the instances described above, we will closely monitor the expected adverse effects and take suitable actions to either control the adverse effect within their limits or terminate the mice, therefore the duration of the adverse effects will be minimum.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice used within this license are expected to fall under the sub threshold, mild or moderate severity categories. Based on our experience and the experiments planned we expect these to be divided as follows:

Sub threshold: 45%
Mild: 15%
Moderate: 40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals to achieve the aims of our work for several important reasons, outlined below:

1. One aim of our work is to study obesity, so we need an obese model. In humans, the main cause of obesity is due to the increase in consumption of high-calorie foods, rich in fat and sugar. Therefore, we need to study an animal model that eats a similar diet to become obese, so that we can study ways to treat and reverse the obesity.

2. Another aim of our work is to study cancer, including prostate and liver cancers. It is very difficult to carry out research on humans, and so we need to use pre-clinical mouse models in order to validate new targets that can be progressed to subsequent studies in man, including clinical trials.

3. In order to study energy metabolism, we need to precisely measure metabolism by monitoring oxygen consumption and carbon dioxide production to determine the amount of calories burned. These valuable data cannot be collected from non-animal studies such as cells in culture, necessitating the use of animal models.

Which non-animal alternatives did you consider for use in this project?

We have considered using cell-based approaches. For some of our cancer-related studies, we will use human patient-derived cancer cells. These human cells offer an alternative approach to the mouse models. However, there are some serious limitations for their use, such as the relatively short time frame (24-72 hours) available for experimental treatment, meaning that they cannot fully replace the animal models.

Why were they not suitable?

Cell-based approaches are useful for some studies and can give important results regarding the effect of altering specific enzymes on metabolism. However, it is not possible to recapitulate all of the effects of interactions between multiple cell types e.g. hormonal responses, in cell-based models, and so information regarding inter-organ communication can be lost. Similarly, metabolic changes that occur in a specific cell type can have a dramatic influence on immune responses and these can also be lost in cell-based models. Moreover, some of the readouts that we are interested in measuring e.g. food intake, cannot be studied in isolated cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is based on the projected number of mice needed for our project aims and takes into consideration our experience of previous studies that have been conducted under our previous Home Office Project Licence in which we used similar experimental approaches and similar mouse models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The choice of genes that we will study is based on previous cell based and in vitro biochemical approaches. Only genes encoding proteins that have been shown to be involved in regulating energy metabolism in other experimental systems will be examined. Although these in vitro studies cannot predict the effect of manipulating the gene in living organisms, they provide valuable clues enabling us to prioritise our experiments and keep animal numbers to a minimum. In designing our experiments, we plan to obtain the maximum possible data from a single animal. All studies are designed with careful statistical considerations with respect to sample size, utilise strategies to minimize bias such as blinding and randomisation and involve precise and reproducible assays which together ensure that the information we gain is robust while using the minimum number of animals. As well as drawing on our significant prior experience and published work, we have consulted the NC3Rs experimental design assistant allowing us to calculate the appropriate sample size based on each experiment. This will ensure that we are using the fewest number of animals and that each animal is being utilised to its full potential.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will take the measures listed below to optimise the number of animals in our project:

1. When breeding genetically modified mice we will use strategies to maximise the use of offspring wherever possible.

2. For physiological investigations, whenever possible procedures will be combined sequentially, and longitudinal studies on the same mice (including non-invasive imaging and serial phenotypic studies) will reduce the overall numbers of mice required to reach the scientific end-points.

3. We will always strive to use the most refined techniques available in order to reduce animal numbers through improved accuracy of measurements.

4. To reduce animal usage, where it is anticipated that a genetically modified line will no longer be of immediate interest embryos may be harvested and stored (frozen) to reduce the need to continue breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice, both wild type and genetically modified. We will study mice with loss and gain of gene function mainly in specific cell types, although in some cases we will study mice with global genetic changes. Targeting specific cell types minimises the chance that genetic manipulations themselves have broad effects on animal well-being. In most cases, the models we use cause no pain, suffering, distress or lasting harm from the genetic manipulations themselves. We need to use genetically modified animals with adverse phenotypes as these are the only models available for our studies and/or alternative models have similar or worse phenotypes. However, we will restrict our use of these models to the minimum number needed for completing our studies. In addition, we will establish and use monitoring and scoring systems relevant to the physiological system(s) affected by the modification, and endpoints will be established. The inclusion of inducible gene targeting is a further refinement as the genetic alteration can be restricted to adults following viral or chemical e.g. tamoxifen, treatment, thus bypassing any potential detrimental effects of genetic alteration on development. In some of our studies we will use interventions e.g. administration of drugs to target key metabolic pathways. In most cases we use established treatments that do not themselves cause pain, suffering, distress or lasting harm.

Dosing regimes will adhere to good practice guidelines and will follow our previous experience using similar strains and/or available literature using the same or related mouse strain. LASA guidelines will be adhered to and the most refined method will be used. Local AWERB guidelines for administration of tamoxifen and doxycycline will be followed. Doses and duration of dosing will not exceed those reported to have the desired scientific effects in the literature. For tumour progression, mice will be monitored regularly. The stages of tumour development that we study are subclinical, with no overt clinical signs expected. Advice from the NVS / NACWO will be sought should any unexpected adverse effects arise. Immune deficient mice (such as athymic nude or NSG mice) may be

used in tumour studies. To reduce risk of accidental infection these mice will be housed in sterilised cages and maintained on sterilised bedding/food/water.

Some mice may undergo recovery surgery. However, appropriate anaesthesia and pain relief will be given to the mice to reduce pain and stress during surgery and post-surgery. Pain, suffering, distress and harm will be monitored following the surgery, and appropriate actions such as treatment for wound infection or termination will be taken to minimise suffering.

Why can't you use animals that are less sentient?

We study metabolic regulation in mice with a view to understanding the potential causes of metabolic diseases such as obesity, diabetes and cancer in humans. In order to carry this out we need to study free-living animals with a similar level of complexity and metabolic regulation seen in mammals and humans. Thus we cannot use species that are less sentient than mammals. In some cases, we need to undertake studies on the same animals over time to see how their metabolism changes, and so these studies cannot be done in terminally anaesthetised mice. In other cases, anaesthesia has effects on the metabolic pathways that we want to study, and would therefore interfere with the measurements.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will take the measures listed below in order to refine the procedures to minimise the harms for the animals. Different measures will be applied depending on the animal experience.

1. Although we anticipate that the majority of our studies will not harm the animals in any way, where there is no prior knowledge of the outcome of the intervention (for example if a new genetic model is being used) and may have an adverse effect, pilot studies may initially be carried out on a small cohort of animals to determine appropriate dose rates/treatments/end points, being informed wherever possible by published data. Animals being used in such pilot studies will be closely monitored for signs of adverse effects and action taken to minimise suffering.

2. Anaesthesia, where used, will be of depth sufficient to prevent the animal being aware of pain arising from the procedure. All surgical procedures will be performed using aseptic, sterile surgical techniques and will be carried out by trained competent personnel reducing the possibilities of post- operative complications and mortality. Mice will be kept warm and monitored regularly until they have recovered from the anaesthesia. Peri- and post-operative analgesics may be administered to alleviate pain or distress for surgical procedures and other procedures which may cause more than transient pain. In all cases, protocols involving surgery will be agreed in advance with the NVS. The grimace scale will be used post operatively to aid in the assessment of presence or absence of pain. The use

of antibiotics following surgery will be administered where appropriate, as agreed with the NVS. Experimental protocols, including dosing and sampling volumes and frequencies, will be in accordance with current best practice (using sources such as the NVS, NACWO, NC3Rs, LASA).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow government guidelines such as the Guidance of the Operation of the Animals (Scientific Procedures) Act, the ARRIVE guidelines, LASA guidelines, the relevant published literature on studying metabolism in mice as well as the PREPARE guidelines, NC3Rs website and locally published guidelines from the 3Rs advisory group of our establishment.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult with resources such as the NC3R database and the 3Rs advisory group at our institute. We will consult regularly with colleagues, animal technicians and vets about best practice and potential further refinement of our procedures. Our Institute has recently appointed an Animals Governance Officer and we will liaise closely with this post to ensure we maintain best current practice. Additionally, we will keep up to date with the scientific literature to follow the published best practice in monitoring and assessing mouse metabolism in vivo.

To effectively implement the 3Rs in our work, we will discuss these issues in our weekly group meetings so members of the group who carry out animal work are kept informed to maintain best practice. One role of the animal facility governance is to implement the 3Rs to the whole institute, so we will closely work with this person and work on this person’s feedback on implementation of the 3Rs. We will encourage members of the group to take part in internal and external competitions on 3Rs, which will be a very effective way to implement the 3Rs in our work.

86. Immunity, Resilience and Repair

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunity, infection, cancer, healthy ageing

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We want to understand how lymphocytes interact with other cells types to promote immunity, resilience and repair at the organismal level. To achieve this we will combine physiological, cellular, molecular and computational approaches across the life course.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system is now understood to be a collection of distinctive cell types that mediate immune effector functions, such as antibody production or cellular cytotoxicity, to promote immunity. However, the molecular basis for this, including the genes that promote the durability of immunity to infection and limit the effector functions of immune cells to avoid harmful reactions against self and promote resilience remains to be understood. The molecular and cellular basis of how immune cells promote the healing and repair process is essential to understand how these mechanisms operate optimally and deteriorate as organisms age and will be fundamental to treating the common human diseases of the 21st century.

What outputs do you think you will see at the end of this project?

We anticipate the principal outputs will be scientific publications. The intellectual property we develop may underpin the development of new therapeutic modalities.

Who or what will benefit from these outputs, and how?

Other Researchers:

Our work will create unique research tools, methods and data resources relevant to the development and function of lymphocytes. Through publications, presentations and the use of data repositories our work will influence other researchers, although this may not be fully realised until completion of the project.

Industry:

Our previous work on immunomodulation has a proven track record in translational outcomes and successful working with partners in small and large commercial enterprises. We anticipate continuing impacts and our findings will be commercialised, where possible, through collaboration with industrial partners.

Patients and Clinicians:

We will continue to ensure that our research models are relevant to prevention and treatment of human disease.

How will you look to maximise the outputs of this work?

We will continue to publish our findings in peer-reviewed journals making use of open access, preprints and journals that accept negative findings or replication studies.

We will collaborate with colleagues in Universities, Medical Centres, other Institutes and the commercial/ biotechnology sector to promote awareness and influence the research direction of others.

We will deposit datasets and analytical tools in repositories and promote data accessibly through careful annotation, metadata and data visualisation applications.

We will share our research tools and know-how freely.

We will protect intellectual property and patent findings when appropriate.

Species and numbers of animals expected to be used

- Mice: 108070

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse immune system is extraordinarily similar to the human. While there are differences, these are far outweighed by the similarities; the fundamental appreciation that the cells and genes that regulate immunity in the mouse overlaps substantially with humans has brought fundamental health benefits in a global scale e.g., vaccination, skin grafts, therapeutic monoclonal antibodies, cell therapies. Remarkable discoveries such as regulatory T cells and subsets of innate lymphocytes were first made in mice and then found in humans. B and T cell receptors for antigen are formed by similar molecular processes and their repertoires selected and maintained by similar mechanisms.

The mouse has a long history of contributing to fundamental and applied immunology. The ability to delete individual genes in mice - in specific cells, at specific times - enables studies that are not possible in humans. The ability to perform infections or study the growth of defined tumours and take tissue samples for research is impossible or impractical with humans. Studies of controlled ageing cohorts under defined and constant environments are also impossible for researchers to perform over the human life-course.

Typically, what will be done to an animal used in your project?

Female mice (<2000 animals) will be injected with hormones to increase the production of embryos (superovulation) after which they will be killed to recover embryos (Protocol 1). To establish new mouse strains a small number of female mice (<500) will receive embryos via surgical or non-surgical procedures (Protocol 2). A very small number of male mice (<20) will be vasectomised to produce pseudo-pregnant embryo recipients (Protocol 3), these males will be kept until twelve months of age.

We will breed and maintain genetically altered (GA) mouse strains for experimentation. The maintenance until a maximum of 15 months of age will cover the mice used in this study under Protocol 4 where no or rare (<10%) mild effects are anticipated (< 84000 procedures). The majority of mice of both sexes will be studied either after killing by a humane method to address questions on lymphocyte homeostasis, or under the

experimental protocols below to study lymphocyte responses. We will recover post-mortem tissues and purify and/or grow lymphocytes for use in the studies below.

Some GA mouse strains may manifest moderate clinical signs as a consequence of the alterations to their genomes. Protocol 5 (< 150 animals) enables us to address questions of immune homeostasis in mice that may develop clinical signs that exceed mild limits of protocol 4 such as marked piloerection, intermittent hunched appearance, abdominal distension. We have a good understanding of the age of onset of clinical symptoms and when clinical features arise we shall aim to euthanise mice to recover tissues within 24 hours of symptoms being reported, or before exceeding moderate severity, to avoid suffering. Some mice with conditional Myc expression, a PI3K E1020K mutation or BCL6 transgenes may develop lymphoma. We have designed our breeding programme to minimise the numbers of mice that have an oncogenic combination of transgenes. We freeze bone marrow from these mice to use as donor cells for transplantation experiments under protocol 10 to generate a cohort of experimental animals in which the onset of disease is more synchronous.

A minority of mice including inbred strains with no genetic modification with no or mild phenotypes will be aged beyond 15 months (no more than 1300) to enable us to study changes in immunological processes with age (Protocol 6).

One important experimental approach we use, common to several of the following protocols is to use inducible gene deletion. Tissue specific and temporal gene regulation in cells can be achieved using a number of genetic alterations. These studies will involve a minority (~15%) of all procedures.

For the majority of our studies of immunity we will challenge the immune system using non-replicating antigens which trigger lymphocytes through their antigen receptors together with adjuvants or other immunomodulators (Protocols 7: 16,900 animals 7 and 8: 2000 animals).

The distinction between these protocols is that Protocol 7 will use genetically altered mice that have been bred specifically for the protocol, or mice into which we have transferred cells (adoptive transfer) to study how well they perform their specialised functions and how they influence other cells in the host; while Protocol 8 will use mice that have been prepared by stem cell transfer into irradiated recipient mice. The fewer than 2000 mice studied under Protocol 8 need 8-12 weeks to reconstitute the immune system before they can be used for studies of homeostasis or immunity.

When we use infectious agents that replicate, we will prioritise the use of attenuated bacterial or viral stains, live vaccines, or expose to doses of infectious agent from which we expect the animals to recover after experiencing moderate severity. This may result in some discomfort similar in duration and severity similar to that of a vaccination or infection, but is rarely found to lead to severe outcomes.

Under Protocol 9 mice will be inoculated with tumours which will grow for up to two weeks before administration of immune cells and subsequent study of the effect this has on tumour growth. These experiments should not last longer than 32 days and the numbers of animals used will be 500.

The study of the development of lymphoma will be conducted under Protocol 10 (< 400 animals). Frozen bone marrow or other sources of stem cells will be used to reconstitute the haematopoietic (blood cell) systems of irradiated mice. These will be monitored until the onset of clinical signs which is usually within six months of reconstitution.

In order to be able to investigate the ability of T cell subsets to regulate a graft versus host (GvH) response, Protocol 11 will use a proven allograft model using T cell-depleted bone marrow from C57BL/6 mice transferred into lethally irradiated Balb/c recipients and co-transfer of T cell subsets to elicit an immune response (<300 animals). These experiments will typically last less than 60 days.

What are the expected impacts and/or adverse effects for the animals during your project?

For most of the mice, including immunodeficient strains, we do not expect any impacts or adverse effects in our high-quality AAALAC accredited specific pathogen-free (SPF) animal care facility. NOD SCID Gamma (NSG) immunodeficient mice mice can exhibit progressive hearing loss that can be profound at three months of age.

Embryo transfer and vasectomy are surgical procedures with short term post-surgical pain. Post- surgical pain will be controlled by giving pain relief and any animal not fully recovered (eating, drinking, return to normal behaviour) within 24 hours will be euthanised.

For some GA animals bred on this licence there will be adverse events associated with loss of immune homeostasis. These can manifest as lack of weight gain, or even weight loss. Other visible impacts of inflammation include intermittent hunching, piloerection, deterioration of coat condition, a reduction in activity, abdominal distension, scaly/scurfy skin on ear, around eyes and on tails.

Although ageing is a major risk factor for adverse effects, we know that the vast majority of our aged mice remain healthy throughout the duration of their lifetime. There is an increased incidence of adverse effects not observed in young wild-type mice including altered coat condition, diarrhoea, eye abnormalities, abdominal distension, movement issues, tremors and seizures. A tiny minority of these develop tumours, but regular checking by our experienced animal technicians ensures these are detected early, and the mouse euthanised immediately. A specific code of practice for caring for aged mice is in place.

The adverse effects of irradiation can be infection or failure to repopulate the haematopoietic system. These effects, when they arise, are manifested within the first two

weeks following irradiation, most conspicuously as anaemia and weight loss. Some mice may lose pigmentation as a longer-term impact of irradiation.

The adverse effects of immunisation/infection or immunomodulation include systemic or specific tissue inflammation which will be transient, lasting for a few days. In the case of influenza virus there will be substantial weight loss which is restored within two weeks. Intermittent abnormal breathing may occur, but this will be transient lasting only a few days.

Some viruses will induce chronic infections with adverse effects such as weight loss and while this may be moderate in C57BL/6 other inbred strains manifest enhanced vascular permeability, lung immunopathology and animals will be closely monitored according to the humane endpoints detailed.

Tumour inoculation may lead to organ failure or affect breathing, feeding or drinking. Transplantation of human cells into non-irradiated NSG immunodeficient mice can lead to graft versus host disease (GvHD), but adverse effects will be reduced by introducing a genetically engineered Chimeric antigen receptor (CAR) into the transferred T cells. Cytokine release syndromes and neurotoxicity associated with these tumour immune models manifest as reduced activity, piloerection and weight loss.

The harmful manifestations of lymphoma may include reduced activity, intermittent hunching, marked piloerection, intermittent diarrhoea and occasionally intermittent abnormal breathing.

The adverse effects of GvHD include weight loss, which can become severe if not closely monitored. Signs of inflammation such as intermittent hunching, piloerection, flaking or reddening of the skin are also likely within days of the onset of GvHD.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for most of the mice will be mild or sub threshold Total animals used = 108070

- Mild: 24% (26440)
- Moderate: 2% (1830)
- Sub threshold: 74% (79800)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal experimentation is necessary because we want to understand the systemic properties of immune cells at the organismal level.

While we recognise limitations of mouse models and the need, where possible, to verify findings in other systems and species, we emphasise the mouse has proven overwhelmingly successful for the discovery of new cell types and the molecular genetic mechanisms underpinning their function. It has yielded essential basic knowledge of the immune system now being applied to improve the health of the humans and economically-important mammals.

Furthermore, it is extremely difficult to study lymphocytes in the bone marrow or lymphoid tissues of humans, because it is very difficult to obtain these from healthy donors.

Which non-animal alternatives did you consider for use in this project?

We have considered using cell culture methods, including organoids and do use these when appropriate. For example, we are using an in vitro model to investigate molecular pathways involved in germinal centre formation and plasma cell differentiation to complement the in vivo studies.

Why were they not suitable?

Features such as the distribution of lymphoid organs throughout the body and the intrinsic properties of lymphocyte recirculation cannot be recapitulated in tissue culture or organoids making investigations in the whole animal context essential.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals we will use based on our previous studies using these protocols. The numbers of mice required for the generation and rederivations of genetically altered mice are based on extensive experience of staff who regularly perform these protocols.

The use of colony management software and knowledge of the breeding performance of individual strains has enabled us to predict the numbers of mice of the correct genotype that we will produce from breeding, and the numbers of aged mice that we will need.

The numbers of mice required for experimental groups are based on power calculations, appreciation of variability and a knowledge of biologically meaningful effect sizes. We have factored in the need for experiments to be replicated independently and for greater variation in the responses of aged mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We reduce the numbers of animals used by paying careful attention to the design and planned analysis of the results including consultation when needed with a biological statistician in the Bioinformatics department and we use the NC3R's Experimental Design Assistant to ensure we are considering all relevant aspects of design. We perform our experiments in carefully controlled animal facilities that reduce biological and environmental variation; the use of optimised experimental procedures, including the use of genetically identical strains, blinding and randomisation to reduce technical variation; the multiparameter analysis of individual mice; the adaptation of new technologies such as the use of ribonucleoproteins to create knockouts or other genetic modifications; improving the sensitivity of techniques to enable measurement to be made on small cell numbers isolated from a single animal. For some experiments we are using in vitro methods to promote cell differentiation to defined states under controlled conditions, thus enabling access to cell numbers that would be unfeasible to obtain from mouse tissues.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible we will share mouse strains rather than generate new strains by transgenesis. Our mouse facility has an extremely efficient pipeline of tissue biopsies and rapid genotyping by a commercial provider, that provides timely results to enable efficient breeding.

Selective deletion of individual genes in specific tissues will be achieved by the use of Cre-Lox recombination to delete the gene of interest in defined cells. We employ rigorous quality control to ensure the fidelity of these systems. Pilot studies ensure minimum use of mice before decision points are reached in experimental design.

We have an established and highly successful programme of sharing of tissues with other investigators which we will continue.

We will prepare frozen stores of biological samples (tissue cells from infection and immunisation studies; bone-marrow; serum; and tissue sections) so that experiments can be performed on previously gathered tissues rather than using new mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use young-, adult- and aged-mice up to 26 months that are wild-type, transgenic, gene-targeted or contain reporter genes.

The small number of animals that will be embryo recipients, or undergo vasectomy, will experience transient pain due to surgery. This will be ameliorated by analgesia.

GA mice usually have a single gene altered, but multiple genes may be altered in the case of genetic redundancy or to combine gene mutation with reporters of cell fate. Typically, mutation is achieved by conditional deletion thus sparing any harmful or unwanted side effects of mutating a gene in all cell types of the body. In many cases, there is no pain, suffering, distress, or lasting harm expected with these models. In our facility which is pathogen free the animals with modified immune cells can live for normal lifespans without harmful effects of infection. The exception to this is for a small number of animals with abnormal immune regulation that may experience some symptoms of autoimmune or inflammatory disease - where mice displaying clinical signs will be killed and used for tissue collection before clinical signs exceed moderate severity.

Some animals will experience infections or immune challenges that will elicit immune responses. These experiments will be further refined by using Cas9-based methods to inactivate genes in cultured primary lymphocytes. This will refine some experiments in which cre-expression may cause unwanted effects that are difficult to control for. It will also reduce the numbers of animals bred.

The use of non-replicating antigens, vaccines, and attenuated microorganisms and in some cases vaccine strains (which have limited pathogenicity) will enable questions about immune responses to be answered.

Some experiments will use protein degron technology (where short amino acid sequences - as degradation signals - are used to manipulate protein degradation) as an alternative to genetic deletion of the gene. This important innovation allows protein ablation, but unlike gene ablation it is revertible. Moreover, it is not limited by the features of the cre-lox system which requires Cre to be expressed at a specific time.

Some experiments will involve injecting sources of haematopoietic cells to reconstitute the immune system. These experiments provide detailed in vivo knowledge that studying cells ex vivo cannot do. This can occasionally lead to ill health, either as a consequence of the irradiation or graft versus host disease, but these mice will be carefully monitored and any animal exhibiting moderate pain or distress will be culled.

We will use a specific type of immunodeficient mice (NSG) for transplantation of human tumour cells as these are considered to be a relevant preclinical model for adoptive cell therapy.

Suffering will be minimised by provision of analgesia where appropriate, provision of diet-gel food on cage floors should animals have difficulty accessing water due to mobility impairment, sub-cutaneous hydration if dehydration is apparent, housing in heat room/on heat pad if temperature drops significantly (e.g., following anaesthesia).

Why can’t you use animals that are less sentient?

Importantly, 'less sentient' species are not applicable for studies of B and T cells and the choice of species is limited by the fact that in evolutionary terms the adaptive immune system is largely a vertebrate invention. Even so, in some vertebrate species such as Zebrafish, the properties of lymphocytes differ significantly from humans and mice making them interesting but unsuitable for our project.

The mouse is the species of choice because of the extensively validated tools and resources available for quantitative immunological phenotyping and mechanistic studies across the life-course. Studies of ageing in the mouse have provided key insights into human immune systems but require the long-term care of mice with which we have much experience. The availability of inbred stains and well annotated genomes is important for our studies as they develop into the investigation of molecular mechanisms ex vivo and in vitro. The requires careful and attentive monitoring of breeding programmes and quality control.

Early-stage mouse embryos are unsuited to these studies as the adaptive immune system and immunological memory is a feature of adult animals and we propose to study these features in adulthood and ageing animals.

Terminal anaesthesia is inappropriate for long-term experiments that require systemic immune responses, but may be used to prepare tissues for further study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are mindful of the increased incidence of poor health for some individual mice as they age and that this may be affected by genetic modification, which may have a positive or negative impact on this process. We observe these mice with increased frequency and have developed a detailed checklist of possible age-related changes, and procedures for

monitoring and treatment. Data gathered from these studies will be available to further refine best practice.

We will implement any refinements developed by our animal house staff, who have a long history of innovative practice, including environmental enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments which will integrate refinements from the NC3Rs such as the ARRIVE guidelines on design and reporting; the LASA aseptic guidelines; LASA Diehl guidelines on volumes and frequency limits and the most up-to-date veterinary knowledge.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs during this project through attention to the work and outputs of the NC3Rs including workshops and webinars; by invited seminars on the 3Rs; and seminars on Research Integrity - which covers experimental design and data management. We will actively stay updated with our field of research through collaboration, conference attendance and reading the literature which frequently highlights innovations (e.g., Cas9 methods). We will use Home office advice made available to us through our dedicated Home Office Liaison.

To implement advances effectively, we will follow guidance from our local AWERB. Our animal facility also has a dedicated Strategy Committee and a User group, into which we influence and are made aware of emerging best practice. These groups discuss and make collective decisions about advances in the 3Rs and advise on how they can be implemented, both across the organisation, and by individual researchers.

87. Molecular Genetics of Hearing and Deafness

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Hearing, Deafness, Genetics, Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify and characterise genes required for mammalian hearing, and to elaborate upon the mechanisms of hearing loss. Provide proof-of-principle intervention studies to test the potential of possible therapies to restore or preserve hearing function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Hearing impairment is the most common sensory deficit in the human population. According to figures from the World Health Organisation there are currently around 360 million people worldwide living with mild to profound hearing loss, which includes all types of hearing loss (e.g. conductive and sensorineural) and age of onset (e.g. congenital, early-, and late-onset). Approximately half of these cases have a genetic basis, with the hearing loss occurring either as an isolated condition (non- syndromic, 70%) or presenting with additional phenotypes (syndromic, 30%). Around 150 non- syndromic loci have been identified in human and over 400 genetic syndromes are known that include deafness. To date, around two-thirds of the genes for non-syndromic deafness loci are known, and while the causative genes for several of the most common deafness syndromes have been elucidated, the vast majority of genes underlying syndromes with deafness are unknown. As such, we are far from having a complete understanding of the genetics underlying hearing function. In addition, a recent Lancet Commission on Dementia identifies midlife peripheral hearing loss as the highest individual risk factor for dementia, and this is pertinent as age-related hearing loss (ARHL) is the most prevalent sensory deficit within the population affecting >30% of individuals older than 55-years. However, currently little is known about the genes underlying ARHL.

Mouse genetics has played an important role in our understanding of the development and functioning of the mammalian auditory system. Utilising forward-genetic screens many deafness mouse mutants have been identified, and characterisation of these have enabled genes critical for hearing function to be elucidated. Allied with gene-driven approaches, mouse mutants continue to help elaborate the molecular mechanisms and physiological bases of human hearing impairment. Furthermore, mouse models offer the opportunity to study cochlear pathologies resulting from mutation of these ‘hearing’ genes, something that is not possible in humans due to the cochlea being encased within the hardest bone in the human body. Moreover, the increased understanding of the biology of hearing disease gained from studying mouse models will continue to allow the advent of therapeutic interventions designed to protect or restore hearing, and potentially reduce dementia incidence.

What outputs do you think you will see at the end of this project?

The identification and characterisation of new mouse models of hereditary hearing loss will increase our understanding and knowledge of how the mammalian auditory systems functions. Moreover, by generating mouse models carrying human deafness-causing mutations we will be able to identify the pathological changes occurring within the cochlea, which is important for understanding disease onset and progression. Investigation of these models will help to further define the molecular and cellular basis of hearing and hearing loss.

Over the next 5-years, it is our intention to: validate and characterise up to 6 candidate deafness genes by generating and phenotyping the appropriate mouse model; elaborate upon the functional interactome of known 'hearing' genes; and, identify up to 3 therapeutic targets for future work.

The primary objectives of this project are to:

1. To breed and maintain genetically altered mouse models

2. Identify and functionally characterise novel genes required for mammalian hearing.

3. Establish new insight to the molecular mechanisms and pathological processes involved with hearing loss.

4. Undertake proof-of-principle studies of potential therapies for auditory dysfunction.

Each novel model that we characterise has the potential to implicate additional molecular targets for investigation, which we will explore in partnership with collaborators from academia and industry.

Moreover, through the validation of human loci and genetic variants we have the potential to provide a genetic diagnoses for patients with idiopathic hearing loss.

Integration of our new data with established knowledge will be facilitated through publication and presentation of our findings.

Who or what will benefit from these outputs, and how?

Our research will have impact in the short-term, and in the long-term after the completion of the project.

In the short-term, the data and resources (mouse models) produced as part of this project will be of great interest to UK and international researchers. We will produce data that will determine the role of specific genes in the function of the mammalian auditory system, and identify the molecular and cellular consequences associated with perturbation of these genes. These new data will be fed back directly to clinicians and patient groups, including large-scale human projects such as the Genomics England 100K Genomes programme, to help provide patients with a genetic diagnosis.

A key long-term benefit will be the provision of new genetic pathways and fully-characterised mouse models that can be tested to determine if they can be modified by therapies to delay or prevent hearing loss. These models will be made available to the scientific community. Moreover, our findings will continue to be disseminated through publication in open-access, peer-reviewed journals and presentations at scientific conferences.

How will you look to maximise the outputs of this work?

It is common for sensorineural hearing loss to be part of a syndromic disorder e.g. Usher (deaf- blindness) syndrome, and many metabolic and neurological disorders. In particular, there is a growing literature suggesting age-related hearing loss is causally associated with cognitive decline and having an increased risk of dementia diagnosis. While we are able to assess our hearing loss models for some of the classic symptoms pertaining to these additional disease areas (e.g. vision, metabolism, neurobehaviour and neurodegeneration), we always look to work with collaborators who are expert in their respective fields to ensure our models are fully characterised.

Dissemination of the new knowledge generated by these works will involve presentation of findings at major international scientific meetings and publications in open-access, peer-reviewed journals. This will include communicating our unsuccessful approaches as well as our successes.

Species and numbers of animals expected to be used

- Mice: 27400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

While it is possible to perform genetic manipulations in flies, frogs and fish, the processes being studied here are being studied in a mammalian context and although other animal and non-animal species can be informative in this regard, they cannot supplant studies specifically in mammals. While flies and fish both have mechano-sensitive cells that are required for stimulus detection, and can be thought of as similar to the sensory cells required for mammalian sound reception, it is only mammals that have evolved cochleae - the organ of mammalian hearing. As such, mice remain the model of choice for studying the mammalian auditory system due to: the similarities in structure and function of the inner ear; the wealth of the genomics information available; their relevance to humans; and, the technologies to be able to generate, establish, cryopreserve and disseminate mouse colonies.

Moreover, well-developed and characterised inbred strains of mice present an opportunity for reducing variability (thus enhancing reproducibility), and for identifying genetic interaction between two or more genes.

Hearing loss is a common birth defect and it is also the most prevalent sensory deficit experienced by the elderly, as such we are interested in both early- and late-onset hearing loss, and to do this we will study neonatal, juvenile, adult and aged mice. Importantly, the mouse offers the opportunity to study the progressive (age-related) changes associated with the onset and progression of hearing loss, something that is not possible in humans.

In addition to altering genes, we are interested to understand how environmental factors such as noise impacts upon the onset and progression of hearing loss.

Due to the unknown nature of the GA lines that will be tested it is possible that some may not be viable, in these circumstances we may study embryos to help identify why the mice do not survive when a particular gene(s) is perturbed.

Typically, what will be done to an animal used in your project?

Many of the mice on this licence will be used only for breeding. This is due to the complex nature of hearing and the panoply of genes implicated in hearing loss, with our aim being to understand these genes and the cells that affect this disorder. This sometimes requires several steps of breeding to obtain a group of mice with the necessary combination of genes that can be studied. We will also maintain breeding lines to ship to collaborators (authorized to accept GA lines) to allow specialised studies to be undertaken, with the aim of maximising our understanding of the hearing deficit in our mice while also reducing overall animal use.

Approximately 4,000 mice will undergo phenotype testing to characterise preclinical models and for hypothesis-testing. The majority of mice will undergo single, or recurrent, auditory threshold testing, which involves anaesthesia used for immobilisation. Some will experience a combination of tests over their life-span, most of which are non-invasive, although a small number involve anaesthesia used for immobilisation, for imaging, physiology recordings, or the administration of substances to modulate gene expression.

Typically, mice undergo a final terminal study, performed under anaesthesia, and in some cases a terminal bleed or perfusion may be carried out. All experiments are expected to end by 78 weeks of age.

What are the expected impacts and/or adverse effects for the animals during your project?

There are many possible adverse effects that could occur due to genetic modifications of the mouse genome. Moreover, in some cases we will be breeding the genetic alteration to homozygosity for the first time. Possible adverse phenotypes are those that lead to sub-viability such that homozygotes die between birth and weaning.

The genetic alterations studied in this project may lead to hearing loss in the mice, which in itself does not lead to overt adverse effects in mice. However, due to the developmental, physiological and genetic similarities between the cochlea (organ of hearing) and the vestibular apparatus (organ of balance) that together comprise the inner ear, there is the potential for deafness genes to also cause vestibular dysfunction leading to balance defects. In severe cases this may manifest as a stereotypic circling behaviour.

Moreover, it is common for sensorineural hearing loss to be part of a syndromic disease e.g. Usher (deaf-blindness) syndrome and many metabolic and neurological disorders. As

such, other adverse effects that might occur during the lifetime of the mice include deterioration in health, tremors and lack of condition.

Also, there is a growing literature suggesting age-related hearing loss is causally associated with cognitive decline and having an increased risk of dementia diagnosis. As such, genetic alterations in the mice used in this project may lead to the development of dementia-relevant phenotypes. In mice these changes may lead to: increased aggression/fighting; decreased food intake leading to weight loss; or, changes in memory and behaviour that may not be apparent in the home-cage, but require additional testing to measure.

For auditory threshold testing mice will need to undergo anaesthesia. All anaesthetic use in mice carries a risk of mortality, which may differ between genetically altered lines.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

14,000 mice on the mild breeding and maintenance protocol are not expected to suffer any adverse effects and the vast majority will not reach higher than a sub-threshold severity.

On the moderate breeding and maintenance protocol, it is anticipated that any mice carrying the disease-causing phenotype could exhibit a moderate phenotype. Moreover, it is anticipated that of the GA lines being bred to homozygosity for the first time, 50% could exhibit a moderate phenotype. As such, approximately 25% of the 2,100 mice may suffer a moderate severity.

4,000 mice on the phenotype characterisation protocol 90% expected to reach a moderate severity. This is in part due to the phenotype of the mice, in which the genetic alteration could lead to a moderate severity. However, this mostly reflects that the majority of these mice will undergo a hearing test and the combinatorial effect of repeating mild tests over the life span of the animal in order to understand the progression of disease. This will lead to an overall moderate experience for aged animals that have undergone recurrent longitudinal phenotyping.

Of the 500 mice expected to experience a noise-challenge, 100% will reach a moderate severity due to all receiving at least one hearing test.

Of the 500 mice to be used to assess therapeutic interventions for hearing loss, 100% will reach a moderate severity due to all receiving at least one hearing test.

What will happen to animals at the end of this project?

- Killed

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The mammalian auditory system is highly complex, having a sophisticated, tonotopic organisation that needs to be maintained from the cochlea to the brain. Given the complexity of the auditory apparatus, with its myriad of interacting cell types, it is impossible at this juncture to reproduce and study this biological system using non-animal alternatives. In particular, the combined use of genetics technologies allied to the study of the cochlea during the ageing process, or in response to noise, would not be possible in an in vitro or ex vivo system.

Mice continue to be the predominant model organism for hearing research. Similarities in auditory structure and physiology between mice and humans, the close evolutionary relationship of genomes, short lifespan, genetic standardisation and the available genetic toolkit together make the mouse a useful and crucial model organism for studying the functional genomics of the mammalian auditory system. Furthermore, we are interested in identifying co-morbidities in other organ systems (e.g. syndromic hearing loss) and hence a whole animal approach is required.

Which non-animal alternatives did you consider for use in this project?

As we begin to functionally characterise our new mouse models of hearing loss and to investigate the underlying molecular mechanisms we may be able to make use of newly developing techniques. For example, Liu et al (2016) have reported a 3D culture system that can generate large numbers of functional sensory cells. However, these ESC-derived organoid hair cells resemble vestibular hair cells rather than auditory cochlear hair cells. More recently, McLean et al (2017) have shown they are able to take acutely dissected organs of Corti and, in a 3D culture employing a cocktail of drugs and growth factors, clonally expand these cells into a nearly pure population of hair cells in high yield. These could be an alternative if wanting to study sensory hair cells in isolation (i.e. mechano-transduction).

However, our work is focused on trying to elaborate upon the mechanisms involved in the maintenance of cochlear function, and trying to understand the genetics of progressive and age-related hearing loss. Unfortunately, the current state-of-the-art inner ear organoids do not permit these types of studies as they model immature hair cells in isolation.

While non-mammalian model organisms (e.g. fly, worm and fish) are unsuitable for many auditory studies they can be employed for preliminary expression analyses to help prioritise genes for further investigation. Indeed, we continue to work with collaborators in the USA to assess the expression of novel hearing loss genes arising from the International Mouse Phenotyping Consortium (IMPC) programme in the fly.

Over the duration of this licence we will continue to monitor the development of new in vitro and ex vivo systems, and if suitable ones become available we will replace the relevant in vivo assay.

Why were they not suitable?

Currently, we cannot grow or replicate the cochlea in a dish. While there is much interest in trying to develop organoids for auditory research, at present using this type of approach we are not able to recapitulate: the complexity of the mammalian auditory system; ageing within a body; or, the response to noise exposure. Moreover, using in vitro or ex vivo cell-based studies alone we cannot identify the wider ranging effects of a gene across multiple body systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A recent study utilizing the UK Biobank resource has identified 44 independent associated genomic loci for self-reported adult hearing difficulty. We have been generating knockout (KO) mouse models for these loci/genes, and have been recurrently phenotyping cohorts of mice to 18-months of age. If a hearing deficit is identified, the KO model is then further characterized to determine the associated pathobiology and elucidate the molecular mechanism leading to the hearing loss. Going forward, we intend to continue to elaborate upon the genetics of human ARHL through the validation of additional genes showing association with adult hearing difficulty. In the first instance, KO models for these genes will undergo validation studies, if these are found to have an auditory phenotype the model will require further characterisation. In addition, the spatial and temporal requirement of these genes may be further investigated using a conditional KO approach. Provided here are example breeding schemes that will be employed:

To validate candidate hearing loss genes of interest, a cohort breed will be undertaken using the cross GeneX+/- x GeneX+/-. To obtain the three required genotypes GeneX+/+, GeneX+/-, and GeneX-/-. This will be undertaken on the C57BL/6N-repaired background.

16 mice (8 females and 8 males) per genotype group will be used. Therefore, 48 mice (24 males and 24 females) will undergo longitudinal auditory and behavioural phenotyping, as well as terminal tissues being taken for histopathology and imaging studies. For each gene, to obtain 8 mice per sex genotype will require 12 litters, producing ~80 pups.

To characterise a confirmed new hearing loss gene, breeds will be undertaken using the cross GeneX+/- x GeneX+/-, to obtain cohorts containing the three required genotypes GeneX+/+, GeneX+/-, and GeneX-/-. These cohorts will each be aged to specific time points to allow progressive pathological changes occurring within the cochlear to be determined. From our experience of similar previous studies, it is likely that 8 mice (4 females and 4 males) per genotype group will be sufficient to identify histological changes. Therefore, 24 mice (12 males and 12 females) will be aged for terminal tissues to be taken for histopathology and imaging studies. For each aged cohort, 4 mice per sex genotype will require 7 litters, producing ~50 pups. It is expected that four timepoints will be investigated.

To ascertain the spatial and temporal requirement of hearing loss genes, conditional knockout mice will be generated utilising a ‘hair cell-specific’ (Myo15-cre) and a ‘global inducible’ (Ubiq-creERT2) cre driver line, respectively. Using the Myo15-cre as an exemplar, the cohort breed will be undertaken using the cross: GeneZfl/+; Myo15cre/+ x GeneZfl/+; Myo15+/+. To obtain the ‘Test’ animals (GeneZfl/fl; Myo15cre/+), and the five required ‘Control’ genotype groups (GeneZfl/+; Myo15cre/+, GeneZfl/+; Myo15+/+, GeneZ+/+; Myo15cre/+, GeneZ+/+; Myo15+/+, GeneZfl/fl; Myo15+/+). On a C57BL/6

background. For each cohort breed, 8 mice (x4 females and x4 males) per genotype group (x6) will be used. As such, for each cohort breed 48 mice (24 males and 24 females) will undergo longitudinal auditory and behavioural phenotyping. To obtain 4 mice per sex genotype will require 13 litters, producing ~80 pups.

To investigate potential therapeutic interventions for hearing loss, biological substances will be delivered either directly to the inner ear, or systemically, to wild-type and homozygous mutant mice. A typical experiment will involve performing 'experimental' and 'control/sham' injections on a cohort of mice (10 mice/genotype/sex/intervention). As such, for each cohort breed 80 mice (40 males and 40 females) will enter an intervention study. To obtain 20 homozygous mice per sex genotype will require 29 litters, producing ~200 pups.

To generate the required experimental cohorts and to support the maintenance of the parental lines (including cre-driver lines etc), in total we estimate we will need to breed around ~22,500 mice for this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to embarking on a project the absolute number of mice required for the phenotyping assay will be determined. We will employ best practice in experimental planning, including using statistical approaches such as power and resource equations based on real data sets, to predict the number of animals required.

Where possible, we will maximise the data obtained from each cohort of mice. Combining tests in the same mice allows the interpretation of data to be correlated directly, rather than inferred. This allows us to carry out more advanced statistical analysis to detect correlated trends between assays. Directly correlated effects have a greater sensitivity as the major source of variance (between mice) is removed, enabling the detection of subtle phenotypes. We will also phenotype over the life-span of the animal to improve power and to understand the progression of disease and effect of age.

Standard Operating Procedures have been written, which standardise the way data are collected. Thus, reducing variability and consequently the required sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most crosses use dynamic mating systems, where the male is removed prior to littering thereby avoiding second litters and the risk of overbreeding.

Mouse lines will only be maintained while there is a justified use for their continued breeding and will be cryopreserved for future collaborations or the use of other scientific groups. All breeding schedules will be informed by the fecundity and productivity statistics calculated from previous experience of breeding any animal models used.

Whenever possible, genetically modified lines will be sourced from repositories to avoid re-making of lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Hearing loss in itself is not painful. However, in a syndromic form it can be associated with other, more debilitating, conditions. We are particularly interested to elaborate upon the genetics and pathobiology of age-related hearing loss, which while generally termed non-

syndromic, has been reported to be a risk factor for dementia diagnosis as well as being associated with depression, social isolation and frailty.

To date, little is known about the genetics of age-related hearing loss and how this condition might lead to dementia. This project aims to identify robust models for progressive hearing loss and to investigate these for signs of cognitive decline and other co-morbidities. These models will not only provide an understanding of the molecular causes underlying auditory decline, but will offer an opportunity to test interventions to prevent or slow age-related hearing loss.

Test

Why is this the most refined method

Ear biopsy

Mice need to be ear clipped for identification and the same piece of tissue is used for genotyping. Genotyping protocols have been optimised to use these very small samples to avoid the need for other samples to be taken. This is more refined than other methods such as a tail biopsy.

Induction of transgene expression and changes in gene expression using injection of genes

In most cases this will be done by oral dosing, which is more refined than injection, as while it involves restraint there should be no pain. Injections may be necessary depending on the type of recombinase line used and the age at which it needs to be activated. These methods can be used to avoid developmental issues that may prevent a mouse from growing properly, which may therefore reduce the number of mice needed for some experiments. We will continue to review the protocols used for transgene induction, and will modify these to current best practice.

SHIRPA

SHIRPA is an observational test that involves placing the mouse in an arena or a jar and looking for abnormalities. This is non-invasive and can provide a lot of phenotypic information that can be followed up in further, more complex, tests. This is also a good opportunity to identify subtle welfare issues.

Click box

This test is non-invasive and involves monitoring for the movement of the ear in response to a brief high-frequency loud sound stimulus. This provides an opportunity to assess the hearing of a mouse before going on to more in-depth ABR studies, and can inform upon the utility of other phenotyping tests that rely upon a reaction to a sound stimulus.

Swim test

This is a non-invasive test that involves placing a mouse in a tank of warmed water and monitoring their ability to swim normally. Irregular swimming, immobile floating or tumbling are all indicative of abnormal vestibular dysfunction.

Open field

Open field provides data on the reaction of a mouse to a novel environment. The arena is anxiety-inducing in that the mouse has not seen it before and the light is relatively bright. There are no smells or sounds that could cause stress to the animal.

Rotarod

Rotarod is useful to measure activity when a mouse is encouraged to run by placement on a moving rod. It can also be used for cross-laboratory bench-marking to ensure reproducibility of phenotype.

Acoustic startle and PPI

For this test it is necessary to assess the response of the mouse to an audible stimulus. While the stimulus itself is anxiety-inducing, efforts are made to reduce stress by having a constant background noise and performing the test in the dark. A protocol has been developed over many years to maximise the capture of useful data in a short time period.

Ophthalmoscope

For this test the mouse is held while the eyes are examined. This is more refined than more in-depth imaging as it does not involve general anaesthesia. However, the data collected are more subjective and there may be times when in-depth imaging is needed, in which case mice will undergo optical coherence tomography (imaging the eye under general anaesthesia).

Optokinetic drum

This test involves the mouse being placed on a platform in a large enclosed environment under low-lighting levels. The mouse is completely surrounded by monitors which display black and white lines of various widths and moving at various speeds. This assesses the visual response to movement stimuli and adds to the phenotypic information gathered in other eye tests.

Pupillometry

This test measures the pupillary response to light to measure the non-visual functions of the eye. This test is non-invasive, but does require the adjustment to a dark environment and the exposure to a bright light.

Behavioural observations

This test is a non-invasive observational test whereby mice are placed either in an arena or are observed in their home-cage. This can provide a lot of phenotypic information that can be followed up in further, more complex, behavioural tests.

Grip strength

The grip strength test is the quickest, least invasive way of measuring muscle strength. The test lasts for less than one minute and should cause no pain, only stress induced by handling.

Gait analysis

This involves placing the mouse in an arena and video-recording for a short time. This is the most refined method of running test as, unlike some other gait analysis equipment, it does not involve any stimulation to force the mouse to move.

Hanging wire test

This non-invasive test involves placing a mouse on a wire grid (e.g. cage top), which is then inverted and the latency to fall is recorded. This test evaluates motor neuromuscular function.

Spontaneous alternation/Y-maze

This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are set so that the mouse can see, but are not intended to be alternation/Y-maze anxiety-inducing. Spontaneous alternation provides a measure of spatial working memory, as mice should display a tendency to explore new areas.

Elevated plus/zero maze

This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are anxiety-inducing in some areas of the arena, but are darker and not anxiety-inducing in other areas. This is necessary as the test assesses the preference of the mouse for the darker or lighter areas.

Marble burying test

This non-invasive test involves placing a mouse in a cage containing marbles Marble burying test arrange in an ordered pattern. After a set period of time, the animal is removed and the number of 'buried' marbles is counted. This test is used to assess repetitive and anxiety-related behaviour.

Social recognition test

Light levels are low to reduce anxiety. In this test another mouse is present in a section of the arena. This mouse is in a small cage to stop any aggression, but the scent and sight of it are needed to understand how the mouse behaves to a social stimulus.

Barnes maze

This is non-invasive, spatial learning and memory test that involves placing a mouse in an arena and allowing it to explore. Light levels are set so that the mouse can see, but are not intended to be anxiety-inducing.

Recording vocalisations

This is a non-invasive test that involves placing a mouse in a modified 'home-cage' to allow the subsequent recording of vocalisations under normal housing conditions. Ultrasonic vocalisations can be employed as a behavioural marker of disease progression in certain neurodegenerative diseases.

Locotronic analysis

This non-invasive test involves placing a mouse on a horizontal ladder and, as the animal walks along the ladder, foot misplacement is measured. This is a measure of sensory/motor function.

Light dark box

This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are anxiety-inducing in some parts of the arena, but not others. This is necessary as the test assesses the preference of the mouse to the darker or lighter areas.

Echo-MRI

This test involves less than one minute of light restraint whilst body composition is measured. This is more refined than alternative tests that require general anaesthesia and a longer time to gather the data.

Urine collection

Mice are held and urine caught in a container, or in some cases mice are placed on a plate or a modified cage with specialist substrate (i.e. treated sand) that allows for urine collection. In both cases this is less stressful than placing the mouse in a metabolic cage and collecting urine overnight.

Home-cage monitoring

This is non-invasive and measured in the home-cage. After the initial insertion of a microchip under a light sedation, this test involves no further pain, suffering or distress to the mouse.

Olfaction testing

This is a non-invasive test that can be undertaken in the home-cage or an arena. These behavioural experiments allow assessment of olfactory function, including olfactory habituation, discrimination, odour preference/detection/sensitivity, and olfactory memory, to either social or non-social odours.

Electroretinographyof (ERG)

This test is done under general anaesthesia due to the extremely sensitive nature the measuring electrodes and the need for contact lenses to be held over the eyes of the mouse. This test measures the electrical responses of the eye to light stimuli. The electrodes are fine enough to not cause pain.

Auditory brainstem response (ABR)

This test is done under general anaesthesia due to the extremely sensitive nature of the measuring electrodes and the need for a sound-attenuation chamber. Mice are monitored at all times through a window and the electrodes themselves cause no pain. This test measures the electrical activity in the brainstem in response to sound stimuli.

Distortion product otoacoustic

Otoacoustic emissions are responses generated by the sensory outer hair cells (OHCs) when the cochlea is stimulated by two pure tone frequencies. This test,emission (DPOAE) performed under terminal anaesthesia, is used to determine the status of thecochlea in vivo.

Endocochlear potential (EP)

The EP is a positive voltage of 80-100mV observed in the endolymphatic fluid within the scala media compared with the perilymphatic fluid found in the remainder of the cochlear duct. The generation and maintenance of the EP is essential for the proper function of the cochlea, it is measured under terminal anaesthesia using an electrode advanced directly into the endolymph.

Blood sampling

Blood samples are collected to a maximum of 15% total blood volume of the animal, which has shown no adverse effects in previous studies. Samples are taken from the tail vein using a very small cut and mice have a local anaesthetic applied to the area twenty minutes before.

Why can’t you use animals that are less sentient?

The mouse continues to be the predominant model organism for hearing research, in part due to the close similarity in the structure and physiology of their auditory apparatus when

compared with that of the human ear. Additional strengths of the mouse as a model for studying the functional genomics of the mammalian auditory system include: the close evolutionary relationship of their genome to humans; genetic standardisation; and, the genetic toolkit available for the manipulation of their genome. Moreover, the complexity of hearing means that simpler model systems, such as fish and drosophila, do not allow for all aspects of the mammalian auditory system to be studied. In particular, fish and fly do not possess a cochlea, the mammalian organ of hearing.

Furthermore, we are interested to elaborate upon the genetics and pathobiology of age-related hearing loss, which is something that cannot be fully explored in flies or fish due to differences in the anatomy, structure and function of their auditory apparatuses. Moreover, investigating a progressive disorder, such as age-related hearing loss, requires longitudinal ABR phenotyping to monitor and assess auditory decline with advancing age, which requires multiple general anaesthetics with recovery.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all tests it is important that the animal has no additional stress, therefore mice are handled calmly and habituated to testing rooms as well as arenas if possible.

For all tests mice are only housed in modified cages or arenas for the minimum time needed to gather meaningful data. Mice undergoing phenotyping tests are monitored more frequently and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests.

Mice which have had anaesthesia have extra monitoring until fully recovered and extra checks when back in the holding rooms. When general anaesthetics are necessary, the combinations with least adverse effects will be used, for example for all tests inhalation anaesthetics will be used, with the exceptions of Auditory Brainstem Response, Electroretinography and Optical Coherence Tomography, which cannot be carried out on a mouse with a face mask. Pain from tail bleeds is reduced by using local anaesthesia.

All surgery will be undertaken in full compliance with Laboratory Animal Science Association aseptic technique guidance to minimise infection risk.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from Laboratory Animal Science Association good practice guidelines: administration of substances 1998 (http://www.procedureswithcare.org.uk/lasa_administration.pdf).

Surgery will be undertaken as per the Laboratory Animal Science Association Guiding Principles for Preparing for and Undertaking Aseptic Surgery 2017 (http://www.lasa.co.uk/wp- content/uploads/2017/04/Aseptic-surgery-final.pdf)

The animal house has full AAALAC and ISO9001-2015 accreditation. To conform to these standards we must ensure a high level of quality control on all fronts including husbandry, phenotyping and administrative processes.

Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at https://www.mousephenotype.org/impress

ARRIVE and PREPARE guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Over the course of the project I will attend general 3Rs symposia, read the NC3R and RSPCA newsletters, and receive regular email updates from the Animals in Science Committee Secretariat. Also, as Chair of an Animal Welfare and Ethical Review Body (AWERB) I am in a position to hear about new opportunities for refinement. I will also attend auditory-focussed conferences to learn about new opportunities for 3Rs specific to my area of scientific research.

88. Genes and Environment in Diabetes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

diabetes, genetics, microbiome, prevention, immunity

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Diabetes mellitus is caused by inherited (genetic) factors and non-inherited (environmental) factors. The aim of this project is to understand the impact of genetic variations and environmental conditions on the development of diabetes mellitus, in order to design better approaches to disease prevention and treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important because, according to the World Health Organisation, there are more than 400 million people throughout the world living with diabetes and it leads to 1.5 million deaths annually. This work will help us to understand the genes and mechanisms that are important in diabetes risk, and also whether there are any environmental factors (e.g. use of antibiotics) that make diabetes more or less likely. This information is critical to preventing diabetes in future.

What outputs do you think you will see at the end of this project?

The outputs of this project will include information about which genes have the strongest effect on diabetes risk and how they function in the immune system and in the development of diabetes.

The project will also provide information on environmental factors that may influence the immune system and the onset of diabetes such as the use of antibiotics, or particular dietary components. Environmental factors under investigation include the gut microbiome, which is a term used to describe all the micro-organisms, such as bacteria, living in the digestive tract.

The data that will be shared with other researchers will include scientific publications describing the findings of the work, as well as detailed datasets being deposited in online resources for scientists to use and analyse.

Who or what will benefit from these outputs, and how?

The short-term outcomes of this work (during the lifetime of the project) will be an improved understanding of the function of particular genes, especially with respect to the immune system and the development of diabetes.

Understanding which genes make the greatest contribution to diabetes risk, and how they do this, will help to identify new treatment or preventative targets in diabetes. This information will begin to emerge within 3-5 years, and in the longer term (5-10 years) would potentially translate to a clinical benefit to patients.

How will you look to maximise the outputs of this work?

Data generated by this study will be disseminated by conference presentations and the publication of scientific papers.

We will continue to network and collaborate with colleagues locally, nationally and beyond to share best practice and ensure that work is not duplicated.

We will also ensure that were benefits are identified with more general applicability, outside the field of diabetes, we will communicate these to the relevant audience.

Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice for this research as there are well-characterised spontaneous models of diabetes mellitus in this species that can be used to study the impact of genetic mutations in the development of disease. Some genes that are potentially important in diabetes are conserved across a range of species including mouse, rat, dog, zebrafish and chicken, but many genes of interest are not found in C.elegans (worms) or Drosophila (fruit flies). It is challenging to undertake diabetes-related research on zebra fish, as unlike mice - where a simple urine test is possible, it is impossible to make a diagnosis of diabetes non-invasively in a fish.

Typically, what will be done to an animal used in your project?

Typically we will use a strain of mouse that has a high possibility of developing spontaneous diabetes mellitus from the age of 11 weeks, meaning that from this age the mouse will undergo regular (typically weekly) urine tests for to detect diabetes as early as possible.

In some cases, the mice might have a mutation in a particular gene of interest that will allow us to study the impact of this change on the immune system and on the development of diabetes.

We might also test the immune system further by administering a substance designed to stimulate the immune system and taking blood samples to measure the response.

In some mice, we will try to change the composition of the microbes (for example bacteria) in the gut, for example using antibiotics, to see if this changes the risk of diabetes. The immune system of these mice might also be monitored by blood sampling.

What are the expected impacts and/or adverse effects for the animals during your project?

If diabetes develops, this can cause excessive thirst, passing of large volumes of urine, and weight loss. If not recognised early, it can progress within days to weeks to cause reduced movement, quiet behaviour and reduced appetite.

Administration of substances to challenge the immune system should not be associated with anything other than transient pain (if the substance is injected). Animals are monitored

closely for unexpected responses to challenge of the immune system, but with the substances and doses planned, adverse effects are not expected.

Alteration of the microbes (for example bacteria) in the gut (e.g. by administration of antibiotics) is not expected to lead to adverse effects, although occasionally transient diarrhoea can be seen.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- 50% Sub-threshold
- 40% Mild
- 10% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune system and the development of diabetes is very complex. Diabetes itself is the result of many genetic variations, combined with a wide range of environmental triggers in a whole organism. It is a complex disease affecting the whole animal and so cannot be replicated in a test tube. Other organisms such as fish and worms do not have diabetes, nor do they have the genes being studied, so it is not possible to do these studies on these species.

We work on the human immune system and collaborate with other laboratories studying the human immune system, so wherever possible we will translate findings to human studies as early as is feasible.

Which non-animal alternatives did you consider for use in this project?

We considered (and actively use) tissue culture for examining the impact of genetic mutations on cell function, and this informs the work we undertake with animals. However in a cell culture model it is impossible to replicate the complexity of the pancreas, and to measure diabetes as a potential outcome of genetic variation.

We also, wherever possible, consider findings from human studies before undertaking studies in mice.

Why were they not suitable?

Whilst we can learn some information by mutating a gene within a cell line in tissue culture, in a cell culture model it is impossible to replicate the complexity of the pancreas, and to measure diabetes as a potential outcome.

In human studies, genetic variations typically have a very small but real effect on diabetes risk, and environmental conditions are highly variable, therefore it can be extremely challenging to learn about the function of genes that have been associated with diabetes risk.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Several factors have gone into this calculation:

1. This will be the third licence we will have held for diabetes research, therefore we have been able to make estimates based on results from previous years

2. We have also considered mouse numbers within the context of the expected funding and staffing available for the work.

3. We know from experience that non-obese diabetic (NOD) mice can have very large litters (up to 15 pups) so this has also been considered in our calculation.

4. We will use the minimum number of mice required for experimental need to test our specific hypotheses, making sure that where possible we use pilot data to determine this in advance. Where possible we will also archive samples for future experimental use (e.g. tissues, faceal samples), to ensure that we gain the maximum possible information from each mouse bred on the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In applying for the current (Medical Research Council) funding for the proposed work, we used power calculations, incorporating previous data from diabetes-incidence studies in our setting, to determine the minimum number of animals to be used consistent with our

scientific objectives. Going forward, for new studies, we will also use the NC3Rs Experimental Design Assistant to visualise our experiments, and to receive support and feedback on our design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Prior to beginning any experiments, we will investigate all possible means of reducing the number of animals used, including exploring publicly available data to ensure that our research question cannot be answered without using animals.

We will continue to use a range of methods to optimise the number of animals used:

- we will undertake efficient breeding, ensuring that we avoid breeding diabetes-prone females of 10 weeks or older. This reduces the risk of the female and the litter having to be culled before weaning due to the female becoming diabetic

- we will continue to collect and archive material from mice (e.g. pancreas tissues) that can be used in future studies without having to breed more mice

- we will undertake pilot studies where appropriate to ensure we can make informed decisions about the design of larger experiments

- we will continue to share tissue, as appropriate, with other researchers

- we will refresh our diabetes-prone colony, approximately every 10 generations to avoid genetic drift and to ensure that the diabetes phenotype is maintained at high incidence, since a high incidence of diabetes reduces the number of mice required per study

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be studying mice and our particular focus will be on their development of diabetes.

For this purpose, an important model of spontaneous diabetes is the NOD (non-obese diabetic) mouse, in which, in our colony, 80% of females develop diabetes by 30 weeks of age and <50% of males. No additional intervention is required for diabetes to occur in

these mice, and diabetes monitoring can be achieved by regular non-invasive urine testing. This means that we are usually able to detect diabetes before the mouse displays overt clinical signs.

In addition to studying the standard NOD mouse, we will also study genetic mutations in genes that have been identified as having a potential role in diabetes risk. These mice may have a NOD diabetes- prone genetic background or may have a non-diabetes background, such as a wild-type mouse.

Where more than one mouse line is available with a mutation in a gene of interest, we will select the line most suitable for the purpose, carefully considering the potential harmful impact of each mutation.

In addition to monitoring these genetically-modified mice to determine whether the genetic mutation has had an impact on diabetes development, we may also investigate the function of the immune system in these mice or study the impact of altering the microbes (e.g. bacteria) in the gut on the age at which diabetes develops.

The models that we will use to investigate the immune system will involve using specific substances to target particular immune pathways. This is an alternative to infecting an animal with a live virus or bacteria and is less likely to result in side-effects that make the animal feel unwell. Similarly, when we undertake work to alter the microbes in the gut, we will use the least invasive and harmful method possible - for example administering substances in food or sweetened drinking water.

Why can’t you use animals that are less sentient?

The mouse is the lowest sentient species in which diabetes mellitus can be straightforwardly induced or monitored.

The less sentient species also do not have some of the genes of interest that we =need to study, as they are specific to mammals.

As we are studying diabetes mellitus - a disease which develops over several weeks to months, it is not possible to undertake this work on animals that have been terminally anaesthetised.

We are also interested in the immune system, diabetes risk and the microbes (e.g. bacteria) that live in the gut, and the relationship between these elements. This is only possible to study in a live organism that has an immune system similar to humans, and from which we can collect samples of faeces.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have developed and refined a protocol for care and monitoring of diabetes-prone mice. This includes regular urine testing (which is less invasive than blood sampling) and allows early identification of diabetic mice, so they may be humanely killed before they develop clinical signs.

For the investigation of the immune system, we will use the method that causes the least pain, distress, suffering or lasting harm and that allows us to achieve our objectives. For example, we will administer substances in drinking water where possible, and if a substance needs to be injected, we will use a sub-cutaneous injection where feasible. We will base doses and routes of injection on published resources and pilot work.

When altering the gut microbes, there are several published methods to do this, and we will identify the most effective route to achieve this alteration whilst also minimising harm and distress to the mice. For example we will avoid gavage where a substance (e.g. probiotics) may instead be administered through drinking water. Where a procedure has taken place that could result in harm to the individuals, we will undertake very close monitoring during the immediate post-intervention phase. When introducing a new procedure into our work, we will undertake a pilot study, typically with 1-3 animals, to check that our expectations regarding potential harms are correct.

When administering substances in food or water, we will observe the mice closely to ensure these have not become unpalatable and will intervene (e.g. with sweetener in water) if necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use a range of resources when conducting our experiments - local and national.

Specifically, the published resources we will use include the ARRIVE guidelines, the Laboratory Animal Science Association (LASA) best practice guidelines and the NC3Rs Experimental Design Assistant.

In addition we use, and regularly update, our own Standard Operating Procedures for care and maintenance of mice with specific genetic modifications. We also typically use and discuss experimental planning sheets prior to embarking on experiments, including consultation with the animal welfare officer where relevant, so that all possible refinements are considered before work begins.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Members of the group attend and participate in internal animal welfare meetings at which projects are discussed in terms of advances made in the 3R’s.

We also have representation at local AWERB level which again give us the opportunity to gain information from named people and other investigators. We also attend an internal 3R's day at the establishment.

Information can also be accessed via the establishment's intranet and we will also use relevant web resources e.g. www.nc3rs.org.uk and https://science.rspca.org.uk

We also have access to an NC3R's regional manager.

89. Production of Antibodies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunisation, Monoclonal antibodies, Immunoassays, Drug discovery

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to immunise animals to generate antibodies as therapeutic agents or as tools to support drug discovery projects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antibodies have a variety of roles in drug discovery. They may be therapeutic entities in their own right or they might be tool reagents to validate a drug target or provide immunoassays to support drug development.

What outputs do you think you will see at the end of this project?

Outputs will be antibodies of appropriate functional and biophysical properties to support early drug discovery projects and to facilitate transition from the research to clinical development.

Who or what will benefit from these outputs, and how?

Patients with severe diseases and current unmet need mainly in the area of immunology.

How will you look to maximise the outputs of this work?

Data supporting drug development will be shared with regulators and disseminated at conferences or publication.

Projects that are unsuccessful may be evaluated for publication. Evaluation will look at the risk benefits in terms of whether publication will result in significant added value to the medical literature and whether any additional animal work might be required to complete a publication.

Species and numbers of animals expected to be used

- Mice: 3000
- Rats: 300
- Rabbits: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mammals (rabbits, rats, mice) will be used as these have a mature immune system necessary for the generation of antibodies. We also have experience humanising antibodies from these species for development as therapeutic antibodies. Genetically modified animals may also be used. We have acquired a licence to access mice that produce fully human antibodies with the potential to greatly reduce development time for therapeutic antibodies (by removing the need for humanisation).

Additionally, other genetically modified animals may provide a background that enhances the raising of antibodies to a particular target (eg knock out animals whose immune systems have never seen the target immunogen or hyperimmune mice). Having a variety

of immunisation species and mouse strains increases the chances of discovering rare antibodies with very specific functional properties. These might be developed as therapeutics or as a variety of tools to support drug discovery projects.

Typically, what will be done to an animal used in your project?

Animals will be immunised to raise antibodies to the target antigen. Animals may then be boosted to amplify the immune response. Immune enhancing agents may be administered with the immunisations. Periodically, blood samples will be taken to assess the antibody response.

Immunisation rounds and bleeds may be repeated over a maximum of 6 months. At the end of the protocol animals will be killed in order to harvest immune tissues (usually blood, spleen or bone marrow) from which B cells are cultured and antibodies cloned through molecular biology.

What are the expected impacts and/or adverse effects for the animals during your project?

Immunisation and removal of blood will stress animals and give transitory pain. Anaesthesia may be used where the impact of the anaesthesia (stress of induction and transient disorientation afterwards) are considered less than conducting the procedure without. Immune enhancing agents may include Complete Freund’s adjuvant (CFA), that may be used just once, and will cause inflammation at the injected site. We do not expect to see signs of discomfort in animals when CFA is injected subcutaneously according to protocol, but animals are monitored for any signs of ulceration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The licence has a single protocol with a severity limit of mild, and all animals are expected to be reported as such.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immunisation results in formation of antibodies that become naturally affinity matured and become more diverse as the immune system is boosted. Immunisation also results in natural antibody molecules that have favourable biophysical properties as a starting point for antibody engineering and/or for long term storage and production at a variety of scales.

Which non-animal alternatives did you consider for use in this project?

Display technologies (phage and yeast). We have access to these technologies in house. Commercially sourced antibodies.

Why were they not suitable?

Immunisations are accompanied by a request form where non-animal alternatives are addressed case by case for each antigen. Reasons not to use commercial antibodies might include non-availability, inappropriate function, poor purity, unavailability at scale or intellectual property. We generally use display and immunisation techniques simultaneously with a specific justification required if a display campaign is not to be initiated. We find display and immunisation complementary in that they increase the diversity of antibodies at our disposal, but immunisation has been consistently more successful in finding rare functional antibodies with favourable biophysical properties. Display technologies are also challenging for cell surface targets. Within the field of therapeutics, non-animal-derived antibodies cannot currently compete, and the vast majority of approved therapeutic antibodies are from animal- derived origin (Custers & Steyaert, 2020).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers have been estimated from the number of projects we expect to support and the typical immunisation campaigns that are required to support them. Rabbits have generally been favoured as their immune system is distinct from mouse and human (the species most often providing the immunogen) and have been a reliable source of antibodies in the past. We expect to conduct many of our immunisations against human immunogens in mice as we have acquired a licence to access mice that can generate fully human antibodies. Rats only tend to be used if more diversity in antibody responses is required beyond what has been achieved with rabbit and mouse immunisations. At the end of the immunisation period, immune tissues are harvested. It follows that the larger the species

the more material is available, and this is a major consideration for numbers of animals that need to be immunised for each antigen in a given species (mice>rats>rabbits).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We expect in most circumstances than an immunised animal will generate an immune response, although the quality of the response may be different between animals. Animal numbers are therefore typically low and determined more by the amounts of immune material that can be harvested from each species than by a statistical evaluation. More animals are used when immunising for a therapeutic antibody (because of the need to achieve antibody diversity to identify rare functional antibodies), such a campaign may start with 2-3 rabbits and groups of 5-10 mice for each immunogen. There may be follow up as needed with groups of 3-5 rats. There is not much room to reduce numbers for a therapeutic campaign, but for non-therapeutic projects we might start with 1-2 rabbits and only consider further immunisations as necessary.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Although we do not breed animals at our facility, we do carefully monitor colonies of genetically modified animals held for us to ensure that there is not a surplus of animals.

We have a crystallography capability which when combined with computer modelling has sometimes allowed existing antibody sequences to be optimised without the need for further immunisation. Whilst this technology is in its' infancy, it is expected it will increasingly add value over the course of this licence. We're also exploring the use of next generation sequencing together with artificial intelligence to predict from an antibody sequence other sequences that might be consistent with functionality. This has the potential to more deeply mine the immune repertoire and to reduce numbers of animals that need to be immunised.

Increasing the efficiency of immunisations, especially against highly homologous immunogens, has the potential to reduce the number of immunisation campaigns and therefore animals used. When consistent with the authorisation of the licence, new immunisation techniques will be evaluated in small pilot studies to assess whether they are more efficient than our existing immunisation strategies. If such developments are outside of the scope of the current licence, amendment may be sought.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

There is not a choice of models for immunisation as they all work in essentially the same way by exposing an animal to repeated doses of an immunogen in order to generate an immune response. We believe that with best practice we can conduct all our experiments within a mild severity limit.

Why can’t you use animals that are less sentient?

The generation of antibodies (or fully human antibodies in genetically modified mice) requires a mature adult immune system. It takes weeks to generate functional antibodies so it is not possible to use terminal anaesthesia for the procedure.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Wherever possible animals will be sourced locally to minimise stress of transportation. All species will be socially housed where possible. Our experience of immunisation is that females tend to give equivalent or better antibody responses than males. We will therefore use female animals in preference to males, and this will minimise injury and stress brought about by fighting. We will only use males (and females) from colonies of genetically modified animals in order to make best use of the colonies and reduce numbers of animals that might otherwise be killed.

Rabbits come into the Special Facility in batches of up to six and will be housed in pens containing a variety of environmental enrichment including pipes, sticks balls and hay, and supplements to the dietary chow. We acclimatise rabbits for a minimum of 2 weeks. Body weights will be recorded weekly, and this will help with getting animals used to handling. Only if an animal is bullied or showing signs sickness will it be removed to single housing.

The rodents will have plastic or cardboard housing, shredded paper, balls (rats) and exercise wheels (mice) and will be acclimatised for at least a week before going on procedure.

The protocol is mild, but animals will be monitored after each procedure to ensure they are fully recovered before being returned to their holding room. We will assess antibody titres over the course of the immunisation protocol. If animals have mounted a strong immune response, they may be taken off the protocol early to spare further rounds of immunisations and bleeds. There is an insistence on a high level of quality control (eg low endotoxin and sterility) of any immunogen injected into animals.

New immunisation techniques may impact positively for animal welfare (eg reduced need for adjuvants). When consistent with the authorisation of the licence, new immunisation techniques might be evaluated in small pilot studies to assess whether they provide refinement over our existing

immunisation strategies. If such developments are outside of the scope of the current licence, amendment may be sought.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Home Office guidance – Antibody Production: Principles For protocols Of Minimum Severity (2000).

ARRIVE guidelines https://arriveguidelines.org/ NC3Rs

https://www.nc3rs.org.uk/ Norecopa https://norecopa.no/ FELASA

https://felasa.eu/ LASA animal welfare https://www.lasa.co.uk/

Recommended dose volumes - Diehl et al 2001

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

There are many 3Rs resources available. There are internal forums (AWERB, Animal Users Committee, Annual 3Rs Poster competition) and outside forums such as NC3Rs, norecopa, FELASA and LASA (both website and conference attendance). Specific to the procedures in this licence, there will be an internal Immunisation Team to consider 3Rs initiatives and emerging immunisation literature. The licence will conform with Home Office guidance – Antibody Production: Principles For protocols Of Minimum Severity (2000).

90. Determining the Tissue Specificity of Cancer Genes

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

cancer, hypoxia, lineage tracing, DNA repair pathways, metabolism

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to determine why genes expressed in all cells of the body only cause cancer in specific tissues and to do this we will study one such gene, VHL (The Von Hippel–Lindau tumour suppressor gene). VHL protein (pVHL) has many important roles especially targeting Hypoxia- inducible factor (HIF), vital for how our body adapts to low oxygen levels, for breakdown. Importantly, when VHL is mutated or deleted it initiates the most common form of kidney cancer.

To achieve our aim we will delete the VHL gene in a novel mouse model in which a fluorescent marker (flag) lights up in cells when the gene is lost (lineage tracer gene). We can then accurately identify and follow those cells, and their daughters (if the cell divides), in which the gene is no longer functioning properly. We will be able to follow the earliest events that result from this gene loss and can try to understand whether, and how, different oxygen concentrations, repair pathways and/or altered metabolism affect the development and progression of cancer so that we can refine cancer therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Determining the tissue specificity of cancer is a fundamental question for which we have no good answers. Cancer is caused by changes to genes (mutations) that control how our cells function, especially how they divide, leading to uncontrolled growth of abnormal cells in the body. The mutations that cause cancer can be inherited from our parents, or they can arise from mistakes that occur as cells divide, or because of environmental influences. Many cancers have a unique combination of genetic changes some of which accrue as the cancer grows and even within the same tumour, different cells may have different genetic changes. However, some of these changes may be a consequence of the cancer, rather than its cause. Many of the mutations affect genes that work in all cells in the body, but they only give rise to cancers in specific tissues. If we understood why genes that are expressed in all cells in the body drive cancer in specific tissues we might be able to define routes to therapy for cancers including some for which there is currently no treatment at all (such as in some inherited syndromes).

Also, by using a novel mouse model in which a fluorescent marker (flag) lights up in cells when the gene is lost (lineage tracer gene) and reducing the amounts of agents to delete the gene we can study small numbers of cells with gene mutations or deletions more accurately than previously published work and model better the events in man.

What outputs do you think you will see at the end of this project?

The outputs of this project are:

- To determine accurately what happens over time to cells in different tissues following loss of specific genes that are expressed in all cells. Initially we will focus on the tumour suppressor von Hippel-Lindau (VHL) which is the main driver for kidney cancer and is mutated in an inherited syndrome and will use genotypes that mimic those in the VHL patients to follow lineage marked cells.
- To gain insights into the relative roles and interplay of hypoxia, DNA repair pathways, the immune system and metabolism in the survival of cells following loss of genes that are expressed in every cell in the body, particularly in the development of kidney cancer
- To extrapolate our findings to other cancers
- To rethink and assess the use of ‘field changes’ when deleting genes especially for cancer research (e.g. the use of large and repeated doses of Tamoxifen) and instead to use low doses of Tamoxifen (1/10th to 1/100th of normal dose) to better mimic human sporadic cancer.
- To describe our findings in peer-reviewed publications and scientific meetings
- To describe our findings through public engagement

Who or what will benefit from these outputs, and how?

In the short term, the scientific community will benefit from our findings. We believe that our work will give new insights into the cellular and tissue contexts that allow development of cancer and that this basic knowledge will inform new clinical therapies for cancer, including for individuals with inherited syndromes.

We think that the paradigm of novel lineage marking transgenes to delete and mark small numbers of cells, rather than 'field changes', mimics more accurately the situation in human disease and will change the way in which future animal work is conducted. This would benefit both the animals used in experiments and improve the science.

While we hope to begin to publish papers in the near future all of these impacts will be dependent on the publication and dissemination of the research and are unlikely to occur before the end of the application period (approximately 3 years).

How will you look to maximise the outputs of this work?

The outputs of our work are, and will continue to be, maximised by dialogue and collaborations with scientific and clinical colleagues in a variety of specialities. For example we work on a daily basis with scientists, clinicians, statisticians and bioinformaticians who work with cancer patients, tissue biopsies and human cell lines.

New knowledge will be communicated as early as possible through open access journals to allow access of our findings to everyone.

Species and numbers of animals expected to be used

- Mice: 13,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in these experiments will be mice, which are the most appropriate fully developed model for studying sporadic and genetically inherited cancers - accurate in important respects, but the least sentient. These animals will be genetically modified strains, carrying induced, targeted mutations or transgenes. We will be using mainly adults in which gene deletion is induced. Occasionally we will use neonates or foetuses because we also want to understand the significance of the timing of gene mutations/deletions on the different cell types and the subsequent development of cancer.

Typically, what will be done to an animal used in your project?

Mice will be bred, and tissue taken for both identification and to determine their genetic status. Mice of the appropriate genetic status will be dosed with a gene deleting agent typically by the oral gavage route and then by a cell marking agent via injection or in drinking water. A cohort of animals will also be exposed to altered gas concentrations for a short period of around one week. Other cohorts will be treated with one of a group of substances to monitor or preferentially kill cells lacking tumour suppressor gene function and therefore interfere with tumour development. After these procedures mice will be humanely killed and multiple tissues harvested for further analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Some experiments (50%) will cause either no adverse effects or only mild adverse effects. Occasionally mice will experience moderate harmful side effects, such as weight loss, or transient changes in behaviour due to the deletion of specific genes (50%). A subset of animals (<10%) will be aged to approximately to one year and may develop tumours. Such animals will be monitored carefully and the animals killed before the tumours can cause distress. Most of the genetic combinations we are using are not expected to give rise to tumours especially since we are interested in observing the early consequences of gene loss that alter cell biology and support or prevent the survival of cells.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

10% subthreshold
40% mild
50% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are interested in the processes that determine why cancers (both sporadic and those arising from genetically inherited disorders) driven by genes expressed in all cells in the body are tissue specific. Currently it is not possible to study in depth the genetics,

processes and interactions across multiple tissues over a period of time using non-animal approaches.

It is not possible to study all the complexities of either oncogenesis or the altered metabolism associated with loss of these genes within cells of different tissues in anything other than a mammalian system such as the mouse. Furthermore, the mouse model remains the best mammalian system in which to test genetics and understand the downstream complexities of loss of these genes and to allow for translation to medical application where integrative effects on multiple cell types and organ systems can be assessed in the context of any homeostatic mechanisms.

Which non-animal alternatives did you consider for use in this project?

We have used and will continue to use human cell lines and both primary and archived human tumour material, obtained with relevant ethical approvals, to investigate the consequences for different cells of loss of the activity of specific genes known to cause cancer (e.g. VHL, known to be the main driver mutation in clear cell renal cancer). These studies are ongoing in our laboratory. We will also pursue approaches that do not involve animal work using cell cultures, co-cultures and isolated tissues ex vivo to study loss of the genes of interest. We will continue to collaborate with other scientists who have particular relevant expertise e.g. in Systems Biology.

Why were they not suitable?

Human cell lines are already immortalised in some way and therefore do not allow us to investigate the loss of gene function in perfectly normal cells.

We wish to investigate the earliest events (including loss of cells) that may occur when the function of a gene is lost. While studies with human tumour material and adjacent normal tissue are useful these only allow us to see late events in cancer cells compared to normal cells. Also, we only receive small tissue samples and infrequently.

Since we want to determine the reasons why a gene expressed in all cells of the body only gives rise to specific cancers, we need to be able to analyse multiple tissues from a single source. Furthermore,

we want to ascertain whether constraints such as DNA repair pathways, hypoxia and metabolism impact on this process. Currently mouse models are the only system in which to answer these questions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on experience over decades of working with transgenic mice carrying some of the alleles to be used in these experiments. We have also conducted some validation and pilot experiments on another project using a lineage reporter mouse line that we have had made.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the smallest possible group sizes that are still informative for a thorough statistical analysis and logical progression to the next step. Advice is sought, and we use various tools and experts in statistics to support and inform us in these aspects of the programme - for example the NC3R's Experimental Design Assistant and attending seminars such as 'Efficient management of genetically altered mouse colonies'. Also, statistical support is available to the project through members of the group, members of the Department and elsewhere in the University (e.g. Centre for Statistics in Medicine). We are very careful to reduce variation by housing the mice together where possible and ensuring that they are genetically identical. We conduct our experiments in compliance with the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We optimise our colony management to keep breeding cages to a minimum and use a single database to assist us in tracking and managing the breeding strategy. We use ANOVA and other statistical tools to maximise our ability to detect difference in groups with uneven numbers. Where relevant we use small pilot studies to ensure that projects are feasible and to reinforce our ability to detect difference.

These pilot experiments have allowed us consequently to focus on specific genotypes to study and to refine our breeding accordingly. We share tissues to make the most of mice and harvest multiple tissues from a single mouse for analyses over a number of platforms. This also adds power to our results.

Generating new mouse reporter models, where the reporter is in integral to the original construct, reduces the initial breeding required compared to conventional lineage lines which rely on two lines

initially. Also, importantly such reporter lines improve the accuracy of the data. In a single mouse model with multiple alleles these are maintained as homozygous to reduce numbers of mice.

We have a policy of cryopreservation of all lines and this allows us to remove lines when they are not being used.

Since our mouse lines are genetically identical, where possible we integrate controls across multiple lines to reduce the numbers that need to be bred.

We have had mice made by commercial companies and where possible buy new lines (increasingly as frozen embryos).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of our experiments require us to breed and then compare tissues from mice that are normal (wild-type) or genetically targeted to recapitulate human disease and especially cancer. We hope that these experiments will help us to establish the role of specific proteins and biochemical pathways that determine the tissue specificity of cancers related to certain genes. These pathways are perturbed in both sporadic and genetically inherited human cancers and may potentially be targets for therapy. The breeding protocols cause minimal or no distress. Our experiments are designed to deliver statistically significant results in the least harmful way by making power calculations and focusing on only measurable differences in well matched mice and controls.

We are particularly interested in the earliest cellular consequences following loss or disruption of specific genes and for this purpose have generated a novel mouse model in which there is a reporter integral to the gene construct for more accurate identification of cells where the gene has been deleted. Also, we are aiming to study only small numbers of 'targeted' cells in specific tissues more akin to the picture known to occur in man. Hence we will aim to use lower doses of agents, such as Tamoxifen, than are used routinely to delete genes (in some cases 1/10th to 1/100th of normal doses). These will be delivered by the most humane methods, generally by gavage and where possible by one administration. Most analyses will be conducted on tissues harvested from the mice over a number of different platforms.

We continually seek ways to improve all our animal work and to reduce the level of suffering to the animals.

Why can't you use animals that are less sentient?

Mice are the least sentient animals available with multiple tools, including transgenic and inducible knockout strains, for studying the early stages of cancer that invoke complex cellular, humoral and immunological responses that are similar to humans. Furthermore, although we are aiming to study the earliest events following loss of a gene nevertheless we will need to observe live individual animals over several days or weeks and to be able to determine the role in different tissues of factors such as DNA repair pathways, hypoxia and metabolism that allow cells to develop to cancer. This is not possible in animals that are less sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Potential refinements to reduce welfare costs to the animals include:

- enhanced monitoring, for example, when animals are under hypoxia they will be monitored (including measuring body weights) once daily and animals provided with mash at cage floor level if losing >10% body weight
- providing mash at cage floor level to all animals after oral gavage
- use of conditionally inactivated transgenic animal models to avoid adverse effects of ubiquitous gene deletion in development
- use of a specially constructed transgenic mouse model in which a fluorescent signal indicates if any conditional genes have been deleted has allowed us to reduce the amount of tamoxifen to at least one tenth and a single dose for some recombination genes
- endeavouring to provide extra enrichment and housing to animals if they have to be singly housed

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow published protocols which are assessed by our AWERBs in consultation with our veterinary surgeons. Some of the other resources we use include www.nc3rs.org.uk; https://norecopa.no (including the Experimental Design Assistant and the ARRIVE guidelines) and https://www.lasa.co.uk. We will also use any newly published guidance from the establishment Named Information Officer and Named Animal Care and Welfare Officer or through attendance at local events discussing 3Rs which occur on a regular basis.

We endeavour to use 'blinding' and randomisation in our experiments where possible by enlisting the help of technicians and different members of the research group for various aspects of our experiments. We also use codes for animals in our experiments which do not identify specific genotypes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We follow and contribute to our local NC3R committee and attend committees for local users, where we share data and methods. We follow activity at www.nc3rs.org.uk and https://science.rspca.org.uk. We will follow best practice as it evolves. We monitor our animals closely. We will exchange information on animal welfare by engaging with animal welfare officers, Veterinary Surgeons and other investigators in our institute and outside it. We seek advice from our colleagues. We keep careful records so we can refine our protocols to be more efficient over time. We keep our training up to date and adopt new methods when they will improve animal care.

91. Investigating Non-Invasive Neuromodulation by Ultrasound for Neurological Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain, Transcranial, Neuromodulation, Neurodegeneration, Ultrasound

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to determine how brief pulses of ultrasound, when directed across the skull, can change brain function, and how this might ultimately be used as a treatment for neurological diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brain diseases represent a major cause of disability and death in humans. Indeed, current estimates suggest neurological disorders are the second leading cause of death globally. In particular, neurodegenerative diseases are considered a major health challenge as for many disorders age is a major risk factor, and as a society, the proportion of the population of older age is increasing. In Europe alone, 7.8 million people are affected by Alzheimer's disease and 828,000 people are affected by Parkinson's Disease. These diseases are not just profoundly impactful on the individual's quality of life, but also carry significant societal implications. Indeed, in the case of Alzheimer's disease alone, the combined costs of formal and informal care in Europe are thought to be in the region of EUR 160 billion annually. Crucially, there are currently no curing treatments for these conditions, despite many years of pharmaceutical research.

Over many decades of research, sophisticated tools to change the function of the human brain have been developed, and are now used in experimental and therapeutic contexts. From pharmacological approaches to direct electrical stimulation of the brain, various tools are available to us to control brain activity. These have allowed us to better understand the contributions different areas of the brain make to cognitive tasks and provided us with a means to treat neurological disorders. However, these approaches have significant limitations. Drugs have side effects and often modest clinical effects when used therapeutically. Furthermore, whilst direct electrical stimulation of the brain does provide unparalleled target accuracy over where and what in the brain is being regulated, techniques such as deep brain stimulation are invasive and carrying significant surgical risk. Non-invasive ways to affect brain function, that do not require drugs or surgery, such as transcranial magnetic/direct current stimulation, serve as a potential alternative to regulate brain activity. However, they suffer from relatively poor spatial precision. Considering these shortcomings, the development of a non-invasive and spatially precise method to change brain function would be extremely beneficial and could open new avenues for therapies for neurological diseases.

Ultrasound is traditionally associated with medical diagnostic imaging, where it is used to visualise anatomical structures. At the pulse frequencies employed, this type of ultrasound does not induce detectable biological responses or adverse effects and is therefore considered a non-invasive diagnostic procedure. When ultrasound pulses are delivered across the skull at low intensities, however, brain activity can be modified and cognitive effects induced. My group has pioneered developments in the understanding of the genetic, molecular and cellular consequences of ultrasound neuromodulation on the function of brain cells. What is now urgently required is a systematic investigation into the potential therapeutic applications of the novel technique, to establish when, where and how this intervention could be used for medical benefit. The purpose of the studies outlined here is therefore to accelerate and facilitate the development of transcranial ultrasound stimulation as a treatment for brain diseases by characterising the fundamental physiological consequences of ultrasound-mediated neuromodulation.

What outputs do you think you will see at the end of this project?

The main outputs of this study will be the data and scientific publications relevant to the efficacy of transcranial ultrasound stimulation which is essential to determine the potential of this treatment for translation to a human clinical setting.

Who or what will benefit from these outputs, and how?

In the short-term, we will establish critical information concerning the application of ultrasound as a brain-modifying technique. This will occur throughout the life of the project. This will benefit other researchers and engineers in the field who will use our findings to inform their work and optimise the development of ultrasound devices. If the study proves successful, in the medium-term it is expected to facilitate the translation of transcranial ultrasound neuromodulation into human clinical trials and in the long-term benefit patients with a range of neurological conditions for which neuromodulation is a useful therapeutic intervention.

How will you look to maximise the outputs of this work?

The findings of the work will be submitted for publication in peer reviewed scientific journals and presented at national and international conferences. In addition, I will use my existing links with medical companies developing ultrasound devices to disseminate the findings to commercial stakeholders.

Species and numbers of animals expected to be used

- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats will be used for the outline work as the experiments require animals with a brain anatomically similar to that of humans and of sufficient size to enable specific regions to be targeted using transcranial ultrasound. Mice are unsuitable as their brain is too small to enable effective regional targeting. In addition, the limited cognitive ability and behavioural repertiore of mice make them unsuitable for some of the assessment tasks needed to determine the effects of transcranial ultrasound stimulation on memory and cognition.

Adult rats will be used in order to reflect the developmental stage of human patients on whom transcranial ultrasound is most likely to be used.

Typically, what will be done to an animal used in your project?

Upon arrival in the unit, the animals will be group-housed and allowed to acclimatise for a week, during this period the animals will be regularly handled to habituate them to the

research staff. For all initial and terminal studies, the animals will be anaesthetised, the fur over the scalp will be removed and the animals place in a stereotactic frame. Ultrasound gel will be applied to the scalp and the ultrasound probe accurately aligned over the target brain region. Ultrasound stimulation will then be applied for between 30 seconds and 5 minutes. Thereafter, the animal will either be immediately killed, in order to harvest brain tissue for analysis or, allowed to recover from the anaesthetic. Recovered animals may undergo repeat stimulation on up to three occasions.

Attempts will also be made to refine the technique by training the animals to allow transcranial ultrasound stimulation to be undertaken whilst fully conscious. Using appetitive positive-reinforcement, the animals will be trained to voluntarily enter and immobilise within a conical tube. Training will involve encouraging the rat to enter a cone shaped tube to obtain a food reward e.g. sucrose water. Once the rat has learned to enter the tube to obtain a reward, the time spent in the tube to obtain the reward will be gradually increased until it is sufficient to allow ultrasound stimulation to be undertaken.

Plan of work

Initial studies will focus on determining the immediate consequences of ultrasound stimulation on brain function. To evaluate this, rats will be killed by decapitation immediately following stimulation and brain tissue harvested for ex-vivo analysis. Thereafter, studies will be undertaken to evaluate the persistence of effects induced by stimulation. In these studies, the time between stimulation and killing will be delayed by a pre-determined amount. Next, studies will be undertaken to determine whether repeated stimulation has a cumulative effect, beyond that of a single stimulation. For these studies, animals will undergo repeated ultrasound stimulation on alternate days, up to a maximum of 3 times (i.e., 3 stimulation sessions, separated by at least 48hrs between each single session).

A subset of animals, in the delayed recovery groups, will undergo non-aversive behavioural testing to assess the effect of stimulation on memory, cognition or behaviour. This is because we are targeting regions of the brain thought to underly these types of behaviours. It will therefore be important to understand what the effects are of stimulation on cognition. The typical tests used for these studies include: T maze, open field or novel object recognition. Testing may occur both before and after ultrasound stimulation, in up to 3 non-regulated cognitive tests, not more than once daily and for no more than 3 months.

What are the expected impacts and/or adverse effects for the animals during your project?

Prior to undertaking any procedures, the animals will be habituated to human contact for a period of at least one week to minimise any stress caused by handling during the study. During anaesthetic induction and recovery, animals may experience mild transient stress, this may be experience by some animals on up to three occasions. Ultrasound stimulation itself, is not expected to have any adverse effects and all animals are expected to recover

uneventfully from the anaesthetic following stimulation and to resume normal behaviour shortly thereafter. The method of killing used causes instantaneous death with no suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats

- Mild (70%)
- Non-recovery (30%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objectives of this project are to determine the cellular and molecular effects of transcranial ultrasound stimulation on the brain. My group has already performed extensive in vitro experimental work which has established the proof-of-concept for the proposed study. However, our in vitro work does have fundamental practical limitations that prevent further progression towards our main objectives of utilising ultrasound stimulation to treat degenerative brain diseases. To further progress this work requires the effects of ultrasound stimulation on brain function to be determined. This can only be achieved in studies performed on living animals as a fully functional brain only exists in a living animal.

Which non-animal alternatives did you consider for use in this project?

We also considered characterising neuromodulatory effects in human participants.

Why were they not suitable?

Whilst human studies have been conducted into the effects of transcranial ultrasound stimulation, the field is still very much in its infancy, and critical exploratory work needs to be completed first to determine its efficacy and safety before substantive work can be ethically considered in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated animal numbers have been derived by extrapolating from similar work conducted by others in the field, with consideration given to our extensive in vitro data to predict effect sizes. Using the NC3Rs Experimental Design Assistant has ensured due consideration has been given to the design of the experiments and therefore the necessary animal numbers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A comprehensive analysis of similar in vivo studies was undertaken to predict the likely effect sizes of the phenomena we aim to study. This was then integrated with our existing data to derive the final expected effect sizes. This has facilitated calculated best-estimate power analyses to determine the minimum number of animals required across the experiments planned to be conducted. The NC3R's Experimental Design Tool has been used in the planning of the proposed experiments. Where scientifically appropriate, data from control animals/experiments obtained in the early phase of the study will be used as the control throughout the entirety of the study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will undertake multiple parallel assays from the brain tissue we harvest from each animal. Thus, one animal will provide tissue and cell material that can contribute to multiple data sets. This eliminates the need of using one animal per assay. We plan to undertake small-scale pilot studies prior to full- scale investigations in each experimental paradigm. This will allow us to establish ground-truth effect sizes and allow us to adjust our sample sizes with the appropriate statistical analyses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

During this project, we will use wild-type rats. Transcranial ultrasound stimulation is not expected to have any adverse effects. At the end of the study, the animals will be killed humanely.

Why can't you use animals that are less sentient?

To undertake the outlined studies it is essential to use an animal with a brain that is known to function in a manner similar to that of humans in order to have confidence in the translational potential of the safety and efficacy data generated. Rats have been selected for these studies because the anatomy of their brain is similar to that of humans and is of sufficient size to enable specific regions to be targeted using transcrainial ultrasound. Mice are unsuitable as their brain is too small to enable effective regional targeting. In addition, the limited cognitive ability and behavioural repertiore of mice make them unsuitable for some of the assessment tasks needed to determine the effects of transcranial ultrasound stimulation on memory and cognition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be group housed and we will implement cage environment enrichment. A major goal of this project will be to establish an appetitive positive reinforcement training regime that allows for voluntary immobilisation of the animal for ultrasound stimulation. Thus, a major refinement, if successful, will be removing the need to administer anaesthetics.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experiments will be conducted in line with Good Laboratory Practice (GLP) standards. The project will be managed and implemented in accordance to the standards and frameworks defined by the Laboratory Animal Science Association (LASA).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will undertake regular relevant Continuing Professional Development (CPD) to stay informed about advances in the 3Rs. The University Named Information Officer disseminates CPD opportunities on a weekly basis. I will use this to identify courses, webinars and other sources of information on 3Rs developments that I can attend and participate in. In addition, I subscribe to Norecopa's newsletters which contain useful information about developments and implementation of 3Rs principles. My active

engagement in these will be recorded in the University’s electronic training and competency system.

92. Mechanisms and Treatment of Mitochondrial Dna-Related Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

mitochondrial DNA, energy metabolism, organ pathology, neurodegeneration, therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Understanding and rectifying the pathological consequences of the mitochondrial DNA (mtDNA) dysfunction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The DNA in mitochondria (mtDNA) is essential for life: hundreds of mutations in mtDNA and scores in nuclear encoded factors required for mtDNA maintenance cause inherited human diseases, which have a collective incidence of 1 in 5000. Currently, there are no effective therapies that limit the high morbidity and mortality of these disorders. Added to the burden of the genetic diseases, are the 'acquired' conditions in which mitochondrial dysfunction is implicated. Thus, a means of preventing, reversing, or mitigating the loss of mitochondrial function represents a major unmet clinical need. In this regard, the project aims to 1) advance our understanding of the factors that control mtDNA maintenance and propagation of mutated mtDNAs and 2) unravel the sequence of events that lead from mitochondrial dysfunction to organ pathology. The new knowledge will lead to 3) design and test new therapeutic approaches to mitigate the pathological consequences of mtDNA dysfunction not only in genetic forms, but also in more common pathologies where mitochondrial dysfunction is implicated.

What outputs do you think you will see at the end of this project?

By the end on the project, we expect to:

1) Discover novel factors regulating the amount (depletion) and quality (deletions and mutations) of the mtDNA

2) Advance our understanding on the cascade of events leading from mtDNA dysfunction to organ pathology in rare and common disease

3) Establish the therapeutic potential of small molecules identified in vitro and successful tested in preliminary experiment in vivo and identify novel and more targeted compounds for mtDNA- related pathologies.

The novel and exciting information will lead to a) publications in leading scientific journals and b) development of credible therapy for mtDNA-related diseases.

Who or what will benefit from these outputs, and how?

The project is research-based with a profound translation potential. As such, it is expected to benefit academic research working on mitochondrial biology and metabolic disorders. Moreover, because mitochondrial DNA dysfunction features the normal ageing process and neurodegenerative disorders, the findings can benefit researchers working in these two broad fields in the UK and internationally.

Finally, the new knowledge will be invaluable for our clinical colleagues who have been to offer anything than symptomatic treatments to date. In this respect, once established the compounds are effective at restoring biochemical, molecular and phenotypic manifestation in mice, we plan to

a) securing IP for novel compounds

b) perform experimental medicine studies (from 2-5 years)

How will you look to maximise the outputs of this work?

All the knowledge generated through this project will be made available to the scientific community through its publication in peer-reviewed leading journals, as well as its dissemination at scientific meetings and conferences. Also, unsuccessful, or inconclusive approaches will be made available through its publication in journals which facilitate the disclosure of negative results. Moreover, all the biological samples generated during this project will be offered to collaborators for their use in other research topics, thus maximizing the outputs from our work and reducing the number of animals used in other projects.

Species and numbers of animals expected to be used

- Mice: 6400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The current project is intended to use GA mice modelling mtDNA human disease and their correspondent WT animals. Some of the biochemical and phenotypic manifestations resulting from mtDNA dysfunction occur after many years in patients and several months on GA mice, thus requiring the animal study to be extended from very early (neonate-juvenile) to late life (aged animals) stages.

Typically, what will be done to an animal used in your project?

Mice will be bred and maintained under standard conditions following approved procedures at the housing facility. Some of the animals will receive daily treatment with drug candidates aiming to restore mtDNA metabolism or purge pathological mtDNA variants (with a variable duration ranging from 1 to 30 weeks). Peripheral blood samples and biopsies of superficial tissues may be collected, and behavioural tests performed to understand the course-time of the pathology and the effectiveness of any given treatment without the need for killing the animal. At the end point of each experiment, mice will be humanely killed by approved methods and relevant tissues and/or organs collected for downstream analysis. Some mice may have their diet modified (eg: high fat or aminoacid deficient diet) to better mimicking human pathology and to gain insight into the role of mtDNA in rewiring the metabolism, which appears to be common to mitochondrial dysfunction. During all the experiments, any animal showing any unexpected harmful phenotype will be humanely killing to avoid unnecessary suffering.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of the GA mice used in this project will not experience adverse effect greater than mild severity. Some mice may progress to moderate severity in late stages of life (after 12 months of age), displaying body weight loss and motor impairment. If this is the case, animals will be transferred to a specific protocol with moderate severity and carefully monitored.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that the vast majority of the GA mice used in this project (85%) will experience mild severity. Only a subset (15%) of the animals might reach moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research questions that this project aims to address require the study of multiple cell types and organs, and in some cases how the dysfunction of one tissue can affect the others. Thus, despite the advance in the developing of in vitro and in silico models, they fail in modelling the huge complexity of the in vivo pathology.

Which non-animal alternatives did you consider for use in this project?

The in vivo experiments proposed in this project follow extensive work performed in vitro (cell culture) models, which provide critical direction for the animal work. Whenever possible, we plan to continue in vitro approaches in order to avoid and/or to refine our animal experiments.

Why were they not suitable?

While cell culture models can provide invaluable insight into molecular and biochemical disease mechanism, they fail in modelling the huge complexity of the in vivo pathology.

Thus, to proper mimicking and understanding human disorders, the study of animal models is required..

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimation of the number of animals has been done based on the requirements for the maintenance of the different mouse lines and the number of animals required for the experiments detailed in this project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our studies will be designed following PREPARE guidelines (https://norecopa.no/prepare) and considering the available online tools at NC3R's website (https://eda.nc3rs.org.uk/). We have worked closely with statisticians to plan studies to ensure the minimum number of animals are used, and will continue to use power calculations, randomization and blinding where appropriate to obtain statistically relevant results from the smallest group size possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Careful breeding will be undertaken to minimise the numbers of animals bred compatible with the scientific purpose. Where large cohorts of animals are required for experiments, the mice will be bred intermittently to generate age-matched cohorts. Also, when possible, the mice bred and maintained to secure the colony will also be used to provide experimental material. Experiments will be co-ordinated to allow overlapping projects to make use of the tissue samples obtained from these studies, thus reducing the number of animals used. Also, as much post-mortem tissues as possible will be collected and properly stored from each mouse (despite not being used in the short-term), to be offered to collaborators and/or to be used in future studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse is the most versatile and widely used vertebrate species for modelling human genetic diseases and thus for translational research, which forms the bulk of the work proposed in this project licence. In mtDNA-related disorders, multiple organs are involved, and the complex interconnections between them lead to the final disease phenotype. Thus, the study of an animal model of these disorders is crucial.

Why can’t you use animals that are less sentient?

Mouse models of mitochondrial DNA diseases are the closest to human pathology. Despite several models of mtDNA disfunction have been reported in less sentient vertebrate species (i.e. zebrafish), they fail in mimicking human disease, being murine models the only ones where the affected organs are relevant for human mitochondrial pathology. Also, the use of mice allows to access to a wide range of genetic assays and test kits that are not available for other species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When breeding, genotyping will be performed on ear biopsy samples, allowing us to reuse the tissue removed for the purposes of identification and avoiding extra suffering than that resulting from normal husbandry practice. Unavoidably, some mice will be singly housed e.g. when presenting aggressive behaviour or animals out-living their cage-mates. When possible, single housed females will be combined with compatible cage-mates. Regarding compound administration, the preferable route of administration will be always oral and in the less stressful way, e.g. replacing oral gavage for drinking water whenever possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow LASA Good Practice Guidelines (https://www.lasa.co.uk) and/or resources available at NC3R's website (https://www.nc3rs.org.uk/3rs-resources).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about advances in the 3Rs through the training courses and activities disseminated by UCL BS Administration as well as by the NC3R's website (https://www.nc3rs.org.uk).

93. Understanding How Metabolism Contributes to Cancer Development, Progression and Treatment Response

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Cancer, Metabolism, Metastasis, Microenvironment

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how metabolic changes in both tumour and normal cells can affect different stages of malignant progression, and how to target these changes for cancer therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer (in this protocol we are looking at pancreatic, lung, and intestinal, and possibly others in the future depending on how the project proceeds) is a major cause of premature

death worldwide and treatments for late-stage metastatic disease are urgently needed. This project brings together established and novel systems of metabolic control with the recent appreciation of how host factors control cancer, and how these might be used for therapeutic effect.

What outputs do you think you will see at the end of this project?

The project will produce two broad types of output. Firstly, there will be peer reviewed scientific publications that will contribute to the general pool of knowledge about the role of metabolism in cancer (such as pancreatic, lung, liver and intestinal) . This will help to drive the understanding of this area and serve as a platform for further studies in our group and others. These publications will be supported by other means of dissemination of results, such as presentations at international research conferences. A second output will be the identification and validation of new targets for cancer therapy that focus on metabolic pathways. These may lead to the development of new drugs to affect metabolic enzymes or entirely new treatment approaches such as dietary modulation. Several pharmaceutical and biotech companies are already pursuing these avenues and will be well placed to take forward the information generated by the outputs from this project.

Who or what will benefit from these outputs, and how?

In the short term, the key beneficiaries of these outputs will be the general cancer research community, who will be able to build on the data generated through this project to increase our understanding of the mechanisms linking metabolism and cancer. In the mid and long term these outputs will be of benefit to cancer patients and clinicians, through an increased understanding of how to use existing treatments and the development of new therapies. This work is novel and does not seek to reproduce work of others but will be used to build on our previous and ongoing findings.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work through peer reviewed publication in open access journals, seminars and presentations at international meetings and conferences. Where appropriate, we will work with the communications teams at our Institute to disseminate our results more broadly to the public, for example through press releases and lay talks. We will also maintain close links to industry partners and other external collaborators to ensure the most rapid translation of our work to patient benefit.

Species and numbers of animals expected to be used

- Mice: Mice: We expect to use up to 7,000 mice per year over 5 years. It should be noted that 50% of these will not undergo scientific procedures, but will be used solely for breeding and maintenance of colonies or if appropriate provision of tissues.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project focuses mainly on the use of adult mice to study cancer development, with the occasional use of juvenile mice, for example in the study of dietary interventions.

Mice are the only suitable animals for these studies for a number of reasons.

1. The physiology of cancer in mice is consistent with the human disease. Our aim is to study the interaction of whole-body systems with cancers, and for this it is necessary to use a mammalian system that mimics these aspects of human physiology.

2. Mice are routinely used to model cancer in a whole animal. As a result, there is a vast body of information and large numbers of models that are used by the whole field. This means the design of our experiments will be informed by previous data, reducing the requirement for preliminary studies.

3. As mice are so widely used, the results from our project will feed into the growing understanding of metabolism in cancer. Our work will be relevant and complementary to other studies, so helping to take forward the entire field.

Typically, what will be done to an animal used in your project?

To study tumour (such as pancreatic, intestinal and lung cancer) development , mice will be exposed to genetic modification (which may be spontaneous or targeted to a specific organ or selected time point in life, such as after birth), known or potential carcinogens and transplantation of tumour cells. These procedures may also involve viral infection.

To study how host responses promote or retard cancer progression, we will use mice of different genetic backgrounds (e.g. to study metabolism we will use obese or diabetic mice) or mice exhibiting co-morbidities , such as infection to induce inflammation, or we will use different diet to induce metabolic changes in the mice to see the effect on tumour development. The effect of aging will also be studied by maintaining the mice for two years.

The effect of different potential treatment options will be assessed using drugs, biological therapies such as antibodies or radiation.

Some mice will receive transplantation of certain immune cells to allow us to modulate and assess the role of the immune response in cancer.

Some mice will be exposed to different diets.

Tumour development will be followed by direct measurement of superficial tumours or non-invasive imaging of internal tumours, in some cases using genetic marking with a reporter

protein such as iRFP (a fluorescence protein that will enable us to observe the tissues in-situ).

Tissues and fluids will be collected from these mice, either from live mice (e.g.blood, urine or faeces collection) or post-mortem (e.g. tumour and other organs).

The duration of these experiments will vary considerably depending on the model, ranging from a few days to years. In most cases we have experience and knowledge of the expected timeframes and experiments will only be maintained for the minimum duration to address the scientific need.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will experience a range of impacts from extremely mild (for example some dietary changes) to moderate (in the case of aggressive tumour development or infection combined with interventions such as surgery). In the latter case we would expect weight loss and abnormal behaviour such as hunching. While we have significant experience and can predict the time frame and severity of each model, unanticipated events can occur and all mice will be monitored closely for signs of ill health or distress.

Experiments will be terminated if they reach moderate severity limit.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals in these studies will be expected to develop tumours. The impact and severity of each experiment will differ depending on which tumour model is used, and the aggressiveness of the tumour combined with the efficacy of any potential intervention. We anticipate that the tumour experiments will result in 50% mice reaching moderate severity as a result of repeated procedures. The other 50% will be a combination of mild and sub-threshold as a result of breeding maintenance of the different cohorts.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
-

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our project aims to understand cancer development in the context of the whole body, integrating the interplay between cancer cells and normal hosts systems to determine mechanism of cancer growth and spread, as well as the effects of systemic therapeutic interventions. The complexity of these interactions cannot be measured in tissue culture systems and the mouse provides an ideal mammalian model to carry out this work.

Which non-animal alternatives did you consider for use in this project?

Our studies include the use of tissue culture protocols such as the standard 2D cultures that uses established cell lines, also 3D organoids (from tumour and normal organs, such as liver, pancreas, intestine and lung) and co-culture systems (i.e. culturing two or many different types of cells together to mimic as close as possible to in vivo situations). These will be used extensively to establish hypotheses, understand mechanisms and examine direct interventions in cleaner, simpler systems. For example, we will be culturing adipose tissues and cancer cells together, and see the effect of adipose tissue on cancer growth or other parameters such as migration of cancer cells. The results from these studies will guide the mouse work and reduce the number of in vivo experiments required, and finetune the subsequent in-vivo hypotheses.. We will also regularly search in the literature, and attend meetings for unpublished new data, to see if there are any new methods that offer better non- animal alternatives, should there be any that is applicable to our aims.

Why were they not suitable?

The value of organoid and co-culture systems is constantly improving, and we will continue to modify and upgrade this work over time. However, even the most sophisticated cell culture models cannot reproduce the complexity of the tumour microenvironment, tumour dissemination to distant organs or the effect of systemic whole-body changes on cancer progression. These questions can only be accurately modeled within the context of the whole live animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in each of the studies is based on extensive (over 10 years) previous experience using the same models, published literature, advice from colleagues using the same models and the advice of our in-house statistical experts . In most cases power calculations will be used to estimate the number if the parameters are known.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. All experiments will be designed to use the minimum number of mice required to achieve statistically meaningful results. This will be developed with the advice of in-house statisticians, where required.

2. In all cases, experimental designs will ensure the extraction of maximum data, for example by measuring primary tumour and metastasis in the same animal or harvesting multiple organs from the same mouse for analysis.

3. Tumours in genetically engineered mice tend to develop over broad time scales, making it difficult to know exactly when to harvest mice for the most informative results. Published data on the models and online tools such as NC3Rs Experimental Design Assistant will provide guidance for the optimal number of animals needed to address the questions. Non-invasive imaging techniques or endoscopy will be used where possible to accurately follow tumour growth over time, limiting the number of mice required to hit the appropriate point of tumour development for the study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. We constantly optimize our breeding strategies to minimize the number of animals needed to achieve the desired genotypes for our genetically engineered models. Where possible, orthotopic tumour transplant models will be used, which do not require the breeding of genetically altered animals and use fewer animals per study.

2. Studies from cell culture models will be used to ensure that only the strongest hypotheses are tested in the mouse

3. Animals will be shared between experimental groups, where possible. For example, normal control animals can be obtained from our breeding colonies where they would not normally be used for a study.

4. Where possible we will share tissue from experiments to enable multiple ex-vivo studies

5. Most experiments will be based on previous studies, allowing us to predict the required numbers of animals. .

6. Using advice from HO efficient breeding of GA animals (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773

553/GAA_Framework_Oct_18.pdf) we constantly monitor animal use and archive lines by cryopreservation when not required over a period of time.

7. Where possible, unwanted genotypes from genetical breeding experiments will be utilized for other experimental studies – this is coordinated across the research group prior to starting the mouse study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project uses genetically engineered mice, models of cancer induction by carcinogens and tumour cell transplantation. Infection models and other models of metabolic syndromes such as obesity and diabetes are also used. In all cases protocols to limit pain and suffering (e.g. ultrasound guided injection to limit surgery) are used. The conditional and inducible nature of many models ensures lesions are targeted to the cell type of interest (if the tissue specific cre allele is available for the tissue of interest) in adults, reducing non-specific off target effects.

None of the protocols exceed moderate severity levels. All mice on procedures are constantly monitored and humanely culled when exhibiting signs of altered health status and /or tumour burden or other specified end point is reached.

Why can’t you use animals that are less sentient?

Less sentient animals do not possess the physiology (e.g organs, hormones, metabolism and immune system) that will allow us to understand the interaction of tumours with these complex host systems which is the focus of our studies. Only mammals can provide the level of complexity required to make these studies relevant to humans. For example, to study effect of insulin signaling that is a key factor in metabolic disease, it is known that cold blooded animals is not a good model as the pathway is not well conserved and their energy metabolism is much different compared to warm blooded animals such as mice and human. Many genes are also not conserved in lower animals as well.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We take advice from the experts within various fields of medical research and share our own experiments of refinements and improvements. We are highly motivated to minimize harms and stress to our mice as this also allows for more accurate and reproducible

experimentation. For example, we have moved to imaging guided transplantation of cancer cells – a technique that avoids surgery. We also follow local NVS policy on post-operative care and pain management. We also increase monitoring of the tumour models to determine the earliest end-point possible, and will use orthotopic models if applicable.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all studies we will refer to the Guidelines for the welfare and use of animals in cancer research (Workman et al, 2010) and ensure best working practice. We consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs/LASA websites). We also consult the Guiding principles aseptic surgery:https://www.lasa.co.uk/PDF/LASA, and Guiding_Principles_Aseptic_Surgery_2010.2.pdf Refining procedures for the Administration of substances: https://doi.org/10.1258/0023677011911345

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Training programmes in monitoring tumour development are mandatory for all users for each of our models. The trainers are specialists and users in specific tumour models and are shadowed by the trainee during the routine checking of the animals for symptoms. The trainees will be considered trained once the trainers are satisfied with their ability to recognize the signs of tumour development, humane end-points, and what samples to be collected and processed. We received frequent updates and recommendations from our NIO and we have an in-house NC3Rs regional programme manager who will provide guidance to the lab to ensure the latest 3Rs recommendations will be implemented whenever possible. Also, we keep ourselves up to date (e.g. from reading literature and attending conferences) to recent developments regarding better mouse models of various human diseases that are relevant to our study in cancer and metabolism

94. Molecular Analyses of Caspases in Infection and Immunity

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

innate immunity, infection, inflammation, gut, pathogenesis

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to better understand the role of the immune system in health and disease. We will investigate how the immune system protects us against infection, and how an over-active immune response contributes to detrimental disease outcomes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system protects us against infectious microorganisms, promotes tissue repair and helps maintains homeostasis. Molecules called the 'inflammasomes' can sense infection, tissue damage or stress. Cells then launch an immediate innate response by releasing many inflammatory mediators called cytokines. Normally, these inflammatory

processes are self-limiting and essential for clearing infections. However, deregulated immune responses are linked to the development of several diseases. We will focus on how the immune response is beneficial during infection, and how its deregulation negatively impacts disease outcomes.

Inflammasomes play important roles in defending against infectious diseases of the gut (e.g., diarrhoea, gastroenteritis) and lung (e.g. pneumonia), as well as non-communicable diseases (e.g., inflammatory bowel disease, neurodegenerative disease, arthritis conditions and heart disease).

Furthermore, mutations in genes encoding inflammasomes are linked to hereditary fever syndromes. Inflammasomes thus affect such a wide-ranging set of organs, tissues, and contribute to different diseases. Previous work in this field has showed that genetically removing inflammasome-associated genes, or pharmacologically blocking them through drugs, reduces inflammation and improves disease outcomes. Indeed, drugs against these pathways (e.g., anti-IL1 therapies) have been approved for use in humans. Current research focuses on finding newer and better therapeutic avenues. This work will complement other in vitro work in the group, and will use wild type or newly derived genetically altered (GA) mice. We hope to shed light on disease pathogenesis and identify potential new therapeutic interventions.

What outputs do you think you will see at the end of this project?

Outputs will include new, fundamental and basic scientific information on the role of innate immune molecules called inflammasomes in infection, sterile inflammation and homeostasis. We will also generate new GA mice that will be of benefit to the wider community of scientists. We could also find out whether newly designed drugs or other substances could serve as starting point for the design of new therapeutics. This information will be disseminated by publications in the scientific literature.

Who or what will benefit from these outputs, and how?

In the short term, our newly derived GA mice will benefit the research community in the field and will be available to other groups nationally and internationally. Our experimental findings will be useful to other basic scientists working in immunology, microbiology, biochemistry, cell biology, among others. In the long-term, our outputs could form the bases of new concepts in mammalian and human immune responses, and future cross-disciplinary work. Therefore, our findings could also inform scientists who undertake translational work more directly connected to the clinic.

How will you look to maximise the outputs of this work?

Peer reviewed research publications and reviews, presentations at conferences, invited seminars and announcements on social media will disseminate our work to groups worldwide.

We will use work-in-progress seminars presented by students and postdocs in the group, my group's participation in the campus-wide collaborative consortia, and interactive Away Days to make our work more widely known.
Species and numbers of animals expected to be used

- Mice: 7300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use inbred strains of wildtype and GA mice for this work. Mice have a proven track-record in the field of immunology and infection because of the presence of both the innate and adaptive immune systems, the latter being absent in invertebrate experimental models. Moreover, like in humans, molecular pathways involving caspases and inflammasomes, which are the main areas of focus in our research, are known to play key roles in immune responses in mice. Our work will therefore build on a robust body of work and provide new insights in this field.

Most work will use adult animals, as they respond robustly to infection and inflammation and provide relevant biological information. We plan to use pregnant animals and embryos only during the derivation of GA mice, or when tissues from non-adult life stages are required for in vitro studies.

Typically, what will be done to an animal used in your project?

Typically, animals will be administered an infectious agent via injection (intraperitoneal (i.p.), intravenous (i.v.), or intratracheal (i.t.)) or orally. Other substances (e.g., transgene-inducing agents, antimicrobials, immunomodulatory agents etc.) may be administered orally or via injection.

In the majority of cases animals will undergo between 3-5 procedures (e.g., typically, 3 oral gavages of transgene-inducing agent over 5-6 days, followed by single administration of infectious agent OR an inflammatory substance, followed by timed killing by a humane method, normally up to 5 days).

Where immunomodulatory substances are tested for their impact on the outcome of microbial infection or inflammation, an additional step may include administration of substances on one or more occasions (e.g. antibiotics in drinking water or i.p. injection of cytokines at timed intervals).

A small number of animals will undergo additional steps, such as those that undergo radiation & reconstitution or those that will be imaged (e.g., experiments using light-emitting microbes, substances or strains of mice) during experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

The infectious agents we will administer cause gut or lung inflammation, and in some cases, invasive disease of the liver, spleen or other organs, leading to overall symptoms such as weight loss, reduced feeding, diarrhoea-like symptoms of soft stools, altered breathing, changes to movement and posture.

The inflammatory substances could trigger localised inflammation in the abdominal cavity and systemic inflammatory symptoms.

Experiments are only expected to reach moderate symptoms and animals will be killed by a humane method at timed intervals that last between hours (e.g. every 6 or 12 h) or days (e.g., 24 h time-points).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity of our experiments is mild to moderate. About 30% animals will experience mild symptoms and 70% moderate symptoms.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Response to infection in the intestine or lung, which contain different cell types and commensal microorganisms cannot be studied in vitro using cell culture systems. Similarly, inflammation that affects multiple tissues and organs, including circulating blood, cannot be recapitulated in vitro. Use of animals for these studies is therefore scientifically justified.

Which non-animal alternatives did you consider for use in this project?

Cell-culture methods, including cell lines and organoids.

Why were they not suitable?

Available cell-line models do not faithfully reflect the behaviour of cells within the natural environment of tissues. Organoid-based are typically only one cell-type and the interaction of epithelial cells with immune cells cannot be studied in these systems. Similarly, the intercommunication between the host and commensal microorganisms cannot be studied in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals reflects the number necessary to achieve the scientific objectives outlined in the work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Wherever possible we will use light-emitting reporters that allow non-invasive optical imaging of the same animal throughout the experiment. This avoids the need for additional animals that would have otherwise been required at various stages of the study.

We will seek advice from statisticians and online resources such as the NC3R website, ARRIVE and PREPARE guidelines, and published literature in designing experiments. Wherever possible, we will use randomised block designs that offer higher power for fewer animal numbers. Relying on principles of the 3Rs, the minimum number of total animals required to obtain statistically significant inferences will be used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible we will use modelling using software, cell lines, organoids or recombinant proteins for our studies, and avoid obtaining cells/proteins from mice i.e., we will avoid using animals only to provide material for routine work.

Colony management will ensure breeding on demand to avoid surplus animals from over-breeding.

While comparing treatment-groups, we will carry out as many conditions as possible in a single experiment to avoid repeated use of untreated/vehicle-treated/uninfected control groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A mouse model causes the least overall harm compared to guinea pigs, rabbits and non-human primates, which experience more severe disease. Inbred mice are widely used and scientifically studied as models for human infectious diseases; their homogeneous genetic background reduces the number of animals required, compared with outbred animals.

Our experiments focus on early immune responses (innate immunity) and are more refined than longer and/or high-dose regimens that can cause longer-lasting harm and discomfort, and more severe disease outcomes. We will aim to use pre-defined time points that reduce pain and suffering, and use refined doses and administration schedule to reduce distress and harm.

Why can’t you use animals that are less sentient?

Adult mice are best suited for models of disease we will study. Insects (e.g. Drosophila) and less sentient vertebrates (e.g. zebrafish) do not possess the molecular components that drive disease- related processes in mammals, and are therefore not suitable for use in our studies. The mouse has a proven track-record of providing valuable insights on mammalian, including human, immune responses. Furthermore, there is a large collection of reagents and genetically altered animals in the field which will help our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will keep up-to-date with literature to employ the latest transgene-inducing and imaging methods, including update our delivery methods, the substances and/or their formulations with the goal of reducing pain and discomfort to animals. We will aim to reduce the number of procedures on an animal by combining steps where possible, for instance, availability of slow-release formulations in the future could reduce the need for multiple injections over time. Where possible, will use sensitive read-outs that could enable us to collect key immune information at earlier time points and thereby reduce pain and suffering; for example, where possible we will use light- or fluorescence-based reporters.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published guidelines issued by LASA, NC3Rs ARRIVE, and the RSPCA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep ourselves updated with latest literature on optimisations and refinements of reagents, treatments, handling of mice etc. and follow any updates to ARRIVE and PREPARE guidelines when planning experiments. We will engage with the institutional 3R group, and keep up-to-date with and follow NC3R principles.

95. Nervous System Injury and Repair Strategies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

hypoxia-ischaemia, neonatal encephalopathy, CNS injury, PNS injury, oxidative stress

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile
Rats	adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Blood and/or oxygen deprivation around the time of birth (birth asphyxia or neonatal hypoxia- ischaemia) affects 1-3 per 1000 live births in the developed world with rates up to 26 per 1000 in developing countries. The affected children either die, or the majority of survivors develop lifelong neurological disabilities such as cerebral palsy, mental retardation or epilepsy. Birth asphyxia can be caused by temporary disturbance of the blood supply to the uterus during pregnancy or through low oxygen levels in maternal blood thus affecting the neonatal brain. Currently, despite the quick development of

neonatal care, there is no cure for neonatal hypoxic-ischaemic brain injury and the only clinically approved treatment is through whole body or head cooling of the infant. This treatment is partially effective. Therefore, there is an urgent need for the development of new therapeutic strategies for neonatal hypoxic-ischaemic brain damage. This project aims to provide better understanding of the mechanisms behind neonatal hypoxic-ischaemic brain damage through breeding and use of transgenic mice and rats that are deficient or overexpressing molecules participating in cell death pathways involved in neonatal hypoxia-ischaemia. We aim to define the molecules which mediate inflammation, neuronal loss and behavioural deficits following neonatal hypoxia-ischaemia and to develop strategies to promote neuronal survival. Maternal infection also has a synergistic effect with neonatal hypoxia- ischaemia and contributes to the brain damage. In this project we aim to investigate the mechanisms behind this synergistic effect and to pharmacologically treat the pregnant mums in order to study and prevent the damage to the neonatal brain. We also aim to treat the fetuses with vectors and stem cells.

We aim to study the mechanisms of neuronal cell loss and tissue repair in adult brain hypoxia and investigate how development affects those mechanisms through comparison to hypoxia in the neonate, including the synergistic effect of infection.

We aim to identify factors mediating inflammation, loss of neuronal cells, fragmentation and disintegration of the axons, as well as axonal growth aiming to re-innervate the target muscles in models of neonatal and adult axonal damage, and compare these cellular changes and their mediators to those observed after local muscle paralysis, ischaemia and infection. The project aims to assess the effects of these factors on central nervous system (CNS) regeneration, particularly in spinal cord injury.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work? Background

Injury to the human brain around birth, during postnatal development or in the adult, frequently causes impairments in communication, movement and the ability to lead an independent life. The main sources of brain injury are trauma, infection and insufficient supply of oxygen and nutrients (hypoxia- ischaemia). The latter is either caused by global hypoxia (due to pregnancy complications affecting the fetus or cardiac arrest in the postnatal or adult life) or by obstruction of the of the blood supply to a part of the brain or spinal cord as in stroke. Neurological recovery after any form of brain and spinal cord injury is complicated by the low potential for neural repair as well as by the secondary brain damage.

Secondary brain damage is a common problem in stroke, brain trauma and hypoxia-ischaemia, and refers to increased neurological impairment following the initial insult to the

nervous tissue. It is often that the insult cannot be avoided and is accompanied by immediate cell death and tissue loss associated with primary damage. However, following restoration of the normal metabolism, a secondary more prevalent wave of delayed cell death and tissue loss occurs, which is related to secondary brain damage. During that stage inflammation plays a major part and contributes to the tissue loss.

However, an underlying infection can have a synergistic effect with an injury to the brain and cause collateral damage to non-infected tissue thus increasing the overall impairment as observed for example in neonatal hypoxia-ischaemia. The inflammatory response following neural trauma is strongly increased following application of an infectious stimulus.

The mechanisms causing secondary damage are poorly understood, but are mainly associated with low potential for repair and increase in energy demand, which causes molecular and morphological changes in the injured neurons, as well as activation of non-neuronal cells and recruitment of peripheral inflammatory cells to the site of injury.

This poor potential for repair after injury to the central neural tracts is partly due to exogenous inhibitors of regeneration, however many central neurons cannot repair and regenerate even if provided with an optimal environment. Failure to express essential molecules needed for regeneration seems to play a crucial role, but the precise minimal and optimal requirements are still only poorly understood. Even in peripheral nerve injury, where the potential for axonal regeneration is high, recovery in spatial maps and in fine perception necessary for precise and coordinated movements is very limited.

Work completed so far

The experiments carried out under the previous project licenses provided important information about the pathways and mechanisms involved in damage and repair of the injured nervous system. One branch of our research focuses on neonatal hypoxic-ischaemic (HI) insult and the mechanism underlying the subsequent brain damage. Data from our group demonstrated increase in acidosis during neonatal HI. We also examined the activation and deactivation of periventricular white matter phagocytic cells during postnatal mouse development and demonstrated the presence of highly active phagocytes in the neighbourhood of vulnerable white matter thus contributing or protecting against axonal damage in the fetus and premature neonate. Our work has also focused on identifying cell-type specific cytokines, transcription factors and signalling enzymes involved in neonatal HI brain damage, including Signal Transducer and Activator of Transcription 3 (STAT3) and extracellular signal-regulated kinase 2 (ERK2). We also looked at the effect of stem cells as treatment for neonatal HI brain damage. Recently, our research focused on the potential of natural compounds such as curcumin as treatment for neonatal HI brain damage.

We also looked at the synergistic effect between HI and systemic exposure to infection and demonstrated that genetic deletion of some pro-inflammatory cytokines can

completely abolishe the synergistic effect between infection and HI. We are currently investigating the cell-type specific role of different cytokines in neonatal HI and whether any of them alone or combined are responsible for the effects on the synergism of endotoxin and HI. Some of our studies looking at the synergistic effects of endotoxin and HI have focused on the role of post-translational modifications following HI, showing that their inhibition reduces neonatal HI brain damage thus suggesting this process as a potential target for pharmacological HI treatment . We are also blocked the alternative complement pathway through global deletion in neonatal HI demonstrated neuroprotection not only for HI, but also for infection- sensitised HI thus suggesting this blockade as a potential pharmacological target in neonatal HI brain injury.

Another branch of our work focuses on the molecular signals involved in neuronal regeneration following peripheral (PNS) and CNS injury. In these studies we investigate the role of transcription factors (STAT3, c-Jun), adhesion molecules and neurotrophins in neuronal survival and axonal regrowth. We confirmed that neuronal c-Jun is necessary for the promotion of regeneration, inflammation and cell death. We also studied the effects of c-Jun on injury-induced Schwann cell de- differentiation response and showed that c-Jun is essential to support motoneuron survival after nerve injury. We are also looking at the potential of natural compounds with anti-inflammatory and anti- oxidant properties, such as curcumin, as a way of provision of quicker and more successful regeneration.

Finally, we are also pursuing viral vectors as a method of tracing connections within the injured and regenerating nervous system, as well as delivering cytokines, trophic factors and other molecules beneficial to functional repair. Since many neurons stop dividing during late fetal or postnatal development, they cannot be replaced by the organism if neuronal loss occurs as the result of failure to implement early neural rescue therapy. Replacement therapies, using normal or genetically modified neural stem cells, therefore hold the key to treating patients with neural loss when the time window for early intervention has passed

What outputs do you think you will see at the end of this project?

This work aims at reduction of the incidence, severity or prevention of neonatal hypoxic-ischaemic brain damage thus saving babies' lives and reducing the socio-economic burden to the affected individuals, families and healthcare system. This project also aims at helping people with brain damage through better understanding and development of potential treatment for patients suffering from bacterial meningitis, head trauma, hypoxia and stroke and improvement of their recovery of mental, sensory and motor functions.

Who or what will benefit from these outputs, and how?

The project will provide insight into the pathways involved in injury to the nervous system and thus opportunities for the development of treatment for people with brain damage.

The proposed project will provide knowledge on the involvement of different transcription factors and their post-translational modifications, as well as oxidative stress, infection and inflammation in cell death pathways triggered by neonatal hypoxia-ischaemia, and adult and neonatal CNS and PNS damage due to bacterial meningitis, head trauma and stroke. The work on the proposed project will allow use of these proteins as targets for inhibition and prevention of neonatal and adult CNS and PNS damage with potential future application in the clinical practice.

Due to the lifelong nature of the disabilities caused by neonatal HI, they impose an emotional and financial burden not just for the affected individuals and their families, but also for the society and healthcare system.

The results from the current project will benefit the scientific society increasing the knowledge on the involvement of different transcription factors, infection and inflammation and oxidative stress in neonatal and adult brain damage, and will provide potential strategies for targeting and treatment of neonatal and adult CNS and PNS damage. Work described in the proposed project will provide numerous benefits in terms of uncovering the molecular basis of brain disease, developing and testing new forms of treatment and giving a rational basis for intervention in human patients.

So far the only clinically approved treatment for neonatal HI is whole body or head cooling, however its success rate is limited and 40% of the treated children still suffer from neurological disabilities. This urges the need for additional or alternative therapies to be used either alone or in combination with cooling to reduce neonatal and perinatal brain damage. Reduction of increased transcription factors or inhibition of their post-translational modifications, inhibition of oxidative stress, maintenance of the balance of pro- and anti-inflammatory cytokines following neonatal HI and adult and neonatal CNS and PNS damage alone or in combination with cooling can prove beneficial and following testing in rodents, can be used in translational models and potentially clinical trials.

How will you look to maximise the outputs of this work?

We will be looking into establishing collaborations with academics, as well as industry. All the data produced in the project will be published and presented at conferences. We will also involve members of the public through participation in In2Science and Nuffield programmes providing university internship placements for young people from minority backgrounds.

Species and numbers of animals expected to be used

- Mice: 16100
- Rats: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Experimental animals will be limited to mice and rats – mice because of the availability of many genetically modified strains, and rats because it allows us to perform surgically elaborate experiments in a larger, docile rodent, with – for a mammal - comparatively moderate level of brain development. The neonatal mouse and rat brain developmentally corresponds to late preterm/term human neonate, thus providing clinical relevance to the outcomes of neonatal hypoxia-ischaemia.

Typically, what will be done to an animal used in your project?

After being bred in Protocol 1 the animal will undergo anaesthesia and will be subjected to surgery (blood vessel occlusion or nerve crush or cut). The animals are pre- or post-treated with different compounds and will remain on study for up to 6 months when they might be used for behavioural assessment and/or subjected to induction of general anaesthesia and injection of tracer 2-3 days before planned killing. The animals are killed either by Schedule 1 or by terminal barbiturate anaesthesia and perfusion with fixative to allow better histological specimen.

What are the expected impacts and/or adverse effects for the animals during your project?

Ear notching should involve only slight and transient pain, and no healing problems. Pain from tail tipping will be controlled by local or general anaesthestic, and in any bleeding after tail-tipping or blood sampling by local pressure. Excessive blood sampling may cause anaemia or haemodilution, so the amount withdrawn will not exceed 15% total blood volume in any 4-week period.

Animals who are immunodeficient lack differentiated T- and B-cells. Thus infections are likely to occur. In animals used in models of motorneuron diseases, paralysis might rarely occur at earlier stage.

Mild cardiorespiratory depression due to anaesthesia and surgery is rare; postoperative pain, post- operative infection (inadvertent), stress, abortion, agranulocytosis. Minimal distress associated with behavioural tasks. No anticipated effects on the dam due to chronic exposure to a hypoxic air mixture (Baud et al., Brain Pathol. 14:1, 2004). Mild stress likely. Animals are likely to become distressed during behavioural tasks. Incidence of other adverse effects is low.

Injection of substances could rarely result in distress. Injection of LPS could very rarely result in sepsis.

Following a Caesarian section the pups will be fostered, but rarely they might be rejected by the foster mum. Following normal delivery, the pups rarely might get rejected by the mum.

Very rarely some animals (<1%) who will be anaesthetised and/or intracerebrally injected, or animals re-anaesthetised for nuclear resonance scanning, might die.

Loss of animals due to anaesthesia or surgery is rare; postoperative pain, post-operative infection (very low), agranulocytosis (very low). Minimal distress associated with behavioural tasks is very low. Sometimes hypoxic ischemic insult following surgery in some strains of mice may result in loss of up to 15% of animals. Some stress is likely during behavioural tests. If an animal struggles in any of the behavioural tests it will be immediately removed from the experiment. Injection of substances could rarely result in distress. Injection of LPS could very rarely result in sepsis. Following HI the pups very rarely might be rejected by the mums. Very rarely some animals who will be anaesthetised and/or intracerebrally injected, or animals re-anaesthetised for nuclear resonance scanning, might die.

Incidence of other adverse effects is low.

- We are seeking to reduce the post-operative mortality rate through:

• Avoidance of use of first litters (those are known to be weaker, runty and often neglected by first time mums)

• Our experience shows that offspring of breeders generated through in house breeding seem to tolerate the insult better and show less abnormalities than those obtained from breeding of commercially purchased animals.

• Currently the device we use allows hypoxia of a group of animals without individual access, and opening it during the experiment would result in re-oxygenation of the rest of the group and would obscure the results. This can explain the postoperative lethality in some strains of mice. On the other hand single animal exposure to hypoxia one at a time is not feasible and would not provide equal exposure to the same conditions of the experimental animals, thus introducing an additional variable and error in the experiment. Optimisation of the device providing hypoxia allowing single animal exposure would allow us to terminate the experiment for each animal as soon as we observe abnormal behaviour associated with suffering and pain. Such device will be put in use as soon as it is available.

• We intend to use therapeutic hypothermia in neonatal mice and are aiming to replace the currently used rectal thermal probes with pacifier thermometer, infrared thermometer, external thoracic thermal probe or a thermal camera, hence avoiding additional distress to the animals through continuous exposure to anaesthesia and invasive procedures, and complying with the 3Rs.

Following neonatal axotomy the pups very rarely might be rejected by the mums. Partial paralysis as a consequence of axotomy is expected, but that is temporary and reversible after 10 days following surgery. In some mouse strains the paralysis might extend beyond 10 days but would not affect behaviour, feeding and motor performance.

Excitotoxic agents can cause convulsions and fits, therefore death is also expected. With the dose to be used in the experiments we would not expect epileptic fits, however the incidence of such is very low (<1%). Incidence of other adverse effects is low.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect all the animals in protocol 1 to have mild severity. We expect 70% of the animals in protocols 2 and 3 to have moderate severity and the rest to have sub-threshold. The animals in protocols 4-6: we expect 60% for the animals in each of the protocols to show moderate severity and the rest 40% to show sub-threshold severity. We expect 50% of the animals in protocol 7 to experience moderate severity and the rest 50% to show sub-threshold.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Work in cell culture has played a pivotal role in many aspects of the projected work, in the identification of neurotrophic substances, excitotoxicity, and the intracellular cell death and differentiation pathways. However, in vitro studies deal with simplified systems, and cannot in the final analysis predict, whether a specific molecule has a detrimental, beneficial effect OR, just as importantly, simply no effect in the complex organism. To answer these specific questions, one cannot avoid doing these experiments in vivo.

Which non-animal alternatives did you consider for use in this project?

Cell cultures, computer modelling

Why were they not suitable?

In vitro studies provide a very simplified isolated system for testing, which can provide some information about the mechanisms underlying neuronal injury and repair. However, these mechanisms are to a great extent associated with intracellular communications which cannot be provided through in vitro testing, but only in the in vivo experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Sufficient predictive power to observe a significant effect or its absence is a key requirement in planning animal experimental work. This applies for all experimental stimuli, in our case a deleted gene, applied neurotrophin, or a specific form of injury. Work started with insufficient number of animals only entails animal suffering without producing significant insights into biology of the disease.

Moreover, each animal is individual and most biological responses show strong variability, even in inbred animals. Thus, previous work in our group showed a relative standard deviation (SD/mean) of 40-80% for lymphocyte recruitment to the injured brain and 25-50% for neuronal cell death. Based on these numbers, we will need a group size of approximately 16 animals per group to be able to identify a statistically significant, 50% reduction. In a comparison between 2 groups of animals (e.g. treated v untreated), we will need 20 animals per test. Taking into account license duration (5 years), this will amount to 10 experiments per protocol and year. This is not unreasonable in view of the number of mutant mice or therapeutic substances in mice and rats that will need to be tested in this programme. Increasing this number has the inherent danger of finding weak but statistically significant effects of questionable clinical relevance. We are also aware that some biological responses show much lower level of variability (10-20%). If this is the case in any of the responses investigated in this programme, we will reduce the number accordingly, down to 4 per group, the lowest number required for a statistically valid assessment. In our experience, such a flexible approach will reduce the overall number of animals, decrease economic cost and minimize animal suffering while still permitting a valid statistical comparison.

In addition to the above, paring down on unneeded group size, we will, whenever possible try to avoid duplication of control groups, using box analysis and ANOVA testing several experimental groups against same group of controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental Design Assistant (NC3Rs), ARRIVE guidelines, using data from past experiments as ground for generation of pilot studies, http://powerandsamplesize.com/Calculators/Compare-2- Means/2-Sample-Equality

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding, cell culturing to replace the use of animals in toxicology essays, and sharing of tissue

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Breeding of wild type and genetically altered animals with mild and moderate severity, maternal surgery/hypoxia and treatment of the offspring, neonatal hypoxia-ischaemia using a modified version of the Rice-Vannucci model, neonatal and adult axonal cut or crush, or local muscle paralysis, adult hypoxia-ischaemia as a model for blood vessel blocking events.

Why can’t you use animals that are less sentient?

Experimental animals will be limited to mice and rats – mice because of the availability of many genetically modified strains, and rats because it allows us to perform surgically elaborate experiments in a larger, docile rodent, with – for a mammal - comparatively moderate level of brain development.

The resemblance between the rodent and human nervous system is well described. Even though there are also similarities with earlier developmental life forms (i.e. C. elegans), those can be suitable for some aspects of cell response, but due to the developmental differences would not provide data which can be incorporated for use in large animal models or clinical trials.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal experiments can lead to considerable stress and it is essential to minimize suffering. In the current programme this will be achieved by limiting extensive, major

surgery (trauma, blood vessel occlusion) to one event. All additional, short invasive procedures will be performed under brief, general anaesthesia. Experiments with animals showing obvious signs of distress and pain (immobility, unkempt fur, no passing of urine and faeces), rapid loss of more than 15% of body weight, will be terminated prematurely. As infection and sepsis have deteriorating effect in neurological diseases, it is important for us to explore their effect in our models. However, in order to control infection and potential lethal outcome, we will be using sterile gram-positive or gram-negative bacterial components so we can mimic those complications under controlled conditions.

Experimental animals will be limited to mice and rats – mice because of the availability of many genetically modified strains, and rats because it allows us to perform surgically elaborate experiments in a larger, docile rodent, with – for a mammal - comparatively moderate level of brain development

Anaesthesia will be achieved by using always the most refined method for the scientific purpose. In neonatal mice from birth will be subjected to inhaled gas or injectable anaesthesia will be used. There are suggestions that pain may be experienced on recovery. In adult animals is assessed through changes in behavior, while in neonates pain is assessed through changes in skin and stomach colour, and rejection by the mum. In our models inflammation is a crucial factor in the trigger of injury, therefore we are unable to use NSAIDS as they would interfere with the outcome. We will try alternative pre-operative analgesia (i.e. opioids, local anaesthesia) and if the effects are detrimental, then we would need to use post-operative pain relief.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs and ARRIVE guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through participation in NC3Rs webinars and close communication with Biological Services and the HO

96. Understanding Initiation Events for Breast Cancer and How Pregnancy may Influence These

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

breast, cancer, initiation events, pregnancy protection

Animal types	Life stages
Mice	juvenile, adult, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the early initiation events that lead to breast cancer, and how pregnancy may influence either early events or downstream events.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK alone over 50,000 women per year are diagnosed with breast cancer, with the majority of these occurring in women post menopause. Research into breast cancer often centres around the detection and treatment of disease, and although this is hugely valuable, understanding initiation events could go a long way to prevention over treatment. Thus far there is limited knowledge surrounding how cancers are initiated. Some, such as colon cancer, come with consistent changes in the genome which could be causative. Breast cancers, despite sharing many features across patients, allowing for subtype generation, have few known shared features which would be suggestive of initiation. BRCA mutations, being one such gene, are only present in 3% of breast cancers, so although highly useful in predicting future breast cancer events, it is clear there is more to discover.

What outputs do you think you will see at the end of this project?

This project will provide detailed information including, gene expression (RNA) and DNA sequencing, epigenetic (the modifications to genes that cannot be seen from standard RNA and DNA sequencing), and environmental cell modifications, regarding the changes that a mammary gland undergoes in the development of mammary carcinoma, and how these may differ before and after pregnancy. We hope to produce peer reviewed publications and provide a good groundwork for on-going research in this area with the development of potentially new (or more developed) and useful models, and an enriched data set that has benefited from up-to-date and advanced methods.

Who or what will benefit from these outputs, and how?

In the short term those working in the field may benefit from any changes to the current experimental designs that are used to study the effects of pregnancy on breast cancer development, particularly those that shorten the time to obtain results. The research field will also benefit from any data that is made available, this will be of interest not only in those working on pregnancy protection, but also on breast cancer in general.

In the long term we hope that the general population will benefit from a treatment that can act as a preventative rather than a cure.

How will you look to maximise the outputs of this work?

We will be open to collaborate with other laboratories that have interesting models, data, or questions where our methods can be applied. Moreover, all the knowledge and expertise generated with this project will be spread through talks, conferences, and publications.

Species and numbers of animals expected to be used

- Mice: 2272 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the least sentient, and most understood (in terms of gene expression and gene modification and cell labelling) animals that represent mammalian biology. They allow us to recapitulate human disease in a way that other, less sentient, animals cannot do. We have many years of experience working on breast cancer in this animal model and have developed tools and strategies that are most suited to mice. We will work with both adult mice and juvenile mice. Adult mice are more tolerant of the methods we wish to use, and they are more developed in terms of their mammary gland / breast tissue system (similar to a human who develops breast cancer would be), whereas juvenile mice (<4 weeks) will be used where we wish to create a newly modified mammary gland. In these cases, their gland will be less developed, thus for transplantation assays this makes for efficient clearance of the mammary gland. Egg/embryo and neonate are included in the event they may be affected (via the ovaries) by the mum having received carcinogen treatment prior to undergoing a pregnancy.

Typically, what will be done to an animal used in your project?

- Typically, an animal will be anesthetized, and a vaginal swab may be taken prior to receiving treatment (to ensure results are not affected by different stages of oestrus cycle). At a designated time the animal will be exposed to a solution containing a cancer causing agent (carcinogen), potentially as an intraductal (via the nipple) injection (termed MIND) under anaesthetic or in the form of oral gavage (direct application through the mouth) (once a week for up to 6 weeks). Mice will be killed at designated timepoints after carcinogen exposure and their mammary glands removed. Some groups of mice from this treatment may be allowed to develop small tumours. In cases where we are looking at the early mammary gland response to carcinogens, mice may not even progress to develop small tumours before being humanely killed

- Alternatively, a mouse may be anesthetized and then have its mammary gland removed. The mouse then may be humanely killed or, for transplantation assays will be injected with mammary gland stem cells which will result in the growth of a new mammary gland with the same genetic make-up as the implanted stem cells. That same mouse may then be exposed to a carcinogen (as above) and some groups of mice may develop small tumours. Some mice may undergo a pregnancy at variable stages throughout these procedures.

- In some cases where we will generate a transgenic mammary gland via an electroporation technique (as opposed to transplantation), mice may be anesthetized and undergo an injection of virus into the mammary gland (via MIND or applied to the fat pad directly), followed immediately by a small electrical current being applied to the exposed gland using tweezer electrodes. That same mouse may then be exposed to a carcinogen (as above) and some groups of mice may develop small tumours. Some mice may undergo a pregnancy at variable stages throughout these procedures.

- A small number of mice (those not having undergone any of the afore mentioned procedures) will go through forced involution, in that pups will be removed within 24 hours of birth, resulting in the mammary gland returning to a non-breast feeding state (as would typically happen once pups have been fully weened). A subset of these post pregnant mice will be kept alive beyond 12 months of age (not exceeding 15 months).

What are the expected impacts and/or adverse effects for the animals during your project?

The mouse may feel some discomfort in the mammary gland/ nipple location for all procedures, but we anticipate this to be transient and reduced with analgesics if required. The mouse may develop small (~0.5cm or less) tumours but the location and size should not cause significant discomfort.

Mice undergoing forced involution may experience some distress with the removal of pups. This may be mitigated by allowing killed pups to be placed back into the cage for a short period of time to allow the mother to come to terms with their loss, or by the addition of 'toys' to provide some distraction.

Mice undergoing forced involution may experience mastitis (although this is unlikely), we will observe these mice carefully to detect this early.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For animals where we are maintaining the tumour growth in vivo the severity would not exceed moderate. For recipient mice developing a new mammary gland from donated stem cells, the severity will also be moderate. For animals which we use for whole organ / or part organ mammary gland culture, or as stem cell donor mice for transplantation assays, or where we will look at very early cell response in the gland to a carcinogen, the severity would be mild. The proportions may somewhat depend on the success of each experiment, but we anticipate a 50% ratio between moderate and mild.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Breast cancer can only truly be studied on animals as it is a complex disease that involves many cell types and many interactions. To combine this with pregnancy makes it impossible to use a cell line/ culture system independent of animals.

Which non-animal alternatives did you consider for use in this project?

We will work hard in this project to develop the use of the mammary gland whole organ / part organ culture assay to address some questions. Although this does not eliminate animals completely, it does remove their conscious harm and could allow us to obtain preliminary data to optimise our use of in vivo models. By using a transplantation model for the generation of genetically modified mammary glands we reduce the need to generate large colonies of GM mice.

Why were they not suitable?

We hope our in vitro assays will generate useful data. Regardless of success here, these assay conditions are not suitable for answering some of the more complex questions that require a whole body system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated this number of animals based on the number of conditions that we plan to test, i.e., the number of different treatment options, and the number of animals that are in each group to ensure we have significant confidence in our result. We have also included the possibility that unforeseen outcomes would occur, requiring us to use additional mice to ensure we have significant confidence in our result.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have followed the best available guidelines on experimental design, including these listed on the NC3R website. In addition, we screened the existing literature to inform ourselves on the best standards currently applied in terms of sample size determination.

Wherever possible, we have attempted to perform multiple measurements from the same dataset (applying the appropriate corrections) and to compare multiple treatments to the same control, reducing the number of control animals required. In addition, where possible we will use independent regions of the mammary gland - both left and right glands, and also distinct regions within the same gland, to compare multiple experiments, and thereby reduce the number of animals required for our experiments. We will also maximize the number of host mice that can receive tissue from a single donor mouse. We will also maximize the number of host mice that can receive tissue from a single donor mouse.

We based our sample size calculations on estimates of effect size and variability from previous data of our laboratory. However, this is just an initial estimate, and we fully expect that our understanding of the data will increase over the project. As this happens, we will refine our sample size calculations and either use less animals, if possible, without reducing scientific significance, or seek permission to enrol more animals in the study if we realize that a higher number of replicates is needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Any mouse colonies will also be maintained using efficient breeding.

We will use both the left and right mammary glands for the majority of our experiments. We will also investigate the possibility of testing multiple gene modifications even within the same gland. We will also maximize the number of host mice that can receive tissue from a single donor mouse.

We will carry out pilot studies, prior to data collecting studies, to ensure we have developed the techniques to the best of our abilities and that they reflect the desired outcome in terms of gene expression/ gland development etc.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We intend to use mouse model systems during this project. Part of our project will be to develop optimal cancer inducing models for the breast. Much of the methods we wish to use are via injection through the nipple into the mammary duct of the mouse, which is considered more representative to human disease (as ~80% of human breast cancers diagnosed are considered to originate from the duct), and is also a far less invasive method for the mouse than standard mammary gland injections (via surgical procedure). Injection into the nipple of the solution containing the cancer inducing agent (carcinogen), would be a refinement over the standard procedure (administration via the mouth) as this reduces the number of body parts exposed to the carcinogen, and is a less distressing technique for the animal (given the animal will be anaesthetised during the nipple injection, where they are not when given the treatment via the mouth).

Why can’t you use animals that are less sentient?

In some instances, we intend to use animals that have been terminally anaesthetised. For instances where we require a transformed duct (either as an early or later stage cancer), we need to make use of the entire body system, and all the different cell types that come with this. In other instances, we may require an extended latency period before we see a cell effect after the cancer inducing treatment, so to maintain the cells alive and in their natural environment we must do this in a living mouse. To look for any effects from pregnancy, we require a mature animal that will represent all the different stages of pregnancy, pre and post.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are proposing to induce cancers via injection of cancer-causing agents directly into the nipple of the mouse. This should cause minimal discomfort for the mouse with no chance of cancer cells expanding between the internal skin layer and the mammary gland and no ulcerations because of this. Typical administration of carcinogens, such as the one we are proposing to use, involved oral application. This inevitably effects more than just the mammary duct and cancers are known to develop in many other organs. We wish to refine this by injecting directly into the mammary ductal via the nipple, thereby reducing the effects on other organs. We are also planning to use a culture system, where possible, to treat or observe a removed [from the mouse] mammary gland and its response to cancer.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our institute has a series of guidelines regulating many of the procedures routinely done to animals, for instance how often an animal can receive an injection, where, and how much,

or how often it can give a blood sample. We will follow all of these, as well as several other standard operating procedures that were developed by a team of specialists at our institute for the explicit purpose of minimizing animal suffering and are periodically updated. While designing experiments we will follow a series of guidelines existing in the literature to design and report our experiments, and will continually consult with an on-site statistician to ensure that we're using as few animals as possible for our study.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute routinely circulate advances in the 3Rs and we will always seek to identify ways these can be incorporated in our project, while ensuring they do not affect the (statistical/ biologically relevant) consistency of our data collection

97. Behavioural and Neurochemical Mechanisms of Innate and Learned Resilience in Psychiatric Disorders

Project duration

5 years 0 months

Project purpose

(a) Basic research

Key words

Anxiety, Fear, Behavioural Neuroscience, Memory, Brain

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The proposed work programme will address pertinent gaps in our knowledge regarding how an experience is encoded and persists as a memory that impacts long term behaviour. We aim to elucidate what behavioural interventions and neurochemical mechanisms can boost innate or acquired resilience against anxiety using rodent models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The function of memory is not to simply look back on experience, but to facilitate adaptive behaviour in light of new challenges. Despite some progress, our fundamental

understanding of how memory is encoded in the brain and how memories can influence subsequent behaviour is still limited. Building our knowledge of how memory 'works' is a priority for discovery neuroscience of this generation. The proposed work programme will specifically examine how memory of an emotionally aversive experience can influence future behaviour, such as vigilance for potential danger. In terms of translation into benefits for Human health, this work will refine rodent models of anxiety disorders and identify mechanisms underlying symptoms that are found across a number of psychiatric disorders including PTSD, Depression, OCD and Phobias. In this programme of work, we will develop our knowledge of what factors (innate or learned) influence resilience to aversive experience. Additionally, as we actively collaborate with pharmaceutical partners in industry, there is real potential that refined models and novel knowledge of the mechanisms underlying resilience could be used for testing of innovative drug therapeutics in the longer term.

What outputs do you think you will see at the end of this project?

By comparing the underlying biological mechanisms that control responses to potential danger that are innate (biologically 'hard-wired') with those that are acquired by experience (remembered), this project will advance our understanding on why hypervigilant responses are difficult to diminish, i.e. resistant to therapy. This is a question of fundamental importance for understanding how memory updating works.

This programme of work will refine the measures used to analyse memory in rodents. We will develop tasks to be able to better detect and measure behaviours akin to symptoms seen in Humans, such as hypervigilance for danger signals. These protocols will be published in wide reaching scientific journals and our computational scripts and research data will be made open access for other researchers to benefit from this information.

Moreover, the findings will have direct pre-clinical relevance for treatment of disorders like anxiety, Phobias and PTSD given we will investigate the analogous neural circuitry that is thought to be disrupted in these conditions. We already collaborate with pharmaceutical industry partners, and we actively seek clinical collaborations in the interests of both enhancing awareness of our basic findings, and refining our research questions based upon clinician and patient experience.

For all objectives, we regularly communicate our data at scientific meetings (conferences, minimum around 3 a year) and publish in peer reviewed journals (at least once a year). Therefore, we would expect at least five original articles to result from this project (original data and theoretical).

Who or what will benefit from these outputs, and how?

In the immediate term, our research group will directly benefit from data concerning the validity of the models as the data is analysed, as these will be used to inform future studies (either continuing with the same model, or investigating alternatives where models are not

validated). In the first two years, we will develop new protocols to screen for individual differences in hypervigilance to potential danger (under conditions of safety), building on our knowledge of experimental psychology and behavioural neuroscience. Scientists in the field of memory research and/or anxiety research will benefit from the fundamental knowledge of how memory works. We will use state of the art techniques to target manipulations to specific neural pathways to understand how specific behaviours are generated. This programme of work will reveal mechanisms underlying learning from aversive experiences that will address outstanding scientific questions. The publication and dissemination of the data should occur within the timeframe of the licence, or shortly afterwards, which will support the field and other groups in their research efforts.

In the long term, these protocols will be investigated pharmacologically using drugs that are deemed to reduce anxiety in Humans to understand how those drugs work and identify potential new targets.

Psychiatric disorders remain a significant challenge for translation. Moreover, as we actively collaborate with industry pharmaceutical partners, there is real potential that a valid model and novel knowledge of mechanisms could be used for testing of novel therapeutics in the longer term.

How will you look to maximise the outputs of this work?

The proposed research programme will bolster and develop our collaborative projects. We actively collaborate with other groups working on mechanisms of memory and have also collaborated with animal welfare researchers to examine biomarkers for welfare/affective state. Nationally, we have active collaborations with groups studying models of psychiatric disorders such as OCD and internationally with industry partners on the development of translational rodent models for psychiatric disorders.

Our primary data papers are published in Open Access format (i.e. free-to-view immediately on publication). Our commitment to Open Access and move to open data maximises the benefits of our research to the academic community, which includes both basic scientists and clinicians. Furthermore, we have a proven track record in publication of negative findings and striving against the positive findings publication biases that exist in the literature.

We also are active in public dissemination of our work. I have contributed to events at Science Festivals. I have also presented internationally at outreach events like “TedX” in Cyprus. I have given many online media (radio, podcast, vlog) contributions to disseminate the knowledge gained by similar research projects.

Species and numbers of animals expected to be used

- Rats: Adult Rats total 2580

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To further our understanding of how memory works and how threats are detected at the neurobiological level we have chosen the adult rat as the most suitable animal model for this project. We cannot use a ‘lower’ species of animal at present, due to a need for behavioural complexity that necessitates an ‘intelligent’ animal, with complex social learning behaviours. The rat is a superior model to the mouse for this programme of work given that one readout we are particularly interested in is ultrasonic vocalisation calls. Mice are documented to produce less rich ultrasonic vocalisations, which is argued to reflect that they have evolved a different repertoire of social behaviours and live under different social hierarchies than rats. Moreover, it is generally accepted that the brain cortical structures involved in learning and memory are more tractable to study in the adult rat than mouse.

We have chosen adults, as their behavioural repertoire is more developed than juveniles, and in terms of biological mechanisms there is a developmental regulation of synaptic proteins in the brain areas we are interested in studying. The majority of the experiments proposed will require testing of males as there is evidence that the behavioural responses of female rats to danger cues are different to male rats and cannot be easily compared. Nonetheless, we are fully aware that psychiatric disorders of anxiety are more commonly diagnosed in women (though this is likely both due to biological and societal factors). Therefore, a subset of work will be carried out on defined predictions (such as dominance testing and screening for vigilance responses) to see whether the protocols can apply to female rats.

Typically, what will be done to an animal used in your project?

In general, our experiments are of a relatively short duration of approximately 2-3 months maximum. A typical rat in an experiment will be housed in a social group upon arrival to the unit and acclimatised for a week. With the exceptions of after a surgical manipulation, rats will be housed in social groups to allow social interaction and with environmental enrichment (e.g. cardboard tubes and chewing blocks) present throughout the duration of the experiments.

Their dominance level within the social group will be determined (see below). They will then be behaviourally examined for characteristics that relate to potential danger response behaviour (e.g. avoidance of lit areas in mazes). Then using aversively driven tasks (pavlovian conditioning), the demonstration of species typical responses to learned (associative) and/or innate (agoraphobia, predator odour) potential danger cues such as freezing behaviour and ultrasonic vocalisations (USVs) will be measured. Then

interventions (behavioural, pharmacological, neural circuit manipulation) will be performed on the rat to understand how that memory was formed and to enhance resilience to subsequent threat responses.

In order to study resilience to potential threat (Objective 1 and 2) this programme of work requires the use of moderate aversive stimuli such as inescapable electric footshock. The majority of animals (<80%) will experience this. Some animals will not be directly exposed to footshocks. These exceptions are for vicarious conditioning experiments, where rats observe a conditioned cage-mate and do not experience any aversive stimulus directly (but learn through observation of the other rat), and Control groups where rats are exposed only to the associated cues (context, sounds, smells) in absence of any aversive stimulus (to measure the specificity of learning).

The typical response of a rodent to an electric footshock is to jump and vocalise for less than a second or so, and then resume normal behaviour. The level of shock we use produces no physical lasting harm to the animal, however, is enough to lead to an aversive memory being formed, which we later measure under conditions of safety. Few aversive stimuli are typically needed to effectively train the animal (<5 presentation of footshock for robust learning). These exposures will be limited to maximum of 4 in any test session and not more than 10 in the lifetime of the animal. The subsequent responses of the rat, such as freezing and USVs (which we will measure), are specifically generated only when the memory recall is tested (and not in the home cage or other environments).

In order to compare learned responses with innate (untrained) responses some rats (<40%) will undergo exposure to innocuous mild stressors such as:

- Derivatives of predator odour: Typical response = avoidance, USVs, freezing
- Elevated mazes or open arenas: Typical response = avoidance, USVs, thigmotaxis (keeping to the wall)
- Observation of another rats' responses (vicarious conditioning): Typical response = USVs, freezing
- Playback of ultrasonic alarm calls of a previously conditioned rat: Typical response = avoidance, USVs, freezing.

We will also study the influence of social hierarchies on defensive behaviour (particularly on vicarious learning and USV production) using tasks that can elucidate the hierarchy based on appetitive resource competition. This appetitive measure of competition does not trigger notable aggressive behaviour during the session nor afterwards on return to home cage, and involves brief (5 min) access to a highly palatable food resource, where rats compete for physical access to a spout to drink, and this can be carried out without food restriction (refinement we carried out from previous licence PA9FBFA9F) using a very palatable drink.

A central goal in understanding brain function is to establish causal relationships between specific cell populations and behavioural outputs to ensure construct validity for relevance in Humans. To test a specific requirement of discrete neurochemical systems in a particular brain region of interest, the rats may undergo a surgical procedure (<25%) performed under general anaesthesia to be implanted with chronic, indwelling guide cannulae or administered viruses to target specific brain regions. Rat will be given pain killers during recovery and typically resume normal behaviour, (active locomotive behaviour, appetite, and responsiveness) within a few hours following surgery. In those animals fitted with cannulae, pharmacological substances may be administered locally to modulate brain activity to test whether our developed tasks have the potential to screen for drugs that are effective in treating Humans. The dose and route of administration will be based on careful review of best practice in the existing literature. At the end of the study the animals will be anaesthetised and killed, and brain tissue collected for further analysis of the mechanisms underlying memory.

What are the expected impacts and/or adverse effects for the animals during your project?

We will design all experiments in consultation with the LASA guiding principle documents, particularly for Behavioural Laboratory Animal Science (2013). We always prepare ‘Pre-Study Briefings’ prior to any experiment where the 3Rs are also considered to minimise any predicted harm to the animals and these will be discussed at team meetings. We maintain detailed records in laboratory notebooks alongside electronic shared cloud storage to maintain all details relevant to the particular procedure (e.g. ambient light intensity, animal weight, food consumption) will be noted as a matter of routine.

For most rats the experiments will be exposure to brief stressors such as injection or brief foot-shocks. We administer injectables using refined procedures to avoid any stress of restraint and the number of administrations will not exceed 20 in the experience of the animal. The level and duration of foot- shocks we routinely use for sufficient associative learning are comparatively weaker than those used often in the rat literature and do not cause any chronic change in general behaviour of the rodent. The acute affect at the point of administration is brief jumping and/or vocalisation for a few seconds. Rats are regularly monitored throughout the sessions in real-time by CCTV footage. The experimenters have years of experience using these procedures and we have never observed tissue damage in the animals, nor have we seen any indications of distress other than the specific behaviour of ‘conditioned freezing’ that animals display on re-exposure to the shock-associated cues or context (under conditions of safety). Furthermore, this ‘conditioned freezing’ behaviour can be quickly extinguished, leading us to believe that despite the use of inescapable shock, this procedure is refined in terms of animal suffering and offers clear parametric control.

Surgery is conducted in accordance with aseptic surgical guidelines, and all Personal Licence Holders conducting surgery receive training specifically on aseptic technique.

Surgery is conducted by a Personal Licence Holder who is trained in aseptic surgery. Any surgeries will be performed under anaesthesia and analgesia, and post-operative analgesia will be administered during the first three days of recovery, which will last at least seven days before any other procedures. Animals are expected to make a rapid and unremarkable recovery from surgical procedures. Analgesic agents will be administered as required. No post-operative complications are anticipated but in the event of any post-operative complications, the opinion of the Named Veterinary Surgeon will be sought to see if such complications can be remedied promptly and successfully using no more than minor interventions. In the case of wound dehiscence, uninfected wounds may be re-closed on one occasion within 48 hours of the initial surgery. Rats with 'head caps' after cannulation (<25%) will need to be initially singly housed to prevent any damage from cage mates to the head cap. In rare cases (<5%) the head cap can become dislodged. If the animal can continue in the experiment as there is no sign of distress, nor clinical signs of ill-health and no longer requires the implant (e.g. it has completed the stage of the experiment for which this is required) then, following consultation with the NVS, the animal may be allowed to continue in the experiment. The majority of animals are not expected to show any persistent clinical signs after one week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall, 93% of the animals are predicted to experience a moderate severity in this project as the behavioural tasks used are aversively driven for the key experience of the animals to model aversive experience learning. A subset of (<7%) will be tested using appetitive (palatable reward) or mild tasks (predator odour) for characterisation and comparison of the mechanisms of appetitive versus aversive learning and innate responses. The vast majority of the animals will undergo behavioural testing of an acute nature (>90%, associative learning or innate threat detection). To validate task translation and investigate neurobiological mechanisms underlying experience-driven behaviour a proportion will receive systemic pharmacological manipulations (~38%). Those that undergo surgical procedures (<25%) would be classed as a moderate severity procedure for the implantation of cannulae or viral transfection for local brain region manipulation.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project aims to measure behavioural responses to threat cues to understand the mechanisms by which the brain coordinates vigilance as a cognitive function. It is not possible to replace this programme of work using an in vitro or ex vivo model as a key outcome measure depends on measuring behavioural responses in the intact rodent, which we consider the least sentient creature for comparison to humans in these outcomes.

Which non-animal alternatives did you consider for use in this project?

In silico Models (Computational), Ex vivo (Brain Slice), and In vitro (Cell Culture) Models.

Why were they not suitable?

These non-vivo models are currently not viable to address the behavioural predictions of this project. Nonetheless the data collected can be subsequently fed back into models to make predictions on driving factors for subsequent work. For example, work on the parameters of how much new information is needed for the animal to update their memory has fed into theoretical models into how learning works.

For future work the behavioural data we collect would provide a useful basis for computational modelling to make some predictions on which factors to focus on, but the observation and measure of real behaviour is necessary first. We are well placed to establish collaborations and networks, to take this forward in the long-term following the completion of this programme of work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The specific numbers of animals estimated for each protocol is based off predictions given our experimental design, including replication and randomisation. Given our track record and projections for future funding and research team size these numbers reflect our predictions to address the programme aims. Estimates of groups sizes are more difficult for novel interventions, so in these cases we will use pilot experiments and power calculations based on an estimated desired effect size. The vast majority of the experimental approaches in this programme of work have been done before on other licences, and as such we draw on the returns for those licences to bolster our estimates of numbers, variance and group sizes needed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To analyse the brain areas that are activated in our tasks, we will use a state of the art approach that requires a surgical intervention (a double virus infusion approach) that can replace the need to breed transgenic rats to control specific brain pathways, thereby minimising the number of animals required for this work.

Where possible we compare within subject data (for example in memory studies) to minimise influence of interindividual variability. Within subject experimental design is assessed using factorial ANOVAs (with the correction if the Mauchly's test of sphericity is violated). For the case of data linked to whether rats produce ultrasonic vocalisations, or not, some animals do not make the calls (for reasons still to be fully understood and which will be explored in this research project), so the data is not normally distributed and requires non-parametric or categorical statistical analysis. Behavioural data will be scored by trained observes that are rendered blind to experimental group and sex. Randomisation will be used to assign rats to the experimental groups. We have extensive experience with the data and statistical data analyses that will be used and will report the findings in line with the ARRIVE guidelines.

We have used the N3CRs Experimental Design Assistant in the past for experiments with a simple design and will refer to this to optimise our experimental design going forward, for example in planning comparison of dominance testing protocol between males and female rats.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have decided to choose a dual-viruses manipulation approach instead of breeding rats for our circuit manipulation studies. For drug-dose related studies we will pilot doses by reference to the previous literature where necessary to isolate effects to the specific behavioural readout of interest (for example ultrasonic vocalisation). In addition, we will investigate whether meaningful heterogeneity (such as dominance hierarchies) can inform the understanding of any contexts where biologically driven behavioural responses differ between animals. We will take advantage of the internal Tissue Sharing Network at the institute so that the maximum use can be gained from surplus tissue at the end of the study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The rat is a valid model species to study emotional memory and associated behaviours. Despite obvious behavioural differences, there is much evidence of conservation of the brain regions involved in emotional learning and responding between Humans and the rat. The use of the rat model allows for localised intervention studies, combined with co-relational studies of interconnectivity of small sub- regions, with a resolution greater than that which can presently be achieved in human brain imaging studies. Our previous work focused on male rats, primarily as the scientific literature has documented differences in females behaviour in aversive learning and memory given changes in oestrus cycle and differences in the sort of behaviour they show (eg. Flight behaviour in females rather than freezing, less vocalisations in females than males). However as more Human females are diagnosed with mood disorders, there is a need to better understand potential biologically driven sex differences in behaviour. Therefore, we intend to begin some select experiments in this programme of work to assess to what extent female and male rats differ in our primary tasks of interest, starting with how our method of measuring dominance in males compares to females, and then testing whether their responses to the vigilance test task are comparable to males.

We have chosen to use the method of inescapable electric foot-shock as an aversive stimulus, which is a widely-used method to model associative pavlovian learning and memory potentially at play in post- traumatic stress disorder (PTSD). We test for the associative learning by presenting the associated cue (typically spatial context, visual, auditory or olfactory cues) in a subsequent session under conditions of safety. The responses to cue that are measured are experimentally robust and consistent across experiments (cue triggered short-lived immobility called freezing, and/or ultrasonic vocalisation alarm calls). We also study the vicarious nature of learned responses to threats, i.e. how one animal learns from observing another. For these experiments an observer rat is placed with a previously trained demonstrator rat in presence of a potential threat cue. The observer learns to react from the social experience. We routinely follow conditioning with extinction protocols (presentation of cues previously associated with shock, but without shock in a context of safety) in order to study how the acquired defensive responses to the cue can be rapidly reduced, within a single session, and this protocol is analogous to exposure therapy in human patients and indeed recruits similar neural mechanisms.

We believe electric footshock is the most refined method for studying acquired aversive learning and memory because:

Firstly, electric foot-shock conditioning is a well-studied procedure where the parameters of shock intensity and duration can be tightly controlled to the lowest levels needed and are known to recruit comparable neural mechanisms in the rodent as in the Human

subject. This so called ‘threat’ conditioning learning is rapid, and the defensive responses are specific to the conditions of the experience (cues and/or context). The response of the animal can be parametrically related to the number of pairings of a cue with the foot-shock, so offers precise experimental control of the extent of any aversive experience. We and collaborators have used a limited number of pairings of footshock with a cue in a single session to produce robust and replicable responding but below engaging any panic-like escape responses. The acute response to these levels of foot-shocks are short lived, on a matter of seconds. In over 10 years of experience, we have never seen any indications of lasting distress nor physical harm after conditioning. Very often (>75% of experiments) we do follow up testing of the behavioural response to the paired cue under conditions of safety, during this session the responses start to be extinguished.

Secondly, electric foot-shock can be used as an aversive stimulus in freely moving animals without any restriction on their mobility. Other stimuli used for conditioning, such as air puff or very loud noises, recruit specific neuroanatomical circuits that differ from those recruited by a footshock.

Thirdly, the appropriate response to a threat cue in rodents is thought to be determined by perceived cue proximity and context. Therefore, we use inescapable conditioning boxes to study specifically freezing and vocalisation responses rather than escapable threat where rodents switch to an active escape and/or avoidance strategy of responses (rather than passive freezing response- thought to be used for impeding detection by a predator). Avoidance can be modelled instead without the use of foot- shocks by using an open field arena or elevated mazes.

Thus, for understanding the psychological, neurobiological and neurochemical basis of pavlovian aversive memories relevant to anxiety disorders, and particular to hypervigilance, we consider the use of mild inescapable electric shocks to represent the most refined procedure that will allow us to address our scientific questions.

In order to study innate (untrained) responses to potential threat, we have chosen to use derivatives of predator odour. The artificial derivative is a refined way to study innate responses to an ambiguous threat (distant / source not obvious) as the responses evoked by this innocuous, but aversive, odour mirror those from a laboratory conditioning task using foot-shock in the short term (freezing and USVs). However, the evidence suggests this is despite recruiting distinct neural mechanisms. We will explore why these responses persist longer (i.e. are resistant to behaviour extinction) than those evoked by footshocks (pavlovian conditioned responses). During a period of several minutes of exposure to the predator odour, unconditioned defence-related behaviour is measured. At the conclusion of testing, the animal is returned to its home-cage and can be tested the next day for retention of any associative (conditioned) contextual learning, under conditions of safety. The duration of exposure needed for experimental analysis is thus relatively short sessions (on the odour of minutes to maximum an hour). The starting concentration and duration of exposure to the predator odour will be based of the existing literature and we will conduct

pilot studies to refine the parameters to a lower limit of exposure that still produces robust levels of freezing behaviour, as defined by being significantly higher levels than evoked by baseline context or stimulus novelty exposure.

Various mazes, mostly the elevated plus maze and open field, are routinely used to measure anxiety- like symptoms in rodents. We will give brief (5-10 minutes) exposure of the rats to these mazes to measure how much they avoid the open and brightly light environment (comparable to an agoraphobia) to study how learned experience impacts these untrained (innate) responses. We performed a series of studies which demonstrated that under our conditions there was no sensitisation to repeated exposure in the elevate plus maze. Such tasks are used in a screening manner to see individual (trait) differences in conflict between the motivation to explore the environment and remaining in the perceived safety of an enclosed space. Therefore, we expect no cumulative effect on the rats' behaviour. Nonetheless, we will monitor the data and envision that the vast majority of the rats will have typically maximum 3 or 4 short trails in the mazes across the duration of the experiments.

To study the consequence of individual differences in social behaviours in rats, ultrasonic vocalisation calls will be played back to the rats for brief durations (order of minutes). This evokes short-lived changes in heart rate and behaviour (approach or avoidance depending on the nature of the vocalisation). We will also study the influence of social hierarchies on behaviour using tasks that can elucidate the hierarchy based on appetitive resource competition. The task uses highly palatable food rewards for limited access periods where they compete for access to the resource. We have previously refined this procedure to be able to carry it out without food restriction, by examining which rewards evoke the strongest motivation to consume (strawberry milkshake versus sucrose solutions) and parametrically measuring the habituation period needed to overcome any neophobia of the resource in the rats. As such this intervention allows us to reliability establish the dominance hierarchy (based on drinking time) without food restriction or stimulation of aggressive behaviours.

To test a specific requirement of discrete neurochemical systems in a particular brain region of interest, the animals may be implanted with chronic, indwelling guide cannulae targeting specific brain regions following intracranial stereotaxic surgery (localised small injection sites). The typical targeted brain areas, which compose the major classical limbic circuitry, include chiefly the amygdala nuclei, bed nucleus of the stria terminalis, hippocampus, and the prefrontal cortical regions (prelimbic and infralimbic cortex) which are arguably particularly more tractable in the rat rather than mice. The guide cannulae allow the subsequent administration of substances that modulate brain function directly to these brain regions via micro injectors. Where the effects of drug dose, or the effects of different drugs, on a specific, individually variable behaviour are being investigated, animals may receive treatment with multiple doses of drug or different drugs, with an appropriate recovery period between administrations. The 'washout' period and doses will be based on that described in the literature for the specific drug. To test functional

recruitment of a specific brain area, specialised virus-mediated targeting will be employed. Rats will undergo the stereotaxic surgery and viral vectors will be infused into the brain via stainless steel injectors to transfect regions of interest. Typically rats recover from these surgeries fully within a week. These methods offer the advantage over older approaches that permanently inactivated brain circuits (by lesion) as we can look at recovery of responses in absence of the manipulation and gain more data from each step of the protocol.

In order to test for predictive validity of our tasks we will test drugs that have the desired therapeutic effects in Humans to see whether they alter behaviour in the tasks we refine. Within such a back translation experiment, this will involve assessment of the effects of administering (acutely or chronically) substances hypothesised to modulate neuronal or glial function on a specific behavioural task. The dose and route of administration will be based on careful review of the existing literature. We have adapted our systemic injection technique to reduce restraint based on recent publications in the field. For all experiments, the rodents will be ‘habituated’ to the process and route of administration in a session where they receive a vehicle injection that allows for a within-subjects control for any effects of the procedure.

Why can’t you use animals that are less sentient?

The objectives of the research programme require measurement of behaviour in adult social animals. Although it may be technically possible to use mice to understand some mechanisms of aversive conditioning, their relative poorer social behaviour repertoire renders them a less tractable model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The vast majority of protocols have been used in the lab before without evoking any welfare issues; however, rats will be closely monitored throughout the experiments. The mild foot shocks have been titrated down to the lowest level possible to give robust behaviour and do not cause any lasting physical effects. We have also removed the need for food restriction in our appetitive tasks by comparing and identifying the most palatable food rewards. Any surgical procedures will be carried out under general anesthesia using peri-operative analgesia and aseptic technique, followed by post- operative analgesia and regular health monitoring. If a rat shows signs of ill-health, such as piloerection, hunch posture, inactivity or inappetence it will be humanely killed, unless in the opinion of the NVS, such clinical signs can be remedied promptly and successfully using no more than minor interventions. We will continually review and refine our endpoints in consultation with our NVS/NACWO

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to make use of resources such as the experimental design assistant tool, LASA guidelines (particularly for behavioural neuroscience) and the ARRIVE guidelines for publishing our work. We also make use of G*Power open access software to perform our power analyses to predict our sample sizes and systematic literature review and metanalysis tools such as the PRISMA guideline to bolster the predictions from the background of experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My institute has developed online secure resources for updating on regular user meetings and procedure refinements, and the resources of the tissue sharing network. We will attend regular meetings to share best practice and review our standard operating procedures given any advances that could improve the animal welfare and scientific endeavours.

98. Breeding and Maintenance of Genetically Altered Zebrafish

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Zebrafish, Breeding, Genetic Alteration

Animal types	Life stages
Zebra fish (Danio rerio)	adult, neonate, juvenile, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this licence is to generate genetically altered zebrafish (and larvae) so as to maintain breeding lines and provide animals for scientific purposes, either as larvae or to perform post-mortem tissue analysis directly from this licence, or for transfer onto other licences with appropriate permissions in place.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically altered zebrafish can be used to increase our understanding of the importance of specific genes in a wide range of human diseases. By altering individual genes we can understand their role in development processes in particular their importance in models of

human cancers. An early zebrafish larvae is not a protected animal until it is capable of free feeding - typically 5 days post fertilisation.

Understanding of gene function can be done in the majority of cases using larvae before they become a protected animal.

This service licence will bring the supply to all the individual fish research groups together under one central umbrella. This, in turn, will create centralised expertise and allow for optimisation of the 3Rs.

What outputs do you think you will see at the end of this project?

The main outputs of the project will be:

- Peer-reviewed publications: in these we will share our findings with the academic community;
- Datasets: the data underpinning the publications will be shared freely online;
- Transgenic zebrafish: these are powerful tools to address a host of questions in the biomedical research field. They will be shared with any interested party so long as the appropriate permissions and paperwork are in place

Who or what will benefit from these outputs, and how?

Data obtained from this licence will be shared within the scientific community by publishing results in scientific journals following ARRIVE guidelines, presentation at scientific meetings and sharing of novel genetically altered zebrafish strains to avoid duplication.

The fish themselves will benefit from a centralised PPL as it will ensure high standards of welfare are maintained throughout their life experience and that any new improvements or refinements, whilst enabling improvement to care can be implemented more readily

How will you look to maximise the outputs of this work?

Results will be shared freely within the scientific community, novel genetically altered fish strains will be shared to avoid duplication and published in databases.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 19,500 Zebra fish

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project licence is intended to act as a service licence, in which users are able to create and maintain genetically altered zebrafish lines. To do this, it is imperative that all life stages are included.

Users will also be able to obtain life stages that are not covered by the Animal (Scientific Procedures) Act (pre-protected stages are zebrafish at less than 5 days post fertilisation where they are not capable of independent feeding) for their scientific studies. This reduces the need to use later stages that are more sensitive to experiencing a level of pain, suffering, distress or lasting harm.

It also affords them the opportunity to cryopreserve their lines, in which case adult zebrafish would be needed.

Typically, what will be done to an animal used in your project?

Animals will undergo natural mating which does not cause any adverse effects. In a small number of fish a small biopsy of the caudal fin may be taken under anaesthesia to provide cells for genetic analysis. Where possible this may be done using a mucosal swab rather than a fin biopsy. Fish may be maintained for up to 18 months of age, during which time they may be mated repeatedly for production of embryos.

What are the expected impacts and/or adverse effects for the animals during your project?

There are no anticipated adverse effects that are more than mild and transient. Pain from fin biposy will be controlled by use of anaesthesia and analgesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of fish will only experience sub threshold severity, a small number - less than 10% will experience mild severity associated with the anaesthetic event required for caudal fin biopsy.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are required under this project so as to provide zebrafish for scientific purposes. Zebrafish are required scientifically to investigate interactions between individual cells and populations of cells, within a whole body setting. Where possible, zebrafish larvae will be used as a non-protected model in which to achieve the scientific purposes.

Which non-animal alternatives did you consider for use in this project?

Prior to the use of animals generated under this licence, the scientific aims will first be investigated using in vitro and in silico methods as far as possible.

Why were they not suitable?

Whilst useful in establishing simple interactions in vitro, and predicting interactions in silico, the models available are not yet suitably advanced to allow the full interactions to be modelled and predicted with certainty outside of an in vivo setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals estimated is based upon discussions with our researchers as to the numbers of animals they predict to need. From this we have determined the number of parents required to generate the numbers needed for scientific purposes, and maintenance of the breeding colonies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Given that the outputs from this service licence will not be numerical data, experimental design calculations have not been possible. However, the design of our breeding strategies will be dictated by user demand and will be rigorously reviewed during the lifetime of this licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All breeding under this licence will be stringently managed by highly experienced technicians. Careful management of the fish lines will help to reduce the number of animals produced; i.e. animals will only be produced where there is a justifiable need. Where possible, all animals bred will be shared between research groups, unless genetic status dictates otherwise.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered zebrafish will either be created or maintained under this licence. Only genetic alterations that at most are predicted to cause mild impact on animal welfare will be bred under this licence. Where a new genetic alteration is made, the resulting progeny will be monitored carefully during gestation and the non-protected phases to identify any mutations that could potentially impact on animal welfare. These animals will be additionally carefully assessed for any welfare impacts once they reach free-feeding stages. Any animals found to be suffering more than mildly will be killed humanely and the breeding of those animals re-assessed.

Why can’t you use animals that are less sentient?

Of the animals being generated for scientific purposes, they will principally be immature zebrafish larvae. Where this is not appropriate scientifically, then protected animals will be used, however this will be for post-mortem tissue analysis without undergoing any additional procedures. Where protected animals are being used for maintaining transgenic lines, unfortunately less sentient animals cannot be used due to the nature of the process.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where animals will be subject to painful procedures, for example fin biopsy to obtain genetic material for genotyping, we will use post-operative analgesia to minimise any pain and suffering. We are also exploring alternative methods such as the use of swabbing the mucosal surface to obtain cells that allows for the genotyping of fish.

We have an ongoing programme looking at different tank enrichment items to benefit fish welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult with leaders in the field of zebrafish breeding including the NC3Rs (https://www.nc3rs.org.uk/3rs-resources/zebrafish-welfare) to ensure that procedures are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to the NC3Rs newsletter, attend 3Rs-focussed events, and interact with key individuals in the zebrafish field to ensure we stay informed of 3Rs advances. The advantage of having a centralised zebrafish breeding licence is that any advances are easily implemented leading to immediate and widespread impact.

99. Refining Methods of Resuscitation from Cardiac Arrest

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cardiac Arrest, Defibrillation, Ventricular Fibrillation, Resuscitation, Cardiopulmonary Resuscitation

Animal types	Life stages
Pigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To research technologies that can be used in a simple manner to help untrained rescuers save victims of cardiac arrest. These include new methods to defibrillate and provide coaching on cardiopulmonary resuscitation (CPR).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Survival from out of hospital cardiac arrest is low (typically <10%). New technologies that can help untrained rescuers or bystanders rescue a victim of cardiac arrest have the potential to improve survival rates. This project aims to develop several new aspects of automated external defibrillators (AEDs) including CPR feedback and the methods for delivering shocks all of which can contribute to advancements in and/or proliferation of AEDs.

What outputs do you think you will see at the end of this project?

Outputs from this project will include conference abstracts, publications, new product development; advanced AED solutions, intellectual property and data to support regulatory approval of AEDs.

Who or what will benefit from these outputs, and how?

In terms of publications and academic presentations, the benefits will be realised within 6 months as per our publication targets. In addition other benefits will be realised in the medium term (during the course of this project) including marketing of new products and regulatory approvals. These new technologies will impact outcomes for patients over the longer term by improving lay rescuer CPR performance and potentially reducing the energy required for effective defibrillation.

How will you look to maximise the outputs of this work?

We will seek to disseminate knowledge through internal seminars including stakeholder workshops, national and international conferences and publication in peer review journals. Data generated from this project will be cited against any marketing claims associated with products developed as part of this work.

Species and numbers of animals expected to be used

- Pigs: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

A porcine model produces a good replication of the human cardiovascular system. Pigs feature a barrel shaped thorax compared to a human; however porcine models are preferred for resuscitation studies due to overall anatomical similarities. 10-24 kg pigs are a widely accepted model for paediatric cardiac arrest while 25+ kg pigs are accepted as a model for adult cardiac arrest.

Typically, what will be done to an animal used in your project?

Animals will be brought into the facility with an appropriate period of time to acclimatise prior to the start of the study. They will be housed socially in an environmentally enriched pen with the last animal in any group being held in isolation for no longer than 4 hours. Animal will have access to food until 2 hours prior to premedication, and water will be provided ad lib until premedication is administered.

All procedures will be conducted under general anaesthesia following which the animal will be euthanised. Animals will be sedated prior to induction of anaesthesia administered by intramuscular injection as a sedative. Following this the animal will be intubated and physiological monitoring including cardiovascular and respiratory measurements, will be recorded via the vital signs monitoring. A surgical approach will be made to a jugular vein and at least one artery. An introducer sheath will be placed into a jugular vein and a pacing wire will be placed into the right ventricle to facilitate VF induction a blood pressure transducer will be attached to the sheath on the arterial line. Ventricular Fibrillation may be induced via electrical stimulation and resuscitation procedures including CPR and defibrillation may follow.

What are the expected impacts and/or adverse effects for the animals during your project?

Pigs will be loaded (typically in pairs or groups) onto an approved animal trailer and transported by road (approximately 10 - 30 minutes) to the facility. Pre-anaesthetic medication (to which hyaluronidase may have been added) will then be given by IM injection. A remote (low-stress) technique will be used. The IM injection may cause mild and brief (< 5 s) discomfort. Pre-anaesthetic medication will typically produce sufficient central nervous depression, anxiolysis and muscle relaxation for the animal to be lifted onto, and moved by trolley - without resistance - to the anaesthesia induction area. Here anaesthesia may be deepened (initially) to allow the painless insertion of an IV cannula, after which anaesthesia will be induced, usually by a combined IV and, or inhalation technique. Thereafter, continuous and close monitoring of autonomic nervous and nociceptive reflexes, combined with alerting signals generated from quantitative EEG-based monitoring technologies will ensure the attending anaesthetist is always aware of

the animal's anaesthetic depth, whilst the immediate availability of additional doses of rapidly-acting anaesthetics pre-located in a venous cannula will ensure the rapid restoration of oblivion if required. The study will end once all objectives have been achieved as far as is possible within the permitted time limit. The animal will then be terminated whilst anaesthetized at the end of the study and not released for post mortem examination, or disposal, until physical examination confirms the animal is dead.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Non-recovery

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Resuscitation from cardiac arrest involves complex physiological processes that include mechanical and electrical activity of the heart. At present it is not possible to model these processes or recreate them in bench or lab studies. Pigs are the gold standard for studying resuscitation in the field due to anatomical similarities to humans.

Which non-animal alternatives did you consider for use in this project?

3D cell culture models of heart tissue are emerging and represent a promising future direction for this work, however at present they are not a suitable alternative.

Why were they not suitable?

These models do not yet represent the metabolic, structural, or electro-mechanical properties of the heart that are required to investigate cardiac arrest.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Comparison of this body of work's scope and aims with our historical work. The number of animals in our previous studies are a strong indicator of the number of animals we will use in future work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The level of data required is ascertained in the design phase for each study. Utilising pilot studies, previous work and the vast experience across the broader team the number of animals required to obtain the required data is calculated. The key step is excellent communication across the experienced project team where the details and goals of each study are openly discussed with particular emphasis on reduction.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In our experience relatively small groups of animals, some 6-8 animals per group, are needed for a preliminary evaluation of an idea. For statistical power, particularly if establishing that there is no benefit from an intervention, larger groups of some 10–15 animals are needed. A calculation is made before every study to ensure the right number of animals is used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Porcine model of sudden cardiac arrest. All studies are conducted under general anaesthesia, so the animals are not aware of any of the procedures and feel no pain. When administering anaesthetics to the animal its windpipe could become blocked as it closes over (spasms). However, a breathing tube can be inserted straight into the windpipe to ensure the animal can continue to breathe normally while under anaesthetic. Pain during surgery will be controlled by ensuring adequate anaesthetic and pain relief is provided for each animal. The animal’s blood pressure and oxygen levels, as well as heart

rate will be monitored during the procedure to help ensure the animal remains under anaesthetic. Induction and maintenance of anaesthesia will be conducted by an experienced veterinary team

Why can’t you use animals that are less sentient?

There is no less sentient species that provides the anatomical similarity to the human cardiovascular system. Animals will be terminally anaesthetised for these studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Each animal will be closely monitored, throughout the duration of the study, for physiological status and depth of anaesthesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the NC3R guideline and conduct studies according to GLP, studies will be reported according to ARRIVE.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will read the excellent updates sent by the institution on this topic as well as partake in as many webinars and training courses are reasonably practical, I will also inform myself by reading relevant literature and will contact others including AWERB committee members prior to study start and ask for further advise. Furthermore I will maintain regular communication with NAWCO and trained husbandry/technical staff to ensure optimized animal welfare during the housing prior to procedures and during procedures is ensured.

100. Investigating the Mechanisms Obesity and its Comorbidities and its Interplay with Adrenal Dysfunction

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Adrenal, Hormones, Obesity, Metabolism, Co-morbidities

Animal types	Life stages
